List of Physico-chemical Symbols adopted by the Chemical Society.

[See J.C.S., 1921, **119**, 502—512.]

1. *Mathematical Symbols.*

	Usual symbol.	Alternative symbol.
Base of natural (Napierian) logarithms ...	e	
Diameter	d	
Radius	r	
Ratio of circumference to diameter	π	
Summation.....	Σ	
Variation	δ	
Total differential	d	
Partial differential	∂	

2. *Universal Constants.*

Acceleration due to gravity.....	g	
Mechanical equivalent of heat	J	
Avogadro's constant [number of molecules in 1 gram-molecule (mole)]	N	
Gas constant per mole	R	
Faraday's constant (number of coulombs per gram-equivalent of an ion)	F	
Charge on an electron	e	

3. *General Physics and Chemistry.*

Length	l	
Height.....	h	
Mass	m	
Time	t	
Volume	v, V	
Density (mass per unit volume)	d	D
Pressure	p, P	
Concentration	c, C	
Mole fraction	x	
Critical constants: pressure, volume, temperature (centigrade), temperature (absolute), density	p_c, v_c t_c, T_c d_c	
Reduced quantities: pressure, volume, temperature, density	p_r, v_r t_r, T_r, d_r	
van der Waals's constants	a, b	
Fluidity	ϕ	
Viscosity	η	
Surface tension	γ	σ
Diffusion coefficient	Δ	
Atomic weight	A	
Molecular weight	M	
Velocity coefficient of reaction	k	
Equilibrium constant	K, (K_c, K_p)	
van't Hoff coefficient	i	
Degree of dissociation (electrolytic, thermal,		

4. *Heat and Thermodynamics.*

	Usual symbol.	Alternative symbol.
Temperature (centigrade)	t	θ
Temperature (absolute)	T	
Critical temperature	t_c, T_c	
Reduced temperature	t_r, T_r	
Critical solution temperature	t_{cs}, T_{cs}	
Quantity of heat	Q	
Entropy	S	
Specific heat	c	
Specific heat at constant pressure	c_p	
Specific heat at constant volume	c_v	
Ratio of specific heats, $c_p : c_v$	γ	
Molecular heat	C	
Molecular heat at constant pressure	C_p	
Molecular heat at constant volume	C_v	
Latent heat per gram	l	
Latent heat per mole	L	
Maximum work (diminution of free energy)	A	

5. *Optics.*

Wave-length of light	λ	
Refractive index	n	n_r
Specific refractive power (Gladstone and Dale)	r_G, $[r_G]^t_\lambda$	
Specific refractive power (Lorentz and Lorenz)	r_L, $[r_L]^t_\lambda$	
Molecular refractive power	R_G, R_L $[R_G]^t_\lambda$, $[R_L]^t_\lambda$	
Angle of optical rotation	α	
Specific rotatory power	$[\alpha]$	
Molecular rotatory power	$M[\alpha]$	
Specific magnetic rotation	$[\omega]$	
Molecular magnetic rotation	$M[\omega]$	

6. *Electricity and Magnetism.*

Quantity of electricity	Q	
Current intensity	I	
Resistance	R	W
Electromotive force	E	
Electrode potential, or discharge potential of an ion	E	ϵ
Electrode potential referred to the normal hydrogen or normal calomel electrode respectively, the potential of which is taken as zero	E_h, E_c	ϵ_h, ϵ
Normal potential, *i.e.*, the electrode potential referred to the normal hydrogen or normal calomel electrode respectively, when the solution is molecular-normal in respect of all participating substances and ions of variable concentration	${}_0E_h$, ${}_0E_c$	${}_0\epsilon_h$, ${}_0\epsilon$
Dielectric constant	ϵ	
Conductivity (specific conductance)	κ	
Equivalent conductivity	Λ	
Equivalent conductivity at different dilutions—volumes in litres containing 1 gram-equivalent	Λ_{10}, Λ_v, Λ_∞	

6. *Electricity and Magnetism*—(continued).

	Usual symbol.	Alternative symbol.
Equivalent conductivity of kation and of anion	Λ_k, Λ_a	
Equivalent conductivity of specified ions	Λ_K, Λ_{Cl}	
Molecular conductivity	μ	
Velocity of kation and of anion in cm./sec. when the potential gradient is 1 volt per cm.	U_k, U_a	
Transport number of kation and of anion	n_k, n_a	
Magnetic permeability	μ	
Magnetic susceptibility	κ	

List of Symbols, Arranged Alphabetically.

Symbol.	Name of quantity.
A	Atomic weight; maximum work.
a	Van der Waals's constant.
b	Van der Waals's constant.
C	Concentration; molecular heat.
c	Concentration; specific heat.
C_p, C_v	Molecular heat at constant pressure, and at constant volume.
c_p, c_v	Specific heat at constant pressure, and at constant volume.
D	Alternative symbol for density.
d	Diameter; total differential; density.
d_c	Critical density.
δ	Reduced density.
E	Electromotive force; electrode potential.
e	Base of Napierian logarithms; charge on an electron.
E_h, E_c	Electrode potential referred to the normal hydrogen or the normal calomel electrode, respectively, the potential of which is taken as zero.
${}_0E_h$, ${}_0E_c$	Normal potential, that is, the electrode potential referred to the normal hydrogen or the normal calomel electrode respectively, when the solution is molecular-normal in respect of all participating substances and ions of variable concentration.
F	Faraday's constant (number of coulombs per gram-equivalent of an ion).
g	Acceleration due to gravity.
h	Height.
I	Current.
i	Van't Hoff's coefficient.
J	Mechanical equivalent of heat.
K	Equilibrium constant.
K_c, K_p	Equilibrium constant, when molar concentrations and partial pressures respectively are employed.
k	Velocity coefficient of reaction.
L	Latent heat per mole.
l	Length; latent heat per gram.
M	Molecular weight.
$M[\alpha]$	Molecular rotatory power.
$M[\omega]$	Molecular magnetic rotatory power.
m	Mass.
N	Avogadro's constant (Loschmidt's number) or number of molecules in 1 gram-molecule.
n	Refractive index.

List of Symbols, Arranged Alphabetically—(continued).

Symbol.	Name of quantity.
n_k, n_a	Transport number of kation and of anion.
n_r	Refractive index (alternative symbol).
P	Pressure.
p	Pressure.
p_c, p_r	Critical pressure : reduced pressure.
Q	Quantity of heat; quantity of electricity.
R	Gas constant per mole; electrical resistance.
R_G, R_L	Molecular refractive power, according to Gladstone and Dale, and to Lorentz and Lorenz respectively.
r	Radius.
r_G, r_L	Specific refractive power according to Gladstone and Dale, and to Lorentz and Lorenz respectively.
S	Entropy.
T	Absolute temperature.
T_c	Critical temperature (on the absolute scale).
T_r	Reduced temperature (absolute).
T_{cs}	Critical solution temperature (absolute).
t	Time; temperature (centigrade).
t_c	Critical temperature (centigrade).
t_{cs}	Critical solution temperature (centigrade).
t_r	Reduced temperature (centigrade).
U_k, U_a	Velocity of kation and of anion in cm./sec. when the potential gradient is 1 volt per cm.
V	Volume.
v	Volume.
v_c, v_r	Critical volume : reduced volume.
W	Electrical resistance (alternative symbol).
x	Mole fraction.
α	Degree of dissociation (electrolytic, thermal, etc.); angle of optical rotation.
$[\alpha]$	Specific rotatory power.
γ	Surface tension; ratio of specific heats.
Δ	Diffusion coefficient.
δ	Variation.
∂	Partial differential.
ϵ	Electrode potential (alternative symbol); dielectric constant.
ϵ_h, ϵ	Electrode potential referred to the normal hydrogen or the normal calomel electrode respectively, the potential of which is taken as zero (alternative symbols).
${}_0\epsilon_h, {}_0\epsilon$	Normal potential, that is, the electrode potential referred to the normal hydrogen or the normal calomel electrode respectively, when the solution is molecular-normal in respect of all participating substances and ions of variable concentration (alternative symbols).
η	Viscosity.
θ	Temperature (centigrade), (alternative symbol).
κ	Specific conductance (conductivity); magnetic susceptibility.
Λ	Equivalent conductivity.
$\Lambda_{10}, \Lambda_v, \Lambda_\infty$	Equivalent conductivity at different dilutions (volumes in litres containing 1 gram-equivalent).
Λ_k, Λ_a	Equivalent conductivity of kation and of anion.
λ	Wave-length of light.
μ	Molecular conductivity; magnetic permeability.
π	Ratio of circumference to diameter.
Σ	Summation.
σ	Surface tension (alternative symbol).
ϕ	Fluidity.
$[\omega]$	Specific magnetic rotation.

CXCVII.—*The Inter-relationships of the Sulphur Acids.*

By Henry Bassett and Reginald Graham Durrant.

This investigation arose out of an attempt to explain the genesis of polythionates in the Wackenroder reaction and in the decomposition of thiosulphates by acid. It soon became clear that the reactions of many of the sulphur acids required further study before the formation of polythionic acids could be understood.

In all the reactions of the sulphur acids, the hydrogen-ion concentration plays a very important part and in great measure determines the path followed. Addition of acid, *i.e.*, hydrogen ions, to a system should, in accordance with the principle of Le Chatelier, favour reactions which remove hydrogen ions, whilst hydroxyl ions should produce exactly the opposite effect. These deductions are, on the whole, borne out by experiment.

The method adopted in the theoretical portion of the present paper is to consider all reactions and give all equations in terms of the acids concerned, even although the reactions may occur in alkaline solutions. This has been done for the sake of simplicity and uniform treatment, and must not be taken to mean that the reactions may not follow an ionic course, although we think it probable that many of the reactions discussed do actually involve the non-ionised acids rather than their ions.

A number of equations have to be referred to frequently. These are given in the text in the positions where they are first considered. To each has been given a number by which it is referred to on subsequent occasions, and for convenience in reference all such equations are here collected in the order of their first appearance, equations mentioned only once not being included; *a* after the number of an equation signifies the reaction from left to right, *b* that from right to left.

$$2S + 2H_2O \rightleftharpoons H_2S + (HO)_2S \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (I)$$

$$S(OH)_2 + HO{\cdot}S{\cdot}O{\cdot}S{\cdot}OH \rightleftharpoons H_2S + H_2S_2O_5 \quad . \quad . \quad . \quad . \quad (II)$$

$$H_2S_3O_6 + S \rightleftharpoons H_2S_4O_6 \; (2H_2S_3O_6 + S_2 \rightleftharpoons 2H_2S_4O_6) \quad . \quad (XII)$$
$$H_2S_4O_6 + S \rightleftharpoons H_2S_5O_6 \; (2H_2S_4O_6 + S_2 \rightleftharpoons 2H_2S_5O_6) \quad . \quad (XIII)$$
$$H_2S_3O_6 + H_2S_2O_3 \rightleftharpoons H_2S_4O_6 + H_2SO_3 \quad . \quad . \quad . \quad . \quad . \quad (XIV)$$
$$H_2S_4O_6 + H_2S_2O_3 \rightleftharpoons H_2S_5O_6 + H_2SO_3 \quad . \quad . \quad . \quad . \quad . \quad (XV)$$

In order to save space and avoid repetition, the experimental portion of the paper contains only the practical details of experiments, their connexion with the theoretical discussion being indicated by cross references. Any purely qualitative experiments which are discussed in the theoretical part are not, as a rule, referred to again in the experimental part.

The Hydrolysis of Sulphur. Sulphoxylic Acid.

It has been generally supposed that hydrogen sulphide and sulphurous acid are the first products of the hydrolysis of sulphur (Cross and Higgin, J., 1879, **35**, 249; *Ber.*, 1883, **16**, 1195) and may give rise to thiosulphuric or other sulphur acids.

This view is probably incorrect, for, just as the hydrolysis of chlorine results in the production of equivalent amounts of hydrogen chloride and hypochlorous acid, so the hydrolysis of sulphur should give equivalent amounts of hydrogen sulphide and sulphoxylic acid, $(HO)_2S$. The latter is doubtless a very unstable substance and would readily undergo further change.

Although neither free sulphoxylic acid nor its salts are known, there are two simple derivatives which are readily accessible. These are sodium formaldehydesulphoxylate and sodium hydrosulphite [hyposulphite]. We have shown that when sulphoxylic acid is liberated from the formaldehyde compound by hydrolysis it undergoes decomposition into hydrogen sulphide and sulphurous acid—a change analogous to that undergone by hypochlorous acid. If the hydrolysis occurs in presence of a lead, arsenic, antimony, stannous, bismuth, cadmium, nickel, cobalt, or zinc salt, the sulphide of the metal is precipitated. No acid, other than that present in the solution owing to hydrolysis, must be added in the case of zinc, nickel, or cobalt, otherwise the precipitate of sulphide fails to appear; and very little must be present in the case of cadmium. With salts of silver, copper, and mercury, reduction to metal occurs. This may occur also with arsenic and probably with antimony or bismuth, especially in absence of much acid, whilst, conversely, a little sulphide may be formed in the case of copper and silver in presence of much acid. Precisely what happens in such cases depends upon the relative rates of the oxidation of sulphoxylic acid to sulphurous acid or of its change into hydrogen

sulphide and sulphurous acid. These rates are affected by concentration of reactants, acidity, and temperature (compare results with sodium hydrosulphite, $Na_2S_2O_4$, Firth and Higson, J., 1923, **123**, 1515; *J. Soc. Chem. Ind.*, 1923, **42**, 427T).

In absence of salts of heavy metals, the hydrogen sulphide acts upon the formaldehyde to some extent to yield trithioformaldehyde, which appears as white crystals or oily drops and is readily detected by its characteristic smell. The normal interaction of hydrogen sulphide and sulphurous acid leads to formation of sulphur and polythionic acids (see Expt. D).

On alkaline hydrolysis sulphur gives rise to polysulphide and thiosulphate (Gmelin, "Handbook of Chemistry," Watts's English Transl., 1849, II, 160; Auld, J., 1915, **107**, 480), both of which could result from further action of sulphur on previously formed sulphide and sulphite.

The acid hydrolysis of the formaldehydesulphoxylate occurs rapidly on heating, but is slow at the ordinary temperature; the actual rate depends also upon the acidity. The alkaline hydrolysis is extremely slow, but seems to follow a similar course to the acid hydrolysis, yielding sulphide and sulphite.

The action of formaldehydesulphoxylate on sodium plumbite solutions is slow at the ordinary temperature, but more rapid on heating. A mixture of metallic lead and lead sulphide is usually formed, a high concentration of sulphoxylate and high alkalinity being most favourable to the precipitation of lead sulphide. The reduction to metallic lead is due to the sulphoxylate, and not to the formaldehyde (Expt. A). In presence of plumbite, it is the formation of insoluble lead sulphide which accelerates the hydrolysis of the formaldehydesulphoxylate. Sulphur will produce a similar effect by converting the sulphite, formed on hydrolysis of the sulphoxylate, into thiosulphate. Thus it was found that, after an alkaline solution of formaldehydesulphoxylate had been boiled with sulphur and the polysulphide (much of which was, of course, due to alkaline hydrolysis of the sulphur) removed with lead acetate, the solution was no longer capable of bleaching methylene-blue. A similar alkaline sulphoxylate solution, after being boiled for the same length of time without sulphur, gave no precipitate with lead acetate and still had a strong bleaching action on methylene-blue (see also p. 1424). On boiling an alkaline solution of sodium hydrosulphite to which sodium plumbite has been added, a greyish-black precipitate of lead sulphide and metallic lead is obtained. The same reaction occurs at the ordinary temperature, but much more slowly. If the alkaline hydrosulphite solution is boiled and then cooled to room temperature before the sodium plumbite is added,

an immediate black precipitate appears which consists of pure lead sulphide if only small quantities of hydrosulphite and plumbite are used in the experiment.

The work of Binz (*Ber.*, 1904, **37**, 3549), Bazlen (*Ber.*, 1905, **38**, 1067), and Reinking, Dehnel, and Labhardt (*ibid.*, p. 1069) leaves little doubt that sodium hydrosulphite, $Na_2S_2O_4$, is to be considered as the sodium salt of a mixed anhydro-acid derived from one molecule of sulphoxylic acid and one of sulphurous acid. At the ordinary temperature, it is so stable towards alkali that sodium hydroxide can be used to salt it out from its aqueous solution (Bernthsen and Bazlen, *Ber.*, 1900, **33**, 126). Bazlen (*loc. cit.*, p. 1057) showed that both before and after such salting-out the hydrosulphite had the formula $Na_2S_2O_4,2H_2O$. The experiments with lead, which have just been described, show that the hydrosulphite is hydrolysed slowly in alkaline solution even at the ordinary temperature, and the reactions then observed are the same as those obtained with sodium formaldehydesulphoxylate—both being the reactions of sulphoxylic acid or its decomposition products. If the solution is boiled before the plumbite is added, a precipitate of lead sulphide free from metallic lead can be obtained in the case of the hydrosulphite, because the sulphoxylate is converted into sulphide and sulphite as fast as it is formed. If the plumbite is present during the liberation of the sulphoxylate, some of the latter is oxidised by the plumbite before it is converted into sulphide and sulphite, and so a mixture of lead sulphide and lead is obtained. Alkaline solutions of sulphite give no reaction with plumbite under the conditions of these experiments, whilst thiosulphate in alkaline solution gives a very faint reaction which will be discussed in a later section (p. 1418).

The readiness with which sulphoxylic acid is converted into hydrogen sulphide and sulphurous acid in acid solution, or into sulphide and sulphite in alkaline solution, is quite sufficient to explain why hydrogen sulphide and sulphurous acid have been held to be the first products of the hydrolysis of sulphur. In view of these results, however, it is felt that there is every justification for considering that the primary reaction in the hydrolysis of sulphur, whether this occurs in acid or in alkaline solution, is correctly represented by the equation

$$2S + 2H_2O \rightleftharpoons H_2S + (HO)_2S \quad . \quad . \quad . \quad . \quad . \quad (I)$$

Attempts to verify this equation directly have not been successful, but they do not disprove it.

The action of moist sulphur on silver and other metals, even at the ordinary temperature, is undoubtedly due to slow hydrolysis of

the sulphur, which is accelerated by removal of the hydrogen sulphide as insoluble sulphide of the metal. Similarly, solutions of silver salts, or salts of other metals which form very sparingly soluble sulphides, are readily acted upon by sulphur on boiling. A quantitative experiment in which sulphur was digested with metallic silver in presence of chromic acid was in better agreement with reaction (I) than with a reaction $3S + 3H_2O \rightleftharpoons 2H_2S + H_2SO_3$, since approximately one molecule each of silver sulphide and sulphuric acid were formed (Expt. B).

When finely-ground rhombic sulphur was boiled with silver acetate solution, the alteration of the sulphur was very superficial owing to the dense, coherent film with which it became covered. This so effectively protected the sulphur that it was impossible to remove it completely even by long-continued extraction in a Soxhlet apparatus with benzene or carbon disulphide. Whether the film consisted of a mixture of silver sulphide and silver in the proportion to be expected from equation (I), could not therefore be determined.

The reactions $2S(OH)_2 = H_2S + H_2SO_4$ and $2S(OH)_2 = H_2S_2O_3 + H_2O$ look simple, but we can find no evidence that either of them occurs, although we have a certain amount of negative evidence against them. If sulphoxylic acid could undergo either of these changes, alkali should promote the changes, since both would correspond to a considerable increase in hydrogen ion. We find, however, that there is no sulphate produced when sodium formaldehydesulphoxylate is boiled with alkaline plumbite solution (Expt. C). Neither is any sulphate produced when sodium formaldehydesulphoxylate is hydrolysed in acid solution either alone or in presence of lead or arsenious salts (Expt. D). If the arsenious sulphide formed had resulted from the decomposition of thiosulphate, large amounts of sulphate would have been formed, as special experiments showed (Expt. E).

Long heating of alkaline solutions of sodium formaldehydesulphoxylate did not seem to lead to the formation of any thiosulphate; the sulphoxylate was apparently unchanged.

Sulphur separates at once when a strong hydrosulphite solution is added to concentrated hydrochloric acid, whereas when sodium thiosulphate is so added no separation of sulphur occurs for a long time (see p. 1430). If the sulphoxylic acid formed on hydrolysis of the hydrosulphite changed rapidly into thiosulphate, no separation of sulphur would therefore have been expected. That it does separate is not due to the presence of sulphite, for a solution containing an equimolecular mixture of sodium metabisulphite and thiosulphate did not yield any sulphur on being added to concentrated hydrochloric acid, except after long standing.

Foerster, Lange, Drossbach, and Seidel (*Z. anorg. Chem.*, 1923, **128**, 268) assume that the reaction $2S(OH)_2 = H_2S_2O_3 + H_2O$ does occur, and at one time we thought the same, but we have reached the conclusion that there is no justification or need for the assumption. At first sight such a change seems to be indicated by the fact that sodium hydrosulphite, in absence of air, in neutral or faintly acid solutions, changes quantitatively into sulphite and thiosulphate (Meyer, *Z. anorg. Chem.*, 1903, **34**, 43; K. Jellinek and E. Jellinek, *Z. physikal. Chem.*, 1919, **93**, 325). The solid salt undergoes a similar change, and old specimens contain large amounts of thiosulphate. It is probable that in this change the thiosulphate is not formed directly from sulphoxylic acid, but by a more complex mechanism which is considered on p. 1411.

The mechanism of the change of sulphoxylic acid into hydrogen sulphide and sulphurous acid calls for comment. A reaction $3S(OH)_2 \rightleftharpoons H_2S + 2H_2SO_3$ seems improbable because (i) it would be termolecular although it actually occurs very readily, and (ii) it is more likely that dissimilar molecules are respectively oxidised and reduced. We suggest that it is sulphoxylic acid itself which is reduced, whilst its anhydro-acid, HO·S·O·S·OH, which is isomeric with thiosulphuric acid, is oxidised. This would give a reaction represented by the equation

$$S(OH)_2 + HO{\cdot}S{\cdot}O{\cdot}S{\cdot}OH \rightleftharpoons H_2S + H_2S_2O_5 \quad . \quad . \quad (II),$$

where the $H_2S_2O_5$ is pyrosulphurous acid. The reversal of this change would be the first step in the Wackenroder reaction (see p. 1440)

The position with regard to equilibrium (II), as disclosed by the reactions of formaldehydesulphoxylate with metallic salts, is somewhat peculiar. On the one hand, with arsenious chloride, increase in *acidity* favours precipitation of arsenious sulphide instead of elementary arsenic, which is formed when little free acid is present, but, on the other hand, in presence of sodium plumbite, increase in *alkalinity* favours formation of lead sulphide, the proportion of metallic lead which is precipitated increasing as the alkalinity decreases. These two results, although at first sight contradictory, can be explained on the basis of equation (II). The reaction would proceed from left to right with a considerable increase in hydrogen ions, for there can be little doubt that sulphoxylic acid would be a very weak acid just as hypochlorous acid is. Alkali should therefore favour the change into sulphide and sulphite, which agrees with the results of the plumbite experiments. In acid solution, high acidity might be expected to favour formation of anhydrosulphoxylic acid at the expense of sulphoxylic acid, and this also would accelerate the change of the latter into hydrogen sulphide

and pyrosulphite. The effect of high acidity in favouring precipitation of arsenious sulphide, rather than of free arsenic, would then be intelligible. Increase in acidity would also tend to produce sulphur dioxide at the expense of either sulphurous or pyrosulphurous acid, and this also would hasten the decomposition of sulphoxylic acid. Reaction (I *b*) occurs with decrease of hydrogen ions, and so will be favoured by acidic conditions. It is this interaction of hydrogen sulphide and sulphoxylic acid which leads to the decomposition of sulphoxylic acid in acid solution in absence of metals which form insoluble sulphides. Such decomposition could be represented by the summation equation

$$2S(OH)_2 \rightleftharpoons H_2SO_3 + S + H_2O.$$

To postulate the existence of an anhydro-compound, such as HO·S·O·S·OH, under alkaline conditions may be considered unreasonable. This objection has been raised by Bucherer and Schwalbe (*Ber.*, 1906, **39**, 2814) to the unsymmetrical formula for sodium hydrosulphite. However, sulphoxylic acid may be expected to be a very weak acid, and anhydro- (or pyro-) or even meta-salts of weak acids can certainly exist in alkaline solution; for instance, the borates $Na_2B_2O_4,4H_2O$ and $K_2B_2O_4,2\frac{1}{2}H_2O$ can separate from solutions containing a large excess of alkali (Dukelski, *Z. anorg. Chem.*, 1906, **50**, 41).

Vogel and Partington (J., 1925, **127**, 1522) claim to have prepared solid, crystalline sodium sulphoxylate, Na_2SO_2, and sodium ethyl sulphoxylate, $NaEtSO_2$. The sodium sulphoxylate is said to be practically unattacked by boiling concentrated hydrochloric or sulphuric acid, although attacked by a hot mixture of fuming nitric acid and bromine. Such behaviour is most improbable, and our view is that these authors were actually dealing with more or less impure sodium sulphate. In any case it is certain that sodium sulphate is precipitated on addition of sulphuric acid to a solution of sodium compounds in absolute alcohol, and such addition was an important step in the recorded preparations.

Hydrosulphurous Acid.

The Factors which determine Colour in Simple Sulphur Compounds.—On the whole, the term "hydrosulphite," which is in fairly general use, would seem to be as good as any which has been suggested for the salt $Na_2S_2O_4$. "Hyposulphite," the official term, does not seem satisfactory, partly because this name has become so firmly attached to what is more correctly called thiosulphate, and partly because it is doubtful whether one could correctly apply it to $Na_2S_2O_4$, even if this complication did not exist. We

consider that it is sulphoxylic acid, $S(OH)_2$ or H_2SO_2, which alone has any right to be called hyposulphurous acid. Since $H_2S_2O_4$ is a "mixed" anhydro-acid, it has no right to the name, as it does not belong to the simple sulphuric–sulphurous series at all, any more than thiosulphuric acid does.

We cannot discuss all the evidence for the unsymmetrical anhydro-acid structure of the hydrosulphites, but merely wish to direct attention to the fact that the action of various oxidising agents strongly indicates this structure. Mild oxidising agents, such as silver salts, normally oxidise hydrosulphite to sulphite, but the action of molecular oxygen is exceptional, for Meyer (*loc. cit.*) showed that in this case sulphite and sulphate are formed. His figures indicate that these would be in equimolecular proportion were it not for disturbances due to hydrolysis of hydrosulphite by the acid formed as the oxidation proceeds. This seems to agree particularly well with the unsymmetrical formula. We have found that, in solutions containing sufficient sodium carbonate to neutralise the acid as it is formed, the atmospheric oxidation of hydrosulphite proceeds smoothly as a unimolecular reaction (Expt. F).

Solutions of sodium hydrosulphite, as is well known, become yellowish-brown on acidification. With concentrated solutions, the colour may be as deep as, and very similar to, that of $N/10$-iodine. The smell of hydrogen sulphide is quite evident directly after acidification, but is soon masked by that of sulphur dioxide. This formation of hydrogen sulphide is not generally mentioned, and although Bernthsen (*Annalen*, 1881, **208**, 172) and Meyer (*loc. cit.*) mention that cadmium sulphide is precipitated when hydrosulphite solutions containing cadmium sulphate are acidified, they do not appear to have noticed the hydrogen sulphide itself. Sulphur eventually separates from the acidified solution, but the time which elapses before this occurs may be considerable. The colour persists longest when the acidification has been effected by sulphurous acid. If a strong sodium hydrosulphite solution is added to concentrated hydrochloric acid, one obtains but a momentary brown colour, and a precipitate of sodium chloride and sulphur separates at once.

The colour of acid hydrosulphite solutions has never been satisfactorily explained. It has usually been regarded as the colour of the free acid, but, according to present-day views, since the salts are colourless the acid should be colourless too, unless some change of constitution occurs after it is set free from its salts. The bright, clear, deep-coloured solutions do not at all give the impression of colloidal solutions of sulphur, a possibility which has been mooted (Abegg's Handbuch, 1908, II, Pt. 1, p. 262).

When considering a possible explanation of the colour, several other instances of colour in simple sulphur compounds or their solutions should be borne in mind. The chief of these are : (1) Sulphur itself—the much deeper colour of plastic sulphur as compared with crystalline sulphur is of interest. (2) Sulphur mono- and di-chlorides, which are yellow. (3) Sulphur tetrachloride, which has a brownish-red colour. (4) The polysulphides. (5) The yellow or greenish-yellow solutions obtained by saturating strong alkali-metal or ammonium bisulphite solutions with sulphur dioxide. (6) The yellow solutions obtained by the action of sulphur dioxide on thiosulphate solutions : yellow solids, $K_2S_2O_3,SO_2$ and $Rb_2S_2O_3,SO_2$ have recently been prepared by Foerster and Vogel (*Z. anorg. Chem.*, 1926, **155**, 161). (7) The yellow compounds of sulphur dioxide with potassium thiocyanate and with potassium iodide (Fox, *Z. physikal. Chem.*, 1902, **41**, 458; Ephraim and Kornblum, *Ber.*, 1916, **49**, 2007).

Since potassium bromide and chloride combine with sulphur dioxide to form colourless compounds, it would appear that the colour of the potassium iodide compounds is in some way due to the iodine. The potassium iodide–sulphur dioxide compound need not therefore be considered in the present connexion. The compound $KCNS,SO_2$ would, however, seem to owe its colour in some way to the attachment of sulphur dioxide to the sulphur of the thiocyanate.

According to the modern theories of valency, the sulphur atom in all its ordinary compounds is surrounded by an outer shell of 8 electrons. This is true of all the sulphur atoms in the following, among others : The S″ ion of the sulphides, the HS′ ion, hydrogen sulphide, sulphites, sulphates, thiosulphates, and polythionates. The co-ordination number of these substances ranges from zero in the case of the S″ ion to 4 in the case of the sulphates. Nevertheless, all these compounds (unless a colour-giving positive ion is present) are colourless. The lack of visible colour seems, then, to depend upon the one common characteristic, the shell of 8 electrons, and is evidently independent of the state of the atom with respect to co-ordination.

The existence of the very stable sulphur hexafluoride shows that sulphur in suitable combination can have as many as 12 electrons in its outer shell. This compound also is colourless.

In sulphur tetrachloride, the sulphur atom would have an outer shell of 10 electrons, and since this compound has a brownish-red colour, it may well be that it is essentially the 10-electron sheath which determines visible colour in all the compounds we are considering. In potassium thiocyanate, the sulphur atom has the

normal 8-electron sheath, but when it becomes co-ordinated with a molecule of sulphur dioxide in the compound $KCNS,SO_2$, it is then surrounded by a 10-electron sheath, and the compound is yellow.

Most of the other yellow sulphur compounds referred to above can be accounted for on this basis. The greenish-yellow sulphite solutions owe their colour to H_2SO_3,SO_2—perhaps better written as $H_2\left[\begin{matrix}O\\O\end{matrix}S\begin{matrix}O\\SO_2\end{matrix}\right]$, which is isomeric with pyrosulphurous acid, $H_2\left[\begin{matrix}O\\O\end{matrix}SOS\begin{matrix}O\\O\end{matrix}\right]$. The yellow colour of thiosulphate solutions which have been treated with sulphur dioxide would be due to $H_2\left[\begin{matrix}O\\O\end{matrix}S\begin{matrix}O\\S\cdot SO_2\end{matrix}\right]$. In both these cases the sulphur atom to which the sulphur dioxide becomes attached would have a 10-electron sheath.

When hydrosulphurous acid is liberated from its salts, it will be readily hydrolysed to sulphoxylic acid and sulphurous acid. The yellowish-brown colour is most probably due to a compound, $(HO)_2S\cdot SO_2$, obtained by the co-ordination of one molecule of sulphur dioxide with the sulphur atom of a molecule of sulphoxylic acid. It could also arise directly by a simple intramolecular change. This compound is isomeric with hydrosulphurous acid itself, which may be written HO·S·O·SO·OH. When sulphur dioxide is passed into a solution of sodium formaldehydesulphoxylate, a solution of precisely the same colour is obtained as from sodium hydrosulphite. The properties of the two solutions are similar, and the coloured compound may be the same in the two cases. It is possible, however, that the formaldehyde still remains attached in the one case.

It is noteworthy that formaldehyde removes the colour from solutions of all the above sulphur dioxide addition compounds owing to formation of the very stable formaldehydesulphurous acid.

Sulphur monochloride, S_2Cl_2, would be expected on the above theory to be colourless. Its yellow colour may possibly be due to association in the liquid state, *i.e.*, co-ordination of one molecule with the sulphur atoms of other molecules.

The colour of sulphur itself and of the polysulphides is explicable on the basis of a colourless $S<\begin{matrix}S\\S\end{matrix}$ molecule, with a structure similar to that assigned by Rankine (*Proc. Physical Soc.*, 1922, 35, 33) to sulphur dioxide, in which all three sulphur atoms have 8-electron sheaths, or of an S_3 molecule of structure S=S—S, in which each sulphur atom would also have an 8-electron sheath. In hydrogen trisulphide, which is yellow, one of the sulphur atoms would have a 10-electron sheath, and so on. Hydrogen disulphide, which is

presumably H·S·S·H, is colourless (Walton and Parsons, *J. Amer. Chem. Soc.*, 1921, **43**, 2539).

Sulphur tetrachloride is the only coloured sulphur compound which has been considered that does not contain sulphur–sulphur linkages, but it seems unlikely that such linkages in themselves have any great influence on the colour, since thiosulphates, polythionates, etc., in which such linkages occur, are colourless. The 10-electron sheath seems to be the important factor, although, of course, the actual colour of any particular compound must depend to some extent upon its structure and composition as a whole. It may well be that union of 10-electron sulphur with 8-electron sulphur promotes colour in a similar way to that assumed by Willstätter and Piccard (*Ber.*, 1908, **41**, 1465) in organic compounds with a *meri*-quinonoid structure.

The decomposition of hydrosulphurous acid can be briefly summed up thus:

$$HO\cdot S\cdot O\cdot SO\cdot OH \rightleftharpoons (HO)_2S\cdot SO_2 \quad . \quad . \quad . \quad . \quad \text{(III)}$$

$$HO\cdot S\cdot O\cdot SO\cdot OH + H_2O \rightleftharpoons S(OH)_2 + \begin{matrix} H_2O + SO_2 \\ \uparrow\downarrow \\ H_2SO_3 \end{matrix} \quad . \quad . \quad \text{(IV)}$$

$$S(OH)_2 + SO_2 \rightleftharpoons (HO)_2S\cdot SO_2 \quad . \quad . \quad . \quad . \quad \text{(V)}$$

Whether direct rearrangement of the two isomeric forms of $H_2S_2O_4$ occurs, or whether one form is converted into the other *via* sulphoxylic acid formed by hydrolysis, it is not possible to say. Very likely both methods of change occur.

Since two sulphur atoms are directly united in $(HO)_2S\cdot SO_2$, its ready reduction to thiosulphate might be anticipated. K. Jellinek and E. Jellinek (*loc. cit.*) showed that hydrosulphurous and thiosulphuric acids are successive stages in the electrolytic reduction of sulphurous acid. Oxidation of $HO\cdot S\cdot O\cdot SO\cdot OH$ by $(HO)_2S\cdot SO_2$ probably accounts for the change of hydrosulphite into thiosulphate and pyrosulphite in accordance with the equation:

$$HO\cdot S\cdot O\cdot SO\cdot OH + (HO)_2S\cdot SO_2 \rightleftharpoons H_2S_2O_5 + H_2S_2O_3 \quad . \quad \text{(VI)}$$

The change follows a bimolecular course (K. Jellinek and E. Jellinek, *loc. cit.*). The Jellineks' observation, that in presence of sodium bisulphite the rate of change is greater and roughly proportional to the square of the bisulphite concentration, is probably due to a stabilising effect of the sulphite on the two forms of hydrosulphurous acid in accordance with reactions (IV) and (V).

In acid hydrosulphite solutions there occur, superimposed on the above changes, the two reactions of sulphoxylic acid represented by equations (I) and (II). In addition, there is the possibility of polythionic acid formation, either by interaction of hydrogen

sulphide and sulphurous acid or by decomposition of thiosulphate (see pp. 1416—17 and 1440). Polythionates appear to be always formed during the decomposition of hydrosulphurous acid (Foerster, Lange, Drossbach, and Seidel, *loc. cit.*, p. 278).

The fairly permanent, yellow colour, which remains after the yellowish-brown colour of $(HO)_2S{\cdot}SO_2$ has disappeared, is due to the sulphur dioxide–thiosulphuric acid complex.

Freshly acidified hydrosulphite has a most unpleasant smell suggestive of, but differing from, that of hydrogen sulphide, and not like a mixture of hydrogen sulphide and sulphur dioxide. It reminds one of sewer gas more than anything else, and it may well be the smell of sulphoxylic acid.

The Autoxidation of Sulphurous Acid.

It is known that in absence of air solutions of sulphurous acid slowly undergo a change which is generally represented by the equation $3H_2SO_3 = 2H_2SO_4 + S + H_2O$. This change is greatly accelerated by a high temperature or exposure to light.

Foerster, Lange, Drossbach, and Seidel (*loc. cit.*) have recently made a careful and exhaustive study of this reaction. With some of the theoretical conclusions of these authors we cannot agree, and we shall briefly explain our own views without adducing full details of the evidence. We agree with them (*loc. cit.*, p. 267) that two different molecules must be concerned in the oxidation and reduction which is the first step in the autoxidation, but not with their suggestion that these are two different forms of the HSO_3' or S_2O_5'' ions reacting according to the equations: $2HSO_3' \longrightarrow SO_4'' + H_2SO_2$; $S_2O_5'' \longrightarrow SO_4'' + SO$, where H_2SO_2 is sulphoxylic acid and SO its anhydride.

We consider that the reaction

$$H_2SO_3 + H_2S_2O_5 \rightleftharpoons H_2SO_4 + H_2S_2O_4 \quad . \quad . \quad . \quad \text{(VII)}$$

is far more probable, this equation being regarded as applying to the reactions of the respective ions as well as to the non-ionised acids, as mentioned on p. 1401. We have already (p. 1406) given reasons for the view that pyrosulphurous acid is the oxidising agent in the Wackenroder reaction, and if so, it is probably the oxidising agent in the autoxidation reaction also. Solutions of sulphurous acid appear to contain most of their sulphur dioxide as such (Wright, J., 1914, **105**, 2907), whilst solutions of alkali-metal bisulphites contain some pyrosulphite (metabisulphite) (Baly and Bailey, J., 1922, **121**, 1813; Getman, *J. Physical Chem.*, 1926, **30**, 266). It is not unreasonable to suppose that there is some pyrosulphurous acid even in "sulphurous acid" solutions. Since sulphate appears

from the very beginning of oxidation, sulphurous acid is probably the substance oxidised. $H_2S_2O_4$, hydrosulphurous acid, is then the most probable product of reduction of the pyrosulphurous acid.

Since the hydrosulphurous acid is unstable under the prevailing conditions, it does not accumulate but rapidly undergoes further change (p. 1411). This makes the proof of its formation difficult.

Jungfleisch and Brunel (*Compt. rend.*, 1913, **156**, 1719) stated that they had obtained all the reactions for hydrosulphite at the stage of the autoxidation just prior to the separation of sulphur. Foerster and his colleagues (*loc. cit.*, pp. 277, 288, 293, and 300) could only partly confirm this, although they admitted that in some cases small quantities of hydrosulphite are formed at some stage of the reaction.

The only reaction for hydrosulphite which can be obtained in these sulphite solutions undergoing autoxidation is the bleaching of indigo, which is very delicate (but see p. 1439).

Sulphur dioxide co-ordinated with thiosulphate or iodide [$H_2S_2O_3{\cdot}(SO_2)_x$; $HI(SO_2)_x$] may also be able to oxidise sulphurous acid and perhaps more rapidly than does pyrosulphurous acid. This would be represented by $H_2SO_3 + [SO_2] = H_2SO_4 + [SO]$, where square brackets indicate a co-ordinated condition; such a reaction could account for the remarkable way in which iodide or thiosulphate accelerates autoxidation of sulphurous acid (Foerster *et al.*, *loc. cit.*, pp. 266—269).

If our views expressed on pp. 1409—10 are correct, the yellow bisulphite solutions contain $H_2SO_3{,}SO_2$, in which the sulphur dioxide is co-ordinated in a similar way to that present in the iodide and thiosulphate complexes. The colour and other indications suggest that this form of pyrosulphurous acid is practically absent from sulphurous acid solutions, especially weak ones, which nevertheless undergo slow autoxidation. It seems likely, therefore, that it is the colourless pyro-acid form of $H_2S_2O_5$ (corresponding to the solid, colourless pyrosulphites or metabisulphites) —$SO_2H{\cdot}O{\cdot}SO_2H$— which is normally responsible for the first step in the autoxidation of sulphurous acid solutions (reaction VII), and that it is the pyro-acid form of hydrosulphurous acid —$H{\cdot}SO_2{\cdot}O{\cdot}S{\cdot}OH$— which is produced in this first step.

Some of the pyro-acid form of hydrosulphurous acid undergoes rearrangement to the coloured form, $H_2SO_2{\cdot}SO_2$, and the two forms then react to yield thiosulphate and pyrosulphite (reaction VI).

The middle phase of the autoxidation of sulphurous acid is essentially the decomposition of thiosulphuric acid (discussed on pp. 1416—40). Trithionic acid, one of the first products of this decomposition, gradually yields tetra- and penta-thionic acids as

the concentration of sulphurous acid diminishes with the progress of the autoxidation. The polythionic acids finally decompose in their turn, and the final products of the autoxidation are sulphur and sulphuric acid.

On account of this polythionic acid formation during autoxidation, tri- and tetra-thionic acids are almost always present in old sulphurous acid solutions, whether these have been entirely protected from atmospheric oxidation or not. As the thionic acids are slowly decomposed in acid solution, the amount surviving in any given case depends upon the age and composition of the solution (Expt. G, Table I).

No separation of sulphur occurs for a long time, because the excess of sulphurous acid stabilises both the sulphoxylic and the thiosulphuric acids by yielding with them the sulphur dioxide addition complexes. Formation of thiosulphate from sulphite and sulphur, according to reaction (VIII), is greatly facilitated, and also the formation of trithionate in accordance with reaction (IX), the hydrogen sulphide being removed by interactions with sulphoxylic acid (reaction I), with pyrosulphurous acid (reaction II), or with the sulphur dioxide of the sulphur dioxide–thiosulphate complex. The last reaction could be written $H_2S + [SO_2] = S(OH)_2 + S$, although it only occurs when the sulphur dioxide is combined or co-ordinated in a suitable manner (indicated by the square brackets).

We, like Foerster, suppose that the autoxidation involves the formation of thiosulphate and the breakdown of this by way of the polythionates. Our views differ more particularly as to the manner in which the thiosulphate originates and decomposes. We can find no evidence for the direct conversion of sulphoxylic acid into thiosulphuric acid, which is postulated by Foerster, and do not believe that it occurs (see pp. 1405, 1406, and 1439). The breakdown of thiosulphuric acid will be considered in the next section. Foerster considers that pentathionic acid is the first polythionic acid to be formed from thiosulphuric acid, whereas we consider that trithionic acid is first formed (reaction IX).

During the stage of autoxidation (reactions VII and VI), where thiosulphate is forming, the acidity or hydrogen-ion concentration increases, and addition of acid is consequently unfavourable to the reaction. On this account, bisulphite solutions undergo autoxidation much more rapidly than do sulphurous acid solutions.

This effect of the hydrogen ion is connected with its influence on the equilibria $H^{\cdot} + HSO_3' \rightleftharpoons H_2SO_3 \rightleftharpoons H_2O + SO_2$. The more acid the solution, the greater the proportion of sulphur dioxide present, and since the autoxidation becomes correspondingly slower, this favours the view that sulphur dioxide is not one of the primary

reactants. The well-known photochemical change $3SO_2 = 2SO_3 + S$ will not take place if the gas is absolutely dry (Coehn and Becker, *Z. physikal. Chem.*, 1910, **70**, 89), so that possibly even in this case the reaction follows a similar course to that outlined above, in the film of moisture adsorbed on the surface of the containing vessel.

Liquids other than water may be able to bring about the reaction, as in the somewhat similar case of the interaction of hydrogen sulphide and sulphur dioxide (Matthews, J., 1926, 2270). The view that pyrosulphurous acid is one of the primary reactants in the autoxidation of sulphurous acid is strengthened by the observations of Bennett (J., 1922, **121**, 1794), who found that sulphur, or even hydrogen sulphide, was liberated when sodium sulphite or pyrosulphite, in the solid state or in saturated solution, was added to hot concentrated sulphuric or phosphoric acid. Sulphur dioxide or its saturated solution in water would not act in this way. Under Bennett's conditions, the various stages in the autoxidation are passed through very rapidly, and it is not surprising that only the use of salts enables a sufficient concentration of pyrosulphurous acid to be obtained to make this possible.

It seems probable that, whenever sulphurous acid is reduced in presence of water, the reduction proceeds normally through the stage of hydrosulphite and not directly to sulphur or hydrogen sulphide. These would be products of decomposition of hydrosulphurous, sulphoxylic, or thiosulphuric acid. In certain cases the last may be the second step in the reduction, as in the electrolytic reduction already referred to (K. Jellinek and E. Jellinek, *loc. cit.*). Instances of reactions involving sulphurous acid which can be so accounted for are numerous (Smythe and Wardlaw, *Proc. Durham Phil. Soc.*, 1913—14, **5**, 187; Durrant, J., 1915, **107**, 622; Wardlaw and Clews, J., 1920, **117**, 1093; Wardlaw, Carter, and Clews, *ibid.*, p. 1241; Wardlaw and Pinkard, J., 1922, **121**, 210; Stewart and Wardlaw, *ibid.*, p. 1481; Rogers, J., 1926, 254; Carter, *J. Soc. Chem. Ind.*, 1926, **45**, 207T; Wardlaw, *ibid.*, p. 210T).

Bichowsky (*J. Amer. Chem. Soc.*, 1922, **44**, 116) has shown that at high temperatures (527—613° Abs.) the hydrolysis of sulphur leads to equilibria involving hydrogen sulphide, sulphur dioxide, and sulphuric acid. These can be regarded as resulting from a combination of the hydrolytic equilibria occurring at the ordinary temperature with the autoxidation equilibria.

The Decomposition of Thiosulphuric Acid.

Numerous investigations on the action of acids upon thiosulphates have been published during the last few years, since we commenced

our own experiments, and we disagree with many of the conclusions. We find that thiosulphuric acid decomposes according to the three reversible reactions

$$H_2S_2O_3 \rightleftharpoons H_2SO_3 + S \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (VIII),$$
$$2H_2S_2O_3 \rightleftharpoons H_2S + H_2S_3O_6 \quad . \quad . \quad . \quad . \quad . \quad (IX),$$
$$2H_2S_2O_3 \rightleftharpoons H_2O + H_2S_4O_5 \quad . \quad . \quad . \quad . \quad . \quad (X).$$

Only reaction (VIII) is usually mentioned in text-books.

Reaction (IX).—The fact that hydrogen sulphide is invariably formed in small amounts when acid is added to thiosulphate solutions has escaped notice almost entirely. Spring and Levy (*Bull. Acad. roy. Belg.*, 1876, **42**, 103; Spring's collected researches, 1923, Vol. II, p. 1028) observed it, and so did Colson (*Bull. Soc. chim.*, 1880, **34**, 66). Colson attempted to discover the nature of the reaction and determined the ratio of hydrogen sulphide and sulphuric acid formed. He found that this was variable and seems to have concluded that the hydrogen sulphide was formed by the action of nascent sulphur on hot water. Of later workers, only Foerster, Lange, Drossbach, and Seidel (*loc. cit.*, pp. 245, 307) allude to it. They suppose that hydrogen sulphide is formed by a minor side-reaction, $H_2S_2O_3 + H_2O \rightleftharpoons H_2SO_4 + H_2S$, and do not bring this into their scheme of polythionate formation. The presence of hydrogen sulphide in standard sodium thiosulphate solutions has been attributed by Schulek (*Z. anal. Chem.*, 1926, **68**, 387) to bacterial action.

We find that hydrogen sulphide is always produced when acids or even water alone acts upon sodium thiosulphate. The gas is evolved if carbon dioxide is bubbled through, or if the thiosulphate is warmed with boric acid, whilst stronger acids liberate it readily. Little or no sulphuric acid is produced unless the mixture is boiled for a long time. It then results from the hydrolysis of tri- and tetra-thionic acids (Expt. H).

According to Jellinek (*Z. physikal. Chem.*, 1911, **76**, 257; see also Kolthoff, *Rec. trav. chim.*, 1924, **43**, 216) the oxy-acids of sulphur can be arranged in order of increasing strength in the series

$$H_2SO_3,\ H_2S_2O_4,\ H_2S_2O_3,\ H_2SO_4,\ H_2S_2O_6,\ H_2S_3O_6.$$

Di- and tri-thionic acids are of about the same strength, and so are thiosulphuric and sulphuric acids, whilst sulphurous acid is much the weakest of the series; hydrogen sulphide is still weaker. Reactions (VIII) and (IX) correspond to a definite decrease of hydrogen-ion concentration when proceeding from left to right. They should therefore tend to occur in acid solution, as we find to be the case, whilst they should be reversed in alkaline solution, which is true also.

That polythionic acids are formed by the action of acids on thiosulphates is fairly well known: Chancel and Diacon (*Compt. rend.*, 1863, **56**, 710; *J. pr. Chem.*, 1863, **90**, 55) seem to have been the first to observe it. We believe that our experiments show that reaction (IX) is the most important one by which these acids are formed. It is true that the amount of hydrogen sulphide liberated is very small in proportion to the amount of polythionic acids formed, but this is because reaction (VIII) is that which normally occurs to the greatest extent when acid acts upon thiosulphate. The hydrogen sulphide is thus liberated in presence of a large amount of sulphurous acid and destroyed by the same reactions which occur in the Wackenroder solution, which will be considered presently.

On this basis, trithionic acid becomes a primary, if not *the* primary, thionic acid produced.

The argument used by Foerster and Vogel (*loc. cit.*, p. 173) to show that penta- and not tri-thionic acid must be the primary thionic acid is unsound. According to our scheme, trithionic acid, formed by reaction (IX), combines with sulphur, formed by reactions (VIII), (II), and (I), to yield tetra- and penta-thionic acids. These are also formed by interaction with thiosulphate according to reactions (XIII) and (XIV). The fact that more thiosulphate than sulphite was consumed in Foerster and Vogel's experiments can thus be quite satisfactorily accounted for on the basis of our views.

Tetra- and penta- as well as tri-thionic acids are formed in the action of acids on thiosulphates, but the points which arise in this connexion will be discussed in the next section, which deals with the Wackenroder reaction.

Spring and Levy (*loc. cit.*) are the only authors who have attached any importance to the liberation of hydrogen sulphide, and who have assumed that polythionates result from trithionate formed in the manner just indicated. Of the greatest significance in this connexion is the fact that in alkaline solution the converse change occurs, alkali sulphide and trithionate reacting to form thiosulphate (Chancel and Diacon, *loc. cit.*).

We consider that there is overwhelming evidence that a reaction $H_2S_2O_3 + H_2O \rightleftharpoons H_2SO_4 + H_2S$ does not occur in either direction. The direct formation of sulphuric acid and hydrogen sulphide from thiosulphuric acid would correspond to a small increase in hydrogen ions, so that, if it is possible, it should be favoured by alkali and hindered by acid, whilst the formation of thiosulphate from sulphate and sulphide should be favoured by acidic conditions. Now we have found that in alkaline solutions mixtures of sulphate

and sulphide do not react to form thiosulphate, nor does thiosulphate yield sulphate and sulphide [see Expt. I, (i), (ii), and (vi)]. There seem to be only two ways of explaining these facts: either (*a*) the chemical inertia of the system is so great that unstable conditions persist more or less indefinitely, or (*b*) thiosulphate is not directly related to sulphate and sulphide in the manner indicated by the above equation.

There is considerable evidence in support of (*b*). The precipitation of sulphides of metals by the action of soluble thiosulphates on solutions of their salts, or by decomposition of previously-formed thiosulphates of the metals, is usually supposed to occur in such a way as to give sulphide and sulphate directly, *e.g.*, $Ag_2S_2O_3 + H_2O = Ag_2S + H_2SO_4$, and a similar decomposition of thiosulphuric acid has been inferred. The same result could, however, be reached *via* the trithionate, *e.g.*,

$$2Ag_2S_2O_3 = Ag_2S + Ag_2S_3O_6; \; Ag_2S_3O_6 + 2H_2O = Ag_2S + 2H_2SO_4.$$

Since the trithionates of the heavy metals are nearly as unstable as the thiosulphates, it is difficult to settle this point with simple thiosulphates, although Fogh (*Compt. rend.*, 1890, **110**, 524) has shown quite clearly that when lead thiosulphate is boiled with water it yields, in the first instance, sulphide and trithionate. Fogh states that this decomposition into trithionate can occur quantitatively without any side reactions, but we have always found some decomposition of trithionate with consequent formation of sulphate and liberation of sulphur dioxide. It is certain, however, that the main reaction is that which yields trithionate. With double thiosulphates, it is easier to demonstrate that trithionate is formed, and Spring (*Bull. Acad. roy. Belg.*, 1874, **37**, 45; *op. cit.*, Vol. 2, p. 966) showed that solutions of the double thiosulphates of an alkali metal and silver, mercury, or lead yield on boiling silver, mercury, or lead sulphide and alkali trithionate. Conversely, lead sulphide on digestion with potassium trithionate was converted into lead thiosulphate. When boiled with less than the equivalent amount of alkali, lead thiosulphate is largely converted into trithionate [Expt. I, (vii)], and also when boiled with dilute acetic acid [Expt. I, (viii)]. We find that weakly alkaline solutions of sodium thiosulphate on boiling yield sulphide and trithionate, but only a trace of sulphate. If they are boiled with sodium plumbite, lead sulphide is precipitated and trithionate remains in solution, which is in agreement with Spring's results (Expt. I).

With strongly alkaline solutions of thiosulphate, the above reaction would not be expected to occur to any extent, for, in the equilibrium (IX), increased alkalinity favours the formation of

thiosulphate. A minute trace of sulphide always seems to be formed, however [Expt. I, (iii)].

Since trithionate on hydrolysis can yield sulphate, sulphite, and thiosulphate (pp. 1421, 1422), and thiosulphate yields trithionate, it follows that there are relationships, although indirect ones, between thiosulphate, sulphide, and sulphite on the one hand, and thiosulphate, sulphide, and sulphate on the other. The position can be seen from a consideration of the reactions

$$2H_2S_2O_3 \rightleftharpoons H_2S + H_2S_3O_6 \overset{H_2O}{\rightleftharpoons} 2H_2S + H_2S_2O_7 \overset{H_2O}{\rightleftharpoons} 2H_2S + 2H_2SO_4 \quad \text{(i)}$$

$$\left.\begin{aligned} 2H_2S_2O_3 &\rightleftharpoons H_2S + H_2S_3O_6 \\ 2H_2S_3O_6 &\overset{H_2O}{\rightleftharpoons} H_2S_2O_3 + 4H_2SO_3 \end{aligned}\right\} 3H_2S_2O_3 \overset{3H_2O}{\rightleftharpoons} 2H_2S + 4H_2SO_3 \quad \text{(ii)}$$

From (i) it is seen that in alkaline solution the equilibria of its constituent reactions lie right over to the left as regards the change of thiosulphate into sulphide and trithionate, and completely to the right as regards the hydration of pyrosulphuric acid. For this reason, both ends of the reaction chain (i) appear equally stable in alkaline solution. Only in very strong sulphuric acid solution is any change in the direction of trithionate and thiosulphate possible.

Conditions are somewhat similar as regards (ii). In alkaline solution, the positions of equilibria are well to the left as regards the thiosulphate–trithionate reaction, and well to the right as regards the conversion of trithionate into sulphite and thiosulphate (which occurs in the steps discussed on p. 1447), so that here also it is found that thiosulphate shows no tendency to be hydrolysed to sulphide and sulphite, whilst, on the other hand, sulphide and sulphite will not react to yield thiosulphate [Expt. I, (iv) and (v)].

If only the summation equations $H_2S_2O_3 + H_2O \longrightarrow H_2S + H_2SO_4$ and $3H_2S_2O_3 + 3H_2O \longrightarrow 2H_2S + 4H_2SO_3$ are considered, quite erroneous ideas are formed.

Foerster and Mommsen (*Ber.*, 1924, **57**, 258; see also Foerster and Vogel, *loc. cit.*, p. 168) found that sodium hydrogen sulphide and bisulphite react smoothly to yield sodium thiosulphate: $2NaHS + 4NaHSO_3 \longrightarrow 3Na_2S_2O_3 + 3H_2O$. This summation equation has the same form as (ii) above, but it would seem that it represents a mechanism entirely different from that considered above. In all probability, Foerster and Mommsen's synthesis of thiosulphate involved reactions (II*b*), (I*b*), and (VIII*b*), occurring in succession. Here again, since alkali strongly favours thiosulphate in reaction (VIII) and the mixture of sulphide and sulphite in reaction (ii), we have the curious position that in alkaline solution both thiosulphate and also the mixture of sulphide and sulphite are

equally stable. Only in the neighbourhood of the neutral point is synthesis of thiosulphate possible by this method. We have found that sulphide and sulphite do not react in alkaline solution [Expt. I, (iv) and (v)].

Barium thiosulphate decomposes very slowly when boiled with water. Considerable quantities of polythionates are formed, but relatively little sulphate. The formation of barium sulphate equivalent to the barium thiosulphate would be expected if thiosulphuric acid decomposed according to the scheme $H_2S_2O_3 + H_2O \longrightarrow H_2SO_4 + H_2S$, in which case, moreover, the decomposition should be greatly accelerated by the presence of barium, as it is by the presence of salts of copper, silver, and mercury, even after allowance has been made for the fact that barium sulphate is not nearly so insoluble as the sulphides of these metals.

An experiment due to Muck (*Ber.*, 1871, **4**, 446) seems at first sight to show that direct action of hydrogen sulphide on sulphuric acid *is* possible. This author found that, on boiling manganese sulphide with a solution of ammonium sulphate, ammonia and hydrogen sulphide were expelled and trithionate was formed, although only in small amount. He gives no indication of the amount of trithionate formed and does not prove that it was not thiosulphate. It is clear that in this experiment the manganese sulphide serves merely as a source of hydrogen sulphide, which is liberated by the action of the acid produced from the ammonium salt by hydrolysis. We have repeated the experiment and find that it is thiosulphate which is produced, not trithionate. The amount formed is exceedingly small if one takes precautions to exclude air as thoroughly as possible. It is not easy to prevent the formation of a small amount of black oxide of manganese—a sure sign of oxidation—and the thiosulphate is probably formed by atmospheric oxidation of hydrogen, or possibly ammonium, sulphide, this oxidation being perhaps catalysed by the manganese oxide. It is known that atmospheric oxidation of ammonium sulphide solutions does give rise to thiosulphate. We found that an old ammonium sulphide solution, which had deposited sulphur and lost its colour, had become a strong solution of ammonium thiosulphate (Expt. J).

Hydrogen sulphide and strong sulphuric acid interact, especially when hot, to produce sulphur and sulphurous acid, and this is generally represented by means of the equation $H_2S + H_2SO_4 \longrightarrow H_2SO_3 + H_2O + S$. At the ordinary temperature, the sulphuric acid has to be almost $25N$ before any separation of sulphur occurs on passage of hydrogen sulphide. One would have expected interaction at lower concentrations if non-ionised sulphuric acid were the active agent in the oxidation. It seems much more likely that

it is pyrosulphuric acid which reacts with the hydrogen sulphide in the first instance, and that the oxidation of the hydrogen sulphide by strong sulphuric acid takes place in several steps, the first of which consists in the formation of trithionic acid according to the equation

$$H_2S_2O_7 + H_2S \rightleftharpoons H_2S_3O_6 + H_2O \quad . \quad . \quad . \quad (XI)$$

It is probable that pyrosulphuric acid is present to some extent in acid as concentrated as 25*N*, but it is scarcely likely to be present at much lower concentrations.

Hydrolysis of the trithionic acid in the manner discussed on p. 1447 could yield sulphurous acid and thiosulphate, which would itself give sulphurous acid and sulphur. Sulphur could also be formed by interaction of hydrogen sulphide and the intermediate products of the hydrolysis. We consider that we have obtained small quantities of trithionic acid by the action of hydrogen sulphide on sulphuric acid of such a strength that sulphur is just not deposited when a current of hydrogen sulphide is passed through (Expt. K).

Trithionic acid must be regarded as being thiopyrosulphuric acid, and the hydrolysis of heavy-metal trithionates would yield pyrosulphuric acid in the first instance, and not two mols. of sulphuric acid as shown on p. 1418. On the above basis, the remarkable stability of thiosulphate towards alkali becomes intelligible,

Since an equilibrium $H_2S_2O_3 + H_2O \rightleftharpoons H_2S + H_2SO_4$ does not occur in any circumstances, there is no tendency for thiosulphate to be decomposed in such a manner by alkali, and likewise no possibility of interaction of sulphide and sulphate.

It is to be noted that in the equilibrium (IX) thiosulphuric and trithionic acids are of approximately the same strength, whilst hydrogen sulphide is much weaker. Alkali therefore shifts this equilibrium in favour of thiosulphate, and it is only in feebly alkaline solutions that there is any appreciable decomposition into sulphide and trithionate. Under more alkaline conditions, sulphide and trithionate readily yield thiosulphate, which is thus very stable in presence of strong alkali.

There is a difficulty in connexion with the hydrolysis of trithionates which has been pointed out by Foerster and Hornig (*Z. anorg. Chem.*, 1922, **125**, 119). Both in weakly alkaline and in weakly acid solutions, the hydrolysis of trithionic acid follows a course which can be represented by the equation $H_2S_3O_6 + H_2O \longrightarrow H_2SO_4 + H_2S_2O_3$. This hydrolysis is enormously accelerated by salts of copper, silver, and mercury with precipitation of the sulphides of these metals. This would be explicable, if the above hydrolysis is reversible, by the disturbance of the equilibrium caused by decom-

position of the thiosulphuric acid brought about by the insolubility of the metal sulphides precipitated. Against this view of the matter is the fact that the presence of added sulphate does not seem to slow down the rate of hydrolysis, whilst the presence of barium salts does not appreciably accelerate it, as might have been expected in view of the insolubility of barium sulphate.

The following is a possible way out of the difficulty: Trithionic acid is an equilibrium mixture of the two forms

$$(a)\ SH{\cdot}SO_2{\cdot}O{\cdot}SO_2{\cdot}OH \rightleftharpoons OH{\cdot}SO_2{\cdot}S{\cdot}SO_2{\cdot}OH\ (b)$$

both of which could equally well be formed from thiosulphuric acid by elimination of hydrogen sulphide; form (*b*) seems to be favoured by alkaline conditions, which would indicate that it is the more acidic of the two—possibly because of its greater symmetry. Under ordinary conditions of acidity both forms will be present, (*a*) predominating. Equilibrium between the two forms is probably established very rapidly. Hydrolysis of form (*a*) yields, in the first instance, hydrogen sulphide and pyrosulphuric acid, and it is not surprising that the hydrolysis is greatly accelerated by copper, silver, and mercury salts owing to the insolubility of the sulphides of these metals. There is, however, no reason why a barium salt should accelerate hydrolysis in this direction, for in the equilibria

$$H_2S_3O_6 + H_2O \rightleftharpoons H_2S + H_2S_2O_7 \overset{+H_2O}{\rightleftharpoons} H_2S + 2H_2SO_4$$

the pyrosulphuric acid would be hydrated nearly as quickly in absence of barium as in its presence, since the equilibrium would be almost entirely in favour of sulphuric acid except in very acid concentrated solutions. For a similar reason, sulphate ions have little influence on the rate of hydrolysis.

The results of Kurtenacker and Kaufmann (*Z. anorg. Chem.*, 1925, **148**, 43) and of Foerster and Hornig (*loc. cit.*, p. 86) show that under neutral and acid conditions and in absence of heavy metals the hydrolysis of trithionic acid yields chiefly sulphate and thiosulphate. In presence of sodium acetate, quantitative agreement with the equation $H_2S_3O_6 + H_2O \longrightarrow H_2SO_4 + H_2S_2O_3$ is obtained (Foerster, *ibid.*, 1925, **144**, 337). It does not necessarily follow, however, that this is the primary reaction.

Kurtenacker and Kaufmann (*loc. cit.*, p. 369) have shown that in strongly alkaline solutions the hydrolysis of trithionate yields no sulphate, but only sulphite and thiosulphate: $2H_2S_3O_6 + 3H_2O \longrightarrow H_2S_2O_3 + 4H_2SO_3$. We consider the possible mechanism of this change on p. 1447. With decreasing alkalinity, sulphate is formed as well as sulphite and thiosulphate. In presence of sodium acetate, *i.e.*, under practically neutral conditions, sulphate and thiosulphate

are formed in equimolecular proportion, as Foerster showed. Rapid hydrolysis of trithionate in strongly acid solution yields more than one-third of the original sulphur in the form of sulphate. This agrees with the views expressed above, but does not prove that they are correct, for the extra sulphate might possibly be derived from polythionates formed by the Wackenroder reaction from hydrogen sulphide and sulphur dioxide, which are also formed during the hydrolysis. We do not think this is very likely, however (Expt. L).

We believe that trithionate never yields sulphate and thiosulphate directly on hydrolysis (which is why neither barium nor sulphate ions influence the reaction appreciably). Form (*a*) yields hydrogen sulphide and pyrosulphuric acid only, in the first instance, whilst form (*b*) is hydrolysed in the manner discussed on p. 1447. This in three steps leads to the reaction actually realised in strongly alkaline solution: $2H_2S_3O_6 + 3H_2O \longrightarrow H_2S_2O_3 + 4H_2SO_3$. Now sulphoxylic acid is an intermediate product in the hydrolysis of the (*b*) form, and would react with hydrogen sulphide formed on hydrolysis of form (*a*). If forms (*a*) and (*b*) were present in equal proportion and hydrolysed at the same rates, we should have the following combinations of reactions:

$$\begin{aligned}
\text{(Two steps)}\quad & H_2S_3O_6 + 2H_2O \rightleftharpoons 2H_2SO_4 + H_2S \\
\text{(Two steps)}\quad & H_2S_3O_6 + 2H_2O \rightleftharpoons 2H_2SO_3 + (HO)_2S \\
& H_2S + (HO)_2S \rightleftharpoons 2S + 2H_2O \\
& 2H_2SO_3 + 2S \rightleftharpoons 2H_2S_2O_3 \\
& 2[H_2S_3O_6 + H_2O \rightleftharpoons H_2SO_4 + H_2S_2O_3]
\end{aligned}$$

This balanced state of the two modes of hydrolysis seems to occur in neutral solution.

It is noteworthy in connexion with the above suggestions that hydrogen sulphide is always formed during the acid hydrolysis of trithionate, as was noticed by Kessler (*Pogg. Ann.*, 1848, **74**, 262). The fact that it is noticeable more particularly at the very commencement of the action suggests that it is, in the main, a real primary product rather than a product of decomposition of the thiosulphate.

Needless to say, and as Foerster and Hornig and Kurtenacker and Kaufmann have shown, the other polythionic acids are formed during the acid hydrolysis of trithionate as in all acid decompositions of sulphur acids, but these are due to later changes than those now being discussed. In Expt. M we record two hydrolytic experiments which extend Kurtenacker and Kaufmann's results.

Reaction (VIII).—Under most conditions, reaction (VIII) occurs

to the largest extent. It involves a perfectly definite equilibrium, such that in alkaline solution the thiosulphate is very stable. On this account, thiosulphate is readily formed by boiling alkaline sulphite solutions with sulphur. Nevertheless, even in the alkaline solutions there may be a perfectly definite although very small dissociation into sulphite and sulphur. If alkaline thiosulphate solutions containing alkali sulphide are boiled in absence of air, they become deep yellow owing to formation of polysulphide, the extra sulphur for which is obtained from the thiosulphate. A similar result is obtained by boiling an alkaline thiosulphate solution with sodium formaldehydesulphoxylate. The yellow solution obtained gives an immediate precipitate of lead sulphide with lead plumbite. This is rather an elegant method of showing that sulphide is formed on alkaline hydrolysis of sulphoxylate (compare p. 1403).

The equilibrium between sulphide and thiosulphate may be written $Na_2S + Na_2S_2O_3 \rightleftharpoons Na_2S_2 + Na_2SO_3$, although higher polysulphides might result as well. Such a reaction does not necessarily involve any dissociation of thiosulphates into sulphite and sulphur. There can be little doubt that it is because of such equilibria that a trace of hydrogen sulphide greatly accelerates the reaction between sodium sulphite and sulphur. We have found that sometimes there is a long delay before sulphur begins to dissolve in boiling sodium sulphite solution, and in such cases the effect of passing a few bubbles of hydrogen sulphide into the solution is very marked; once the reaction has commenced it proceeds smoothly. The catalytic action of sulphide has been referred to recently by Watson and Rajagopalan (*J. Indian Inst. Sci.*, 1925, **8**, A, 275), and had been previously noted by Hargreaves and Dunningham (*J. Soc. Chem. Ind.*, 1923, **42**, 147T). Alkali also catalyses the reaction owing to the production of sulphide by hydrolysis of the sulphur. It must be supposed that sodium sulphide or hydrogen sulphide is more efficient in detaching atoms of sulphur from solid sulphur than is sodium sulphite.

Holleman (*Rec. trav. chim.*, 1895, **14**, 71) considered that the decomposition of thiosulphuric acid into sulphur and sulphurous acid followed a unimolecular course, although he recognised that the figures with which he supported this view indicated some complication. He does not seem to have considered the possibility of a bimolecular reaction, although his figures give better values for such a reaction.

His method was to determine by an iodine titration the amount of decomposition which had occurred in sodium thiosulphate solutions of different concentrations one minute after mixing with the equivalent amount of hydrochloric acid. His three experiments

are given below, with the values of k calculated for uni- and bi-molecular reactions.

Mixture used.	$k_{uni.}$	$k_{bi.}$
M-$Na_2S_2O_3$ added to $2M$-HCl	0·437	1·124
$M/2$-$Na_2S_2O_3$ added to M-HCl	0·258	1·209
$M/5$-$Na_2S_2O_3$ added to $2M/5$-HCl	0·068	0·717

The correct values for k cannot be calculated from Holleman's data. He assumed, erroneously, that when decomposition was complete the final value of the iodine titre would be twice the initial titre, and on this basis he calculated the concentration of thiosulphate left after one minute. The true values are less than those used in the above calculations, for, owing to polythionate formation, thiosulphate disappears more quickly than is indicated by the increase in the iodine titre. We find that, instead of increasing to double the original titre, the final titre may be only 20—80% greater.

As it is now generally accepted that unimolecular reactions are very uncommon (see, *e.g.*, Hinshelwood and Topley, J., 1924, **125**, 393), we have examined the kinetics of the decomposition of thiosulphuric acid more fully. The method used was to titrate acidified solutions after different intervals of time with standard iodine solution, continuing until the iodine titre reached a maximum value and became approximately constant or even decreased.

It is evident from the figures quoted (Expt. N) that the maximum value of the iodine titre is smallest for the most dilute solutions, and tends to increase both with increasing concentration of thiosulphate and with increasing acidity. Even in the most acid solution examined, the maximum titre was only 75% greater than the initial. If thiosulphuric acid decomposed only according to reaction (VIII), the iodine titre would eventually become doubled; if the decomposition was entirely according to reaction (IX), the titre would remain unaltered. If both modes of decomposition occur together, then reactions (II*b*) and (I*b*) follow as a matter of course, and, provided reactions (VIII) and (IX) occur in the right proportion, the iodine titre might fall to zero.

The greater part of the sulphurous acid formed in reaction (VIII) becomes either pyrosulphurous acid or sulphur dioxide and, when extended to include these changes, reaction (VIII) corresponds to a greater decrease of acidity than does reaction (IX). It follows that the more acid the conditions under which thiosulphuric acid decomposes, the more may reaction (VIII) be expected to predominate as compared with reaction (IX) (compare pp. 1430—31). The increase in the maximum iodine titration with increasing acidity, in the experiments under consideration, seems to be mainly due to such an increase in the relative importance of reaction (VIII).

The reason for the existence of a maximum iodine titre at all must be considered. From the experiments quoted, it will be seen that it is practically only in the cases where acid and thiosulphate are mixed in equivalent amounts that well-marked maxima exist. Moreover, in these cases the maxima occur at a very early stage of the reaction. In experiments where excess of acid was used, the iodine titre slowly approached a limiting value, and if it subsequently diminished at all it did so very slowly. In those cases where thiosulphate and acid were mixed in equivalent amounts, the acidity of the mixed solution at the commencement may be considered as being due entirely to thiosulphuric acid, which is a strong acid. As decomposition proceeds, according to reactions (VIII) and (IX), supplemented by reactions (II*b*) and (I*b*), a considerable decrease of acidity occurs. Because of this diminution in the acidity of the solution, reaction (IX) tends to increase relatively to reaction (VIII) as the decomposition proceeds, and this could account for the experimentally observed maximum iodine titre, for not only does reaction (IX) itself cause no increase in the original titre, but, in consequence of reactions (II*b*) and (I*b*), it will lead to the destruction of some of the accumulated sulphurous acid and so cause a decrease in the iodine titre.

Even in very weakly acid solutions, reactions (II*b*) and (I*b*) in conjunction seem to occur with great rapidity owing to the considerable decrease in acidity which they produce, and in all but the weakest and least acid solutions we may safely assume that none of the iodine reduction is due to either hydrogen sulphide or sulphoxylic acid. It is because of the rapidity of these reactions that hydrogen sulphide cannot be detected by means of lead salts (Holleman, *loc. cit.*) or even silver salts in acidified thiosulphate solutions, but it can, in favourable circumstances (Expt. H), be detected in the vapours given off from such solutions on boiling, owing to the fact that hydrogen sulphide and sulphur dioxide can coexist in presence of water vapour and need liquid water for interaction to occur (Matthews, *loc. cit.*).

It will be found that the combination of reactions (VIII) and (IX) with (II*b*) and (I*b*) * just sufficient to remove all the hydrogen sulphide formed by reaction (IX) yields the summation equation

$$10H_2S_2O_3 \longrightarrow 4H_2S_3O_6 + 4S_2 + 6H_2O,$$

8 mols. of thiosulphuric acid having decomposed according to reaction (IX), and 2 mols. according to reaction (VIII). Now it is clear that, for any increase at all to occur in the iodine titre of the

* Bearing in mind that $H_2S_2O_5$ is formed from $2H_2SO_3$ by loss of water, whilst HO·S·O·S·OH yields $2S(OH)_2$ by addition of water.

decomposing thiosulphate solution, an additional 10 mols., at least, of thiosulphuric acid must decompose according to reaction (VIII) in the early stages of the decomposition. The 20 mols. of thiosulphuric acid would require 20 atoms of iodine for oxidation to tetrathionate. If, however, 10 decomposed as in the above equation, the products would not react with iodine, but the 10 mols. of sulphurous acid formed by the remaining 10 mols. of thiosulphuric acid would require 20 atoms of iodine for oxidation to sulphate. It would appear that in all the cases we have studied, more than 50% of the decomposition took place in accordance with reaction (VIII), and usually a much larger proportion.

It is evident that if the sulphoxylic acid formed by reaction (II*b*) did persist at all, it would have a large effect on the iodine titre, since 1 mol. of sulphoxylic acid requires 4 atoms of iodine to oxidise it to sulphuric acid. It would be possible for a maximum in the iodine titre to arise, quite apart from any change in the relative proportions in which reactions (VIII) and (IX) took place, from an accumulation of sulphoxylic acid in the early stages of the decomposition of thiosulphuric acid, followed by its destruction by interaction with hydrogen sulphide at a later stage. This is unlikely to occur except in dilute and weakly acid solutions, but we have satisfied ourselves that even in solution (*c*) (see Table V) no sulphoxylic acid can be detected. This solution was found to behave exactly like thiosulphate towards methylene-blue (see p. 1435), whilst with ammoniacal silver nitrate it gave no metallic silver, as would sulphoxylic acid, but after many hours' standing it gave an amount of silver sulphide which more or less corresponded to the thiosulphate left undecomposed at the moment of adding the ammoniacal silver nitrate.

During the early stages of the decomposition of thiosulphuric acid, a certain proportion of tetra- and penta-thionic acids will have been formed in many cases owing to reactions (XIV*a*) and (XV*a*)—and perhaps (XII*a*) and (XIII*a*). Towards the end of the decomposition, the higher polythionates will have become less stable owing to the general decrease of acidity (see p. 1448), and reactions (XIV*b*) and (XV*b*) will tend to take place. Decomposition of the thiosulphuric acid so produced would occur in accordance with reaction (IX), whilst the hydrogen sulphide formed would cause further destruction of sulphurous acid. It is probable that some of the very slow decrease in the iodine titre at the end of the decomposition is to be accounted for in this way.

Moreover, from the fact that more sulphate was formed in the latest stages of the (*b*) experiment (see Table V) than corresponds to the iodine titration, it would seem that slow hydrolysis of trithionate

under the influence of sulphurous acid sets in after an hour or less.

It is evident from the preceding discussion that, in those cases where a well-marked maximum occurs, decomposition of the thiosulphate will probably not be complete when this maximum is reached. The amount of thiosulphate still undecomposed is readily obtained by determining the sulphate present after the iodine titration, assuming that sulphurous and thiosulphuric acids had been the only substances present which reacted with iodine. This determination was made in a number of cases, the titrated solution being heated just to boiling immediately before adding the barium chloride. No appreciable hydrolysis of polythionates occurs under these conditions. The amounts of thiosulphate decomposed at earlier stages [x in the fourth columns of Table V, (a), (b), and (c)] were calculated from the values so found for the maxima, on the assumption that they were proportional to the iodine titre. Using these figures, the bimolecular velocity coefficients were calculated and surprisingly good values were obtained.

In the case of experiments (a) and (b), the sulphate estimation was made in each case after the iodine titration. The tables show that the rate of decomposition of thiosulphate, under the conditions of these experiments, increases very rapidly with increase in concentration of thiosulphate. In the very early stages of the decomposition the amount transformed in a given time is roughly proportional to the *square* of the thiosulphate concentrations, whilst the time taken to complete a certain fraction of the decomposition is, to a rough approximation, inversely proportional to the initial concentration of thiosulphate.

In those experiments where excess of hydrochloric acid was used, the influence of thiosulphate concentration was of the character just stated for a considerable proportion of the reaction, but where acid and thiosulphate were used in equivalent amounts, the figures show that during most of the decomposition the weaker solutions were decomposing at a greater rate than would be expected from the concentration, and this becomes more obvious as the decomposition proceeds.

It is probable that as reaction (IX) increases relatively to reaction (VIII) in the dilute, weakly acid solutions, the increased extent to which reactions (IIb) and (Ib) occur will have an appreciable accelerating effect on both reactions (VIII) and (IX), so that, as a whole, the decomposition of thiosulphate proceeds at a relatively enhanced rate.

When all the results summarised in Expt. N and discussed above are considered critically, they indicate that the decomposition of

thiosulphuric acid follows a bimolecular course over a considerable range. Some caution must, of course, be used in interpreting the results of reaction-velocity determinations with such complex systems as that under discussion.

It is admitted that the decomposition of thiosulphuric acid is a mixed reaction and due to two simultaneous primary changes (VIII) and (IX), but as, under the conditions studied, the change into sulphurous acid and sulphur represented 50—75% of the whole decomposition, such good agreement with the bimolecular formula could scarcely be obtained unless this change were bimolecular. In fact, the results support the view that both primary reactions are bimolecular. Reaction (VIII) must therefore be represented by the equation $2H_2S_2O_3 \rightleftharpoons 2H_2SO_3 + S_2$. This seems to show that the sulphur unit concerned (we hesitate to call it a molecule) is S_2, and may explain why hydrogen sulphide catalyses the reaction between sodium sulphite and solid sulphur. Since hydrogen sulphide can combine with S_2 to form hydrogen trisulphide, whilst sodium sulphite can only combine with one atom of sulphur, 1 mol. of hydrogen sulphide could detach the S_2 unit from solid sulphur, whereas 2 mols. of sodium sulphite would have to co-operate. Since hydrogen disulphide also exists, the trisulphide could pass on its extra sulphur to sodium sulphite in two steps :

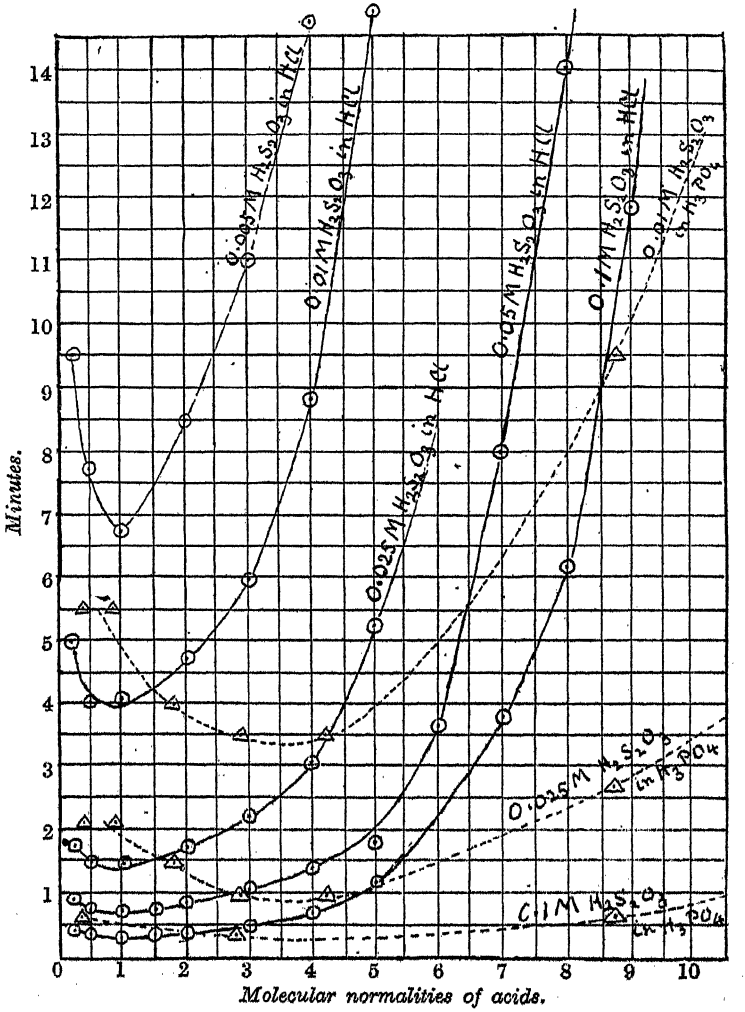
$$\begin{cases} H_2S_3 + Na_2SO_3 \rightleftharpoons Na_2S_2O_3 + H_2S_2 \\ H_2S_2 + Na_2SO_3 \rightleftharpoons Na_2S_2O_3 + H_2S. \end{cases}$$

It may be pointed out that our reaction (I) for the hydrolysis of sulphur suggests that sulphur acts as though composed of S_2 units.

The $\left[\begin{matrix} O & O \\ O & S \end{matrix} S\right]''$ ion of the thiosulphates is very stable, having a very small tendency to drop the second sulphur atom and become $\left[\begin{matrix} O \\ O \end{matrix} S O\right]''$. In dilute solutions of thiosulphuric acid which do not contain another acid, this should still be true. It is probably not until the hydrogen ions become attached to the S_2O_3'' ion by covalencies instead of electrovalencies that rapid decomposition of thiosulphuric acid begins. This occurs the more readily the greater the thiosulphate and hydrogen-ion concentrations. Dilute acid solutions should therefore contain unaltered thiosulphuric acid and its ions for some time. Now one of the most marked characteristics of the S_2O_3'' ion is that it can be readily oxidised to the S_4O_6'' ion. The great majority of oxidising agents which are not too violent actually oxidise thiosulphate to tetrathionate, but it is not commonly realised what a powerful reducing agent thiosulphate is. Spring [*Bull. Acad. roy. Belg.*, 1881, (iii), **1**, 106; *op. cit.*, Vol. II, p. 1109]

found that freshly acidified solutions of thiosulphate bleached indigo, and he attributed this to the presence of hydrosulphurous acid. There can be little doubt, however, that the bleaching is due to thiosulphuric acid, for we find that under suitable conditions either weakly or strongly acidified solutions of thiosulphate can be titrated quantitatively to tetrathionate, either with indigo or, much more conveniently, with methylene-blue. The reaction is bimolecular and is greatly accelerated by hydrogen ions. Litmus and methyl-orange are also reduced by the acidified thiosulphate solutions.

Gil and Beato (*Anal. Fis. Quim.*, 1924, **22**, 84) found that if sodium thiosulphate was added to concentrated hydrochloric acid, pure sodium chloride was precipitated, whilst the separated solution remained perfectly clear, without any deposition of sulphur, for many hours. They concluded that thiosulphuric acid became more stable the greater the acidity of the solution. This view in its simple form is contrary both to experience and to the principle of Le Chatelier. Were it true, then thiosulphate would become less stable in alkaline solution, which is not the case, whilst there can be no question that at low acidities thiosulphate decomposes the more quickly the greater the acidity.



The non-appearance of sulphur does not show that no decomposition of thiosulphuric acid has occurred. Holleman (*loc. cit.*) showed that decomposition began as soon as thiosulphuric acid was liberated from its salts, even although no sulphur had separated. He considered that this was due to the sulphur liberated by reaction (VIII) remaining in colloidal solution, because an acidified thiosulphate solution, if neutralised before the time when separation of sulphur occurred normally, still deposited sulphur. On repeating his experiments, we confirmed these results, but we did not observe this separation of sulphur on neutralisation in all circumstances if the thiosulphate solutions were much weaker than those used by Holleman (see p. 1433).

When the time taken for the sulphur to become visible (compare Gaillard, *Compt. rend.*, 1905, **140**, 652; Oettingen, *Z. physikal. Chem.*, 1900, **33**, 1) is noted for solutions of increasing acidity, it is found to pass through a minimum, and with very high acidities no sulphur separates until after many hours, as in Gil and Beato's experiment. The minimum occurs in solutions which are approximately *N* in hydrogen-ion concentration, no matter what the thiosulphate concentration, as is well shown in Fig. 1; phosphoric acid has a similar effect to hydrochloric acid when allowance is made for its much lower hydrogen-ion concentration (Expt. O).

The delay in the separation of sulphur at high acidities is easily

explained on the basis of our theory of the decomposition of thiosulphuric acid. It is not due to strong hydrochloric acid retarding the change $HS_2O_3' \longrightarrow HSO_3' + S$, as supposed by Foerster and Vogel

FIG. 1.

Times of appearance of sulphur in acidified thiosulphate solutions. All normalities to be multiplied by ½ to obtain actual concentrations.

(*loc. cit.*, p. 183). Both reactions (VIII) and (IX) are accelerated by acid, the former more so than the latter, owing to the fact that the greater part of the sulphurous acid becomes sulphur dioxide. Reaction (VIII), when extended to include the formation of sulphur

dioxide, corresponds to a greater decrease of acidity than does reaction (IX), hence the preferential influence of hydrogen ions on (VIII). The experiments we have already quoted (Expt. N) bear out the correctness of this deduction.

The simultaneous occurrence of reactions (VIII) and (IX) brings in reactions (II*b*) and (I*b*) which are also favoured by acid. Tetra- and penta-thionic acids are formed from trithionic acid either by direct addition of sulphur,

$$H_2S_3O_6 + S \rightleftharpoons H_2S_4O_6 \; (2H_2S_3O_6 + S_2 \rightleftharpoons 2H_2S_4O_6) \; . \quad . \quad (XII)$$
$$H_2S_4O_6 + S \rightleftharpoons H_2S_5O_6 \; (2H_2S_4O_6 + S_2 \rightleftharpoons 2H_2S_5O_6) \; . \quad . \quad (XIII)$$

or by interaction with thiosulphuric acid,

$$H_2S_3O_6 + H_2S_2O_3 \rightleftharpoons H_2S_4O_6 + H_2SO_3 \; . \quad . \quad . \quad (XIV)$$
$$H_2S_4O_6 + H_2S_2O_3 \rightleftharpoons H_2S_5O_6 + H_2SO_3 \; . \quad . \quad . \quad (XV)$$

and all these reactions are favoured by acidity (see p. 1448). The occurrence of these last four reactions represents, in the aggregate, a large decrease of hydrogen-ion concentration and so is greatly favoured by acidity. The more they occur the less the extent to which reaction (VIII*a*) can occur, but this effect on the decomposition of thiosulphuric acid as a whole does not become apparent until a reasonable amount of trithionic acid has been formed by reaction (IX).

That the effect is real is readily shown by acidifying under similar conditions pure thiosulphate or a mixture of thiosulphate with tri- or tetra-thionate. The mixtures take much longer than the pure thiosulphate to give a deposit of sulphur (Expt. P).

We are inclined to think that reactions (XIV) and (XV) are much more important than reactions (XII) and (XIII) for building up the polythionates. We could obtain no certain proof that colloidal sulphur, prepared by Svedberg's method (*Z. Chem. Ind. Koll.*, 1909, **4**, 49), was absorbed at all by trithionic acid, but sulphur liberated in presence of trithionic acid, by the interaction of hydrogen sulphide and iodine, was readily taken up to form tetrathionate. No satisfactory conversion of tetrathionate into pentathionate could be obtained by this method (Expt. Q). A solution of sulphur in benzene seemed to have no action on either trithionate or tetrathionate.

Increase in hydrogen-ion concentration thus tends, on the one hand, to diminish the time required for the separation of sulphur in so far as it accelerates reaction (VIII*a*), but, on the other hand, it lengthens the time required by favouring all the opposing reactions mentioned above. In such circumstances, the occurrence of a minimum time of appearance of sulphur at a fairly definite acidity is only to be expected.

All the reactions occurring in the acidified thiosulphate proceed with a diminution of acidity. They gradually become slower as the limiting concentrations of the several polythionic acids characteristic of the prevailing hydrogen-ion concentration are approached (see p. 1448). Since the hydrogen-ion concentration gradually diminishes, the system is never fully stable—readjustments are continually necessary which ultimately lead to the decomposition of the polythionic acids with separation of sulphur.

It is here appropriate to consider the marked influence of arsenious oxide in preventing separation of sulphur and promoting the formation of pentathionic acid from thiosulphate. This phenomenon was discovered by Salzer (*Ber.*, 1886, **19**, 1696) and has been applied by Raschig (*Z. angew. Chem.*, 1920, **33**, 260). It is known that sulphur oxidises arsenite to oxythioarsenate, and no doubt Salzer was right in thinking that the latter played an important part in the reaction. The oxythioarsenate would act in two ways. (1) Owing to its ready formation, it would prevent separation of sulphur from thiosulphuric acid by reaction (VIII). This would probably be due to the direct reaction $H_2S_2O_3 + H_3AsO_3 \rightleftharpoons H_2SO_3 + H_3AsO_3S$ (assuming that H_3AsO_3S is the only oxythioarsenate involved). The oxythioarsenate would yield its sulphur to trithionic acid, formed in the normal way by reaction (IX), to give tetra- and penta-thionic acids in two stages: $H_2S_3O_6 + H_3AsO_3S \rightleftharpoons H_2S_4O_6 + H_3AsO_3$, $H_2S_4O_6 + H_3AsO_3S \rightleftharpoons H_2S_5O_6 + H_3AsO_3$. (2) It could also take up any sulphur found by reactions (II) and (I) and pass it on as above: $H_3AsO_3 + S \rightleftharpoons H_3AsO_3S$ (or $2H_3AsO_3 + S_2 \rightleftharpoons 2H_3AsO_3S$).

Under favourable conditions, complete conversion of thiosulphate into pentathionate is theoretically possible with the help of small quantities of arsenious oxide, and very good yields are actually obtainable. It will be observed that the arsenious acid is really a vehicle for the handing on of sulphur to trithionic acid just as is sulphurous acid, the oxythioarsenic acid playing the same rôle in the one case as thiosulphuric acid in the other. There is also a superficial resemblance between the action of arsenious acid and of strong hydrochloric acid in preventing separation of sulphur. The reasons for the two actions are different, however, although both depend on the introduction or acceleration of reactions which use up sulphur more quickly than it is produced by reaction (VIII).

If dilute thiosulphate solutions are treated with less acid than corresponds to the minima in the curves of Fig. 1 and then quickly neutralised before sulphur becomes visible, separation of sulphur may be entirely prevented if the addition of alkali has been made an appreciable time before precipitation would normally occur. If, however, the alkali is added very shortly before separation of sulphur

would occur normally, its addition causes immediate separation of sulphur, and in such cases either alkali or lanthanum nitrate will produce a precipitate. Solutions to the right of the minima still give the reactions for colloidal sulphur with separation of sulphur on addition of alkali or lanthanum nitrate, but we believe that they also contain pentathionate (although this is difficult to prove), the proportion of pentathionate increasing with acidity and time and that of colloidal sulphur diminishing (Expt. R).

It is not possible to apply the neutralisation test to the very acidic mixtures, for if the whole amount of concentrated alkali needed for neutralisation is added suddenly, the heat liberated causes complications, whilst if neutralisation is effected slowly, one passes into the less acid regions, where sulphur separates rapidly. Neutralisation of such solutions is therefore incapable of throwing light on the conditions prevailing therein at the stage prior to separation of sulphur.

Reaction (X).—In the very acid solutions, not only is reaction (VIII) delayed, but so also is the formation of pentathionate, and in fact thiosulphuric acid seems to have become more stable, as Gil and Beato suggested. The peculiar facts can be satisfactorily accounted for in terms of a reaction

$$2H_2S_2O_3 \rightleftharpoons H_2O + H_2S_4O_5 \quad . \quad . \quad . \quad . \quad . \quad (X)$$

It is obvious that such a reaction is theoretically possible, and it is to be noted that it would be extremely effective as a means of removing hydrogen ions. It is reasonable, therefore, to suppose that it may occur in very acid solution, but it may well occur to some extent under much less acid conditions, although in such circumstances the active mass of water will usually be so great that it could not proceed very far. It may be noted in this connexion that we have found that a strong zinc chloride solution will greatly delay the separation of sulphur from acidified thiosulphate. In one experiment, sulphur appeared after 6 minutes when zinc chloride was used, but after 35 seconds when the zinc chloride solution was replaced by an equal volume of water. The effect of zinc chloride is thus quite marked, but, as it only depends on a dehydrating action, it is naturally much less than the effect produced by strong hydrochloric acid, which depends on a hydrogen-ion action as well.

There is no reason why $H_2S_4O_5$ should not be much more stable towards loss of sulphur or of hydrogen sulphide than is the simple thiosulphuric acid—in fact we think it likely that it would be. As regards the direct loss of sulphur, it might be argued that, if we are right in supposing that in the case of thiosulphuric acid this occurs in such a way as to eliminate an S_2 unit: $2H_2S_2O_3 \rightleftharpoons 2H_2SO_3 + S_2$,

then it should occur still more readily from $H_2S_4O_5$, where the thiosulphate molecules have already been brought together. But when the known weakness of the second-stage ionisation of sulphurous acid is considered in conjunction with the known tendency for sulphur to become co-ordinated with four atoms or groups, there are good reasons for thinking that the direct loss of sulphur by thiosulphuric acid is largely due to the fact that a hydrogen atom is able to take the place of the escaping sulphur atom.

If this is correct, the decomposition of thiosulphuric acid according to reaction (VIII) is to be regarded as giving rise to sulphur and sulphonic acid, not sulphurous acid:

$$2H_2\left[\begin{matrix}O\\O\end{matrix}S\begin{matrix}O\\S\end{matrix}\right] \rightleftharpoons 2H\left[\begin{matrix}O\\O\end{matrix}S\begin{matrix}O\\H\end{matrix}\right] + S_2.$$

This would be another reason for the great stability of the alkali-metal thiosulphates in neutral or alkaline solution, for the alkali-metal atoms cannot become co-ordinated in the same way as a hydrogen atom—their valencies are always electrovalencies.

In view of the fact that $H_2S_2O_5$, pyrosulphurous acid, is a strong acid, there would not be the same possibility of hydrogen taking the place of sulphur in the manner just indicated were $H_2S_4O_5$ to shed an S_2 unit. $H_2S_4O_5$ may therefore be expected to be very stable towards direct loss of sulphur, but in other directions it would react very much like thiosulphuric acid. This appears to be the case in its behaviour towards oxidising agents. Thiosulphate solutions which have been treated with a large excess of concentrated hydrochloric acid (Gil and Beato's solution) still reduce iodine. Titration with iodine at known intervals of time, in conjunction with subsequent determination of the sulphate present in the oxidised solution, has shown that thiosulphate (actually $H_2S_4O_5$, according to us) persists for a surprising length of time—much longer than in the case of less strongly acidified solutions (compare Expt. N). Even after 2 hours nearly 30% remained undecomposed (Expt. S).

The strongly acid thiosulphate solutions also exert a strong bleaching action on indigo, methylene-blue, litmus, and methyl-orange, and we find that they can be titrated smoothly and rapidly with methylene-blue (indigo can be used, but is not so satisfactory, as it reacts more slowly).

The amount of methylene-blue which is bleached is in close agreement with that required by the reaction

$$\underset{\text{(methylene-blue)}}{C_{16}H_{18}N_3SCl} + H_2S_4O_5 + H_2O = \underset{\text{(\textit{leuco}-methylene-blue)}}{C_{16}H_{19}N_3S} + H_2S_4O_6 + HCl,$$

or more probably (see Expt. T)

$$C_{16}H_{18}N_3SCl + S_4O_5'' + H_2O = C_{16}H_{19}N_3S,HCl + S_4O_6''.$$

The rate at which the methylene-blue is bleached is very greatly increased by rise of temperature. The strongly acidic bleached solutions are comparatively stable towards atmospheric oxidation, but the blue colour is at once restored by a drop or two of strong nitric acid, by hydrogen peroxide, or even by silver nitrate or silver acetate. This behaviour towards silver has prevented us from carrying out any direct estimation of the tetrathionate formed in the reaction between thiosulphate and methylene-blue. We have, however, isolated the *leuco*-methylene-blue formed in the reaction (Expt. T).

The only alternative explanation of the quantitative relationships between methylene-blue and thiosulphate found experimentally would seem to be that a colourless addition compound is formed between one molecule of methylene-blue and one of $H_2S_4O_5$ (or two molecules of $H_2S_2O_3$). Such an explanation appears to be completely ruled out by the fact that the bleached solutions remain colourless under the following treatments: (1) Dilution with air-free water; (2) boiling in absence of air; (3) cautious treatment with hydrogen sulphide or sulphur dioxide, which react with and destroy thiosulphate; (4) addition of formaldehyde, which forms trithioformaldehyde with thiosulphuric acid; or (5) long boiling with 5*N*-hydrochloric acid in absence of air—a complex containing thiosulphuric acid could scarcely remain undecomposed by such treatment. Lastly, it may be mentioned that the action of methylene-blue in preventing the separation of sulphur, which is dealt with in the next paragraph, would be difficult to account for on any other basis than tetrathionate formation.

Even in comparatively weakly acid solutions (of *N*-hydrogen-ion concentration, or even less) thiosulphate can be titrated with methylene-blue, apparently with the same end results as in very acid solutions. If the methylene-blue is added as fast as it is decolorised, no separation of sulphur occurs. This is owing to conversion of tetrathionate into pentathionate according to reaction (XV*a*) (compare Expt. P); but as thiosulphate is oxidised to tetrathionate, more is formed from pentathionate by reaction (XV*b*). As a consequence of this, almost complete conversion of thiosulphate into tetrathionate by methylene-blue is possible if sufficient time is taken and sulphur dioxide is not allowed to escape. Whether, in such weakly acid solutions, the reaction involves $H_2S_4O_5$ must remain undecided. It may occur in two steps, first the formation of an addition compound $H_2S_2O_3$–methylene-blue, and then the interaction of this with a second molecule of thiosulphuric acid.

It is very probable that the reaction between thiosulphate and

iodine is of this character and actually bimolecular. It is generally represented as being termolecular :

$$2Na_2S_2O_3 + I_2 \longrightarrow Na_2S_4O_6 + 2HI \text{ (or } 2S_2O_3'' + I_2 \longrightarrow S_4O_6'' + 2I').$$

In view of the rapidity with which it occurs, it cannot really be termolecular, but it could well occur in two stages, the first involving formation of $Na_2S_2O_3,I_2$ or S_2O_3,I_2'', and the second the reaction of this compound with a second thiosulphate molecule or ion. The iodine and methylene-blue would probably become attached to the outer sulphur atom of the S_2O_3 group, just as sulphur dioxide does in the yellow compounds, $Rb_2S_2O_3,SO_2$, etc.

Some determinations of the time required to bleach a constant amount of methylene-blue with varying concentrations of sodium thiosulphate, taken in excess, and of hydrochloric acid are in agreement with what we consider to be the mechanism of the reduction (Expt. U).

It is likely that the $H_2S_4O_5$ (or S_4O_5'') which acts on the methylene-blue results from the two reactions $2H^{\cdot} + 2S_2O_3'' \rightleftharpoons 2HS_2O_3'$ and $2HS_2O_3' \rightleftharpoons S_4O_5'' + H_2O$, which are equivalent to $2H^{\cdot} + 2S_2O_3'' \rightleftharpoons S_4O_5'' + H_2O$. The rate of bleaching of methylene-blue, dx/dt, would then be given by the expression $dx/dt = k'$ [methylene-blue] $[S_4O_5'']$ $= k$ [methylene-blue] $[S_2O_3'']^2[H^{\cdot}]^2$.

In other words, the rate of bleaching should be proportional to the square of the S_2O_3'' ion concentration, which, in dilute solutions, would be approximately equal to the thiosulphate concentration. If, then, in the solution under investigation, very little of the total thiosulphate was in the form of S_4O_5'', we should expect to find the rate of bleaching proportional to the square of the total thiosulphate concentration and also to the square of the hydrogen-ion concentration; but if practically all the thiosulphate were present as $H_2S_4O_5$ (or S_4O_5''), this would no longer be true, and the rate of bleaching would be directly proportional to the first power of the thiosulphate concentration (since the $H_2S_4O_5$ concentration would be simply half of this), and practically independent of the hydrogen-ion concentration. Intermediate results between these two extremes would correspond to the case where some thiosulphate was present as such and some as $H_2S_4O_5$.

From the results of Expt. U (Table VII), it is seen that, in the solutions of lowest acidity and lowest thiosulphate concentration, the times taken to bleach the constant amount of methylene-blue become closely proportional to the square of the (total) thiosulphate concentration. With the higher concentrations both of acid and of thiosulphate, the times of bleaching are intermediate between those required by a first-power and by a second-power effect of the

thiosulphate. In all solutions less than 2·3*N* with respect to hydrogen chloride, the rate of bleaching is approximately proportional to the total acid concentration, and therefore, in all probability, to the hydrogen-ion concentration. 4·75*N*-Acid has no more effect than 2·3*N*, *i.e.*, above 2·3*N* the reaction seems to become independent of hydrogen-ion concentration. 9·5*N*-Acid is found actually to delay the bleaching as compared with acid of half its strength. This effect has probably nothing to do with hydrogen ions, but may well depend upon such factors as increased viscosity. Rough measurements of the viscosities of 10*N*- and 5*N*-hydrochloric acid show that these are in the ratio of 1·46, whereas the corresponding ratio for 5*N*- and *N*-acid is 1·15, showing that a marked increase of viscosity occurs above 5*N*. That the acid acts according to approximately the first power of its concentration might be regarded as indicating an ordinary catalytic effect, but we prefer to consider that this is due to the fact that, in so far as thiosulphate is present as such, the bleaching reaction depends on the square of the acidity, but in so far as it is present as S_4O_5'', the bleaching is independent of the acidity, where we have no means of measuring S_4O_5'' and S_2O_3'' separately and have to express ourselves in terms of total thiosulphate.

It must be pointed out that even in the least acidic mixtures the concentration of acid was about 50 times that of the thiosulphate. We consider that the close agreement between these experimental results and the deductions made above furnishes evidence in favour of the real existence of the compound $H_2S_4O_5$, and it would seem that under the conditions of the experiments at least half the total thiosulphate was present as $H_2S_4O_5$.

In view of the fact that hydrogen sulphide reduces methylene-blue, one could explain the kinetic results obtained in the weaker and less acid solutions on the basis of such reduction, the hydrogen sulphide being derived from reaction (IX); for it will be found that the rate of reduction in this case would be given by the expression

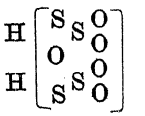
$$dx/dt = k'[\text{methylene-blue}][H_2S] = k[\text{methylene-blue}][S_2O_3'']^2[H^\cdot]^2$$

which is of the same form as that obtained above.

To explain the kinetic results obtained in the stronger and more acid solutions on this basis, it would be necessary to assume that a large proportion of hydrogen sulphide was present, which is certainly not correct. Moreover, both theory and experiment (see p. 1425 and Expt. N) indicate that reaction (IX) tends to predominate at low acidities, not high ones. It may be concluded,

therefore, that the reduction of methylene-blue by acidified thiosulphate is not due to hydrogen sulphide.

Since trithionic acid on hydrolysis can generate thiosulphate, as do also tetra- and penta-thionic acids, it is not surprising to find that in strongly acid solution trithionic acid slowly bleaches methylene-blue. It is possible that in this case some of the reduction is due to sulphoxylic acid (see p. 1447). The bleaching of the dye took several hundred times longer than in the parallel case with thiosulphate.



It should be noted that the observation that thiosulphuric acid can bleach indigo and methylene-blue greatly diminishes the value of such bleaching as a test for hydrosulphurous or sulphoxylic acid.

It is also important to realise that *sulphurous acid* is not without action on methylene-blue (and indigo). The strongest solutions (2—3*N*) act upon the methylene-blue or indigo in a similar way to concentrated hydrochloric acid, and very quickly, removing the blue colour and leaving only a pale purple or brown colour. This action, which appears to be due to the formation of addition compounds of acid and dye, falls off rapidly with dilution of the acid, whether this be hydrochloric or sulphurous acid. Even with 10*N*-hydrochloric acid it is only obvious when very little methylene-blue and an enormous excess of acid are used. In the case of sulphurous acid, it seems to be followed by a definite reducing action on the dye; this action is very slow, however, and is under investigation. We have satisfied ourselves that this action of strong hydrochloric acid or of sulphurous acid does not appreciably affect the results which we record in Expts. T and V.

The formation of tetrathionate from thiosulphate by methylene-blue in strongly acid solution furnishes a strong argument against the view that thiosulphuric acid can yield sulphoxylic acid according to the equation $H_2S_2O_3 + H_2O \rightleftharpoons 2S(OH)_2$ (see pp. 1405—6). Since sulphoxylic acid would probably be a very weak acid (like hypochlorous acid), strongly acidic conditions would be just those likely to favour such a change, were it possible. Experiments with sodium formaldehydesulphoxylate showed that, at the ordinary temperature, it bleaches methylene-blue relatively slowly in strongly acid solution, with formation of sulphite only (Expt. V). Were the bleaching action of the strongly acid thiosulphate solutions due to sulphoxylic acid, four times as much methylene-blue should be reduced as is actually observed.

It seems most probable that the acid $H_2S_4O_5$ is formed by the elimination of a molecule of water from two hydroxyl groups, not from one hydroxyl and one thiol group (which would probably give

off a molecule of hydrogen sulphide to yield one form of trithionic acid). In this case it is to be regarded as having the structure

If, and when, either of the hydrogen ions ceases to be ionised, it can become attached by covalencies to either a sulphur or an oxygen atom. Three tautomeric structures are thus possible for the non-ionised $H_2S_4O_5$ just as two are possible for non-ionised thiosulphuric acid. Systematically $H_2S_4O_5$ might be called dithiopyrosulphuric acid.

Action of Sulphurous Acid and Hydrogen Sulphide on Thiosulphate.

Sulphurous acid and hydrogen sulphide are two acids which act upon thiosulphates in rather special ways, owing to their peculiar relationships to thiosulphuric acid and the polythionic acids.

The action of sulphurous acid is to cause the decomposition of thiosulphuric acid to take place much more in accordance with equation (IX). This it does partly by preventing reaction (VIII), of which it is a product, partly by forming the relatively stable, yellow addition compound, $H_2S_2O_3,SO_2$, and partly by removing hydrogen sulphide by reacting with it in accordance with equations (II*b*) and (I*b*). The sulphur resulting from reactions (II*b*) and (I*b*) does not, under favourable conditions, separate as such, but regenerates thiosulphate according to reaction (VIII). It is thus possible to get practically quantitative conversion of thiosulphate into trithionate, *e.g.*, by acting upon a saturated solution of potassium thiosulphate with strong sulphurous acid solutions at 30° (Hertlein, *Z. physikal. Chem.*, 1896, **19**, 292). Under ideal conditions the reactions which occur could be summarised by an equation such as $K_2S_2O_3 + 4SO_2 + H_2O = K_2S_3O_6 + H_2S_3O_6$. Action does not, of course, cease with the formation of trithionate. Continued action of sulphurous acid causes hydrolysis of trithionate, and ultimately sulphate and sulphur appear; tetra- and penta-thionate may be formed in the intermediate stages.

An elaborate investigation of the action of sulphurous acid on thiosulphate has been made recently by Foerster and Vogel (*loc. cit.*).

When hydrogen sulphide is passed into a solution of sodium thiosulphate, precipitation of sulphur occurs, slowly at the ordinary temperature, but more quickly on warming. This is due to decomposition of thiosulphuric acid displaced by the hydrogen sulphide and to the usual interaction of hydrogen sulphide and sulphurous acid (Reactions VIII*a*, II*b*, and I*b*). On heating, the solution

becomes yellow, owing to the formation of polysulphide, and if the passage of hydrogen sulphide is discontinued, the whole of the precipitated sulphur ultimately dissolves. If the solution is boiled for a sufficient time, the yellow colour disappears, and the solution is then, as a rule, alkaline to phenolphthalein. If hydrogen sulphide is again passed in, more sulphur will be precipitated, and will dissolve on heating, and all the above operations can be repeated indefinitely.

During the boiling, all the reactions of decomposition which occurred during the passage of hydrogen sulphide are reversed with regeneration of thiosulphate, but during this period there is a tendency for sodium sulphide and sulphite to produce some free alkali owing to hydrolysis.

The Wackenroder Reaction and the Genesis of the Polythionic Acids.

If equation (II) is accepted as representing the way in which sulphoxylic acid changes into hydrogen sulphide and sulphurous acid, it follows with reasonable certainty that the first step in the interaction of hydrogen sulphide and sulphur dioxide in the Wackenroder reaction is the converse of this change. The first step would thus give sulphoxylic acid and its pyro-derivative, which would then be hydrolysed to sulphoxylic acid. Interaction of the latter with hydrogen sulphide would give rise to sulphur (reaction I*b*). The freshly formed sulphur would be in a very suitable form to react with sulphurous acid to produce thiosulphuric acid (reaction VIII), which, as has been mentioned already, is relatively stable from the point of view of this reaction in dilute, feebly acid solutions. Trithionate will then be formed from thiosulphuric acid according to reaction (IX) (see p. 1417), whilst it is not impossible that some trithionate may be formed in two steps from sulphurous acid and sulphoxylic acid by a reversal of the reactions considered on p. 1447, as has, in fact, been suggested by Foerster and Vogel (*loc. cit.*), who give a reaction $SO + 2HSO_3' \longrightarrow S_3O_6'' + H_2O$. We found that traces of polythionates were formed by shaking sulphurous acid with a solution of sulphur in benzene, whilst, by passing sulphur dioxide and sulphur vapour simultaneously into water, a solution 0·32*N* with respect to sulphurous acid and about 0·01*N* with respect to a mixture of tri- and tetra-thionic acids was obtained.

In the latest paper on the subject (*Z. anorg. Chem.*, 1926, **157**, 80), Foerster and Centner definitely conclude that, in some cases at least, trithionate cannot result from degradation of pentathionate, but must be formed directly. They favour a reaction $S_2O_3'' + 4HSO_3' + 2H^{\cdot} \longrightarrow 2S_3O_6'' + 3H_2O$, which corresponds to that given by us on p. 1440, and which can only be a summation equation.

If reaction (II) really is the first step in the Wackenroder reaction, all the peculiarities of the initial stages of the reaction which were noticed by Debus (J., 1888, **53**, 336) and Riesenfeld and Feld (*Z. anorg. Chem.*, 1921, **119**, 225) can be accounted for just as readily as on the basis of the primary reaction $H_2SO_3 + H_2S \rightleftharpoons H_2SO_2 + H_2SO$, proposed by Heinze (*J. pr. Chem.*, 1919, **99**, 109), or of the reaction $H_2S + 2H_2SO_3 \rightleftharpoons 3\{SO + H_2O\}$ suggested by Riesenfeld and Feld (*loc. cit.*), or that—$H_2S + H_2SO_3 \rightleftharpoons H_2S_2O_2 + H_2O$—put forward by Foerster and Hornig (*loc. cit.*, p. 92). This matter has been considered by Foerster and Hornig (*loc. cit.*, pp. 87—90), and their explanation will suit our reaction as well as either of the above.

Riesenfeld and Feld's reaction is very similar to our reaction (II), since their $\{SO + H_2O\}$ is really sulphoxylic acid, but a termolecular reaction is much less probable than a bimolecular one.

No proof that sulphoxylic acid is a primary product of the Wackenroder reaction is available, but it is extremely probable that the bleaching of indigo by sulphurous acid solutions freshly treated with hydrogen sulphide is, in the main, due to sulphoxylic acid. This bleaching effect was first noted by Spring (*Bull. Acad. roy. Belg.*, 1878, **45**, 605; *op. cit.*, Vol. II, p. 1060), and we have confirmed it, but in view of the fact that thiosulphuric acid also bleaches indigo, methylene-blue, etc., such bleaching can only be regarded as a very uncertain test for either hydrosulphurous or sulphoxylic acid (see p. 1435).

Whilst the primary reaction in the Wackenroder solution is being considered, it may be pointed out that, since dry hydrogen sulphide and sulphur dioxide do not react, it is unlikely that the one is oxidised directly by the other. Even in presence of water vapour the mixed gases seem to be stable and only to react on the surface of the containing vessel—presumably in the film of adsorbed moisture. We have also found that when hydrogen sulphide is passed into liquid sulphur dioxide no interaction occurs; this is contrary to the statement of Quam (*J. Amer. Chem. Soc.*, 1925, **47**, 103), but agrees with Matthews's observations (*loc. cit.*). The mechanism we have suggested for the interaction of these two gases in presence of water cannot, of course, be applied to their interaction in presence of other dry liquids (Matthews, *loc. cit.*). Some complex other than pyrosulphurous acid must be involved in such cases, as suggested by Klein (*J. Physical Chem.*, 1911, **15**, 1).

Pentathionic acid has generally been regarded as the first thionic acid to appear, both in the case of the decomposition of thiosulphates by acids and in the Wackenroder reaction, tetra- and tri-thionic acids being subsequently formed from it by loss of sulphur. Debus

(*loc. cit.*, pp. 339, 344) considered that in both these reactions the anhydride of pentathionic was formed by direct polymerisation of the anhydride of thiosulphuric acid : $5S_2O_2 = 2S_5O_5$, the necessary S_2O_2 being given by the addition of nascent sulphur to sulphur dioxide. In the Wackenroder reaction, some tetrathionic acid was formed directly according to the scheme $3SO_2 + H_2S = H_2S_4O_6$. In both reactions, he believed that tetra- and tri-thionic acids resulted from degradation of pentathionic acid.

All recent workers on polythionates seem to follow Debus, although there are several variants of the condensation which is supposed to produce pentathionic acid. Raschig ("Schwefel- und Stickstoff-Studien," 1924, pp. 273—304) assumes the polymerisation of S_2O_2 to $S_{10}O_{10}$, which gives pentathionic acid *via* the hypothetical $H_4S_{10}O_{12}$. Riesenfeld and Feld (*loc. cit.*, p. 252) assume that SO is first formed and gives S_5O_5 by polymerisation and thence pentathionic acid by hydration. Foerster and Hornig (*loc. cit.*) suggest an eleventh-order ionic variant of the above polymerisation, $5S_2O_3'' + 6H^{\cdot} \longrightarrow 2S_5O_6'' + 3H_2O$, and this appears to be accepted by the most recent workers in this field, Kurtenacker and Kaufmann (*loc. cit.*, p. 256).

Arithmetically, such polymerisations as the above are simple enough, and this seems to be the chief argument which has led to the suggestion that pentathionic is the first-formed thionic acid. Kinetically, the matter is very different, however, and the polymerisation could only occur in a series of steps. This difficulty has been realised by Foerster and Vogel (*loc. cit.*, p. 163), who now suggest that pentathionic acid is formed by a reaction $SO + 2HS_2O_3' \longrightarrow S_5O_6'' + H_2O$.

We have found that the first thionic acid to appear during the decomposition of thiosulphate by acids is trithionic, although it is generally accompanied by some tetrathionic. It is true that pentathionic acid may appear after a very short time, especially under drastic conditions (see p. 1433). All the observations made in this section of our work make it almost certain that pentathionic acid is the last to be formed, not the first, whilst the experiments and arguments brought forward up to this point are most in favour of the view that trithionic acid is the first to be formed (Expt. W).

When hydrogen sulphide and sulphurous acid interact in dilute solution, we also find that trithionic acid is the first thionic acid to appear, and we think there can be no doubt that, in the Wackenroder reaction also, tetra- and penta-thionic acids are built up from trithionic acid (Expt. X).

The Structural Formulæ of the Polythionates and their Hydrolysis in Acid and in Alkaline Solution.

Dithionic acid is not considered in this paper, as it is not formed under the conditions which give rise to the other thionic acids. The structure and mode of hydrolysis of trithionic acid have already been dealt with on pp. 1421, 1422.

Tetrathionic Acid.—The formation of tetrathionates from thiosulphates by oxidation leads naturally to the structure

$$OH{\cdot}SO_2{\cdot}S{\cdot}S{\cdot}SO_2{\cdot}OH$$

for tetrathionic acid, whilst the ease with which one atom of sulphur is removed from tetrathionate by sulphite to yield trithionate and thiosulphate (Colefax, J., 1908, **93**, 798) supports the structure $OH{\cdot}SO_2{\cdot}S(\cdot S){\cdot}SO_2{\cdot}OH$. A study of the solid model suggests that the two formulæ are probably equally correct in the sense that the slight electronic adjustment needed for one form to pass into the other appears to offer no insuperable difficulty.

Pentathionic Acid.—For this acid the structure $OH{\cdot}SO_2{\cdot}\overset{\overset{S}{|}}{S}{\cdot}SO_2{\cdot}OH$ seems definitely preferable to the alternative $OH{\cdot}SO_2{\cdot}S{\cdot}S{\cdot}S{\cdot}SO_2{\cdot}OH$. The chief arguments in its favour are (i) its compactness and symmetry, (ii) 3 of the 5 sulphur atoms have a co-ordination number of four, (iii) 2 atoms of sulphur are readily removed by sulphite to yield trithionate. The thionic acid formulæ with all the sulphur atoms in one straight chain were originally suggested by Mendeléev (*J. Russ. Phys. Chem. Soc.*, 1870, **2**, 276; 1871, **3**, 871), and they have been more or less accepted ever since, although it has been recognised that the evidence in support was slender.

Formulæ for sodium tri-, tetra-, and penta-thionates have been proposed by Raschig (*op. cit.*, p. 305), but there seems to be nothing in their favour and much against them. Martin and Metz (*Z. anorg. Chem.*, 1923, **127**, 91) also have proposed formulæ for the polythionates.

Many of the objections to the chain formulæ have been summarised by Vogel (J., 1925, **127**, 2248), who suggested the structures $OH{\cdot}SO_2{\cdot}S(\cdot S){\cdot}SO_2{\cdot}OH$ and $(OH{\cdot}SO_2)_2{:}S{\cdot}S{\cdot}S$ for tetra- and pentathionic acids, respectively. With this formula for tetrathionic acid, tautomeric with the chain formula, we agree, but we consider that our formula for pentathionic acid is preferable to Vogel's, for the reasons given above.

In our opinion, it is the tendency of the central sulphur atom in trithionic acid to become co-ordinated with four other atoms in all, which is the prime cause of the readiness with which tetra- and

penta-thionic acids are built up from trithionic. This building-up process comes more or less to an end with the symmetrical pentathionate, and on these grounds the existence of hexathionic acid is improbable. It is true that Debus (*loc. cit.*, pp. 301—309) thought he had some evidence for hexathionates, but no later worker has prepared either hexathionic acid or hexathionates. Higher polythionates than pentathionate only seem likely if the two central sulphur atoms in the straight-chain form of tetrathionic acid can add on additional sulphur atoms in the same way as does the one central sulphur atom of trithionic acid. The building-up process in this case would come to an end with octathionic acid,

$$OH{\cdot}SO_2{\cdot}\overset{\overset{S}{|}}{\underset{\underset{S}{|}}{S}}{\cdot}\overset{\overset{S}{|}}{\underset{\underset{S}{|}}{S}}{\cdot}SO_2{\cdot}OH,$$

with hexa- and hepta-thionic acids as intermediate stages. We have some experiments in progress which seem to suggest that this is actually possible.

The reactions of the polythionates are essentially reactions of hydrolysis and decomposition, and the formulæ proposed above offer a satisfactory explanation of all the facts observed. The hydrolysis of tri-, tetra-, and penta-thionic acids has been the subject of careful investigations by Foerster and Hornig (*loc. cit.*, p. 86) and by Kurtenacker and Kaufmann (*loc. cit.*, pp. 43, 369). Some of the difficulties which arise in connexion with the hydrolysis of trithionic acid have been dealt with on pp. 1421, 1422.

The nature of this hydrolysis is of importance in relation to that of tetra- and penta-thionic acids, for trithionic acid is invariably formed when they are hydrolysed. This seems to occur either by direct decomposition according to the reactions (XII*b*) and (XIII*b*), and perhaps $H_2S_5O_6 \rightleftharpoons H_2S_3O_6 + S_2$, or else by the intervention of sulphurous and thiosulphuric acids, which are products of the hydrolysis of trithionic acid, in accordance with the reactions (XIV), (XV), and (VIII).

In view of what has been stated on p. 1428 in connexion with reaction (VIII), it is very probable that the decomposition of penta- and tetra-thionic acids in accordance with reactions (XII) and (XIII) really follows a bimolecular course, and that the equations should therefore be doubled so as to indicate the formation of S_2 units.

The final products of acid hydrolysis of tri-, tetra-, or pentathionic acid are sulphuric acid, sulphur dioxide, and sulphur, a small quantity of hydrogen sulphide being formed in the intermediate stages. Kessler (*loc. cit.*) alludes to this formation of hydrogen sulphide, and we have noticed that it is always produced.

Under strongly alkaline conditions, the final result of hydrolysis can be represented by the equations

$$2H_2S_3O_6 + 3H_2O \rightleftarrows H_2S_2O_3 + 4H_2SO_3 \quad . \quad . \quad . \quad (a)$$
$$2H_2S_4O_6 + 3H_2O \rightleftarrows 3H_2S_2O_3 + 2H_2SO_3 \quad . \quad . \quad . \quad (b)$$
$$2H_2S_5O_6 + 3H_2O \rightleftarrows 5H_2S_2O_3 \quad . \quad . \quad . \quad . \quad . \quad . \quad (c)$$

(Kurtenacker and Kaufmann, *loc. cit.*, p. 369), but in the case of tetra- and penta-thionates, the tri- and tetra-thionates are formed to some extent as intermediate steps, and in absence of sufficient hydroxyl-ion concentration some hydrolysis of trithionate in the manner characteristic of acid conditions occurs, with consequent formation of sulphate (see p. 1422).

In considering the above results, we wish to stress two important governing factors: (i) Tri-, tetra-, and penta-thionic acids are all of the nature of pyro- or anhydro-acids, and so would be expected to break up in alkaline solution or on dilution, and to be relatively more stable the more acid the solution. Complications are introduced by the instability of the products of hydrolysis, thiosulphuric and sulphurous acids, but the general correctness of these deductions is illustrated by the great difficulty in preparing pentathionates, owing to the readiness with which they decompose, although in strongly acid solution, pentathionic acid is the most stable of the three acids. (ii) The tendency for a sulphur atom to become co-ordinated with four other atoms is the second governing factor.

Equations (*a*), (*b*), and (*c*) above are only to be regarded as summation equations, but if we consider them for a moment as representing directly reversible reactions, and bearing in mind that thiosulphuric and tri-, tetra-, and penta-thionic acids are all strong acids, whilst sulphurous acid is much weaker, we see that the formation of pentathionic acid according to equation (*c*) would correspond to a much greater decrease of acidity than would the formation of either tri- or tetra-thionic acid according to equation (*a*) or (*b*). This is probably a main reason for the greater stability of penta-thionic acid in acid solution, and its great instability under alkaline conditions.

In discussing the relative stability of compounds, it is most important to realise that this cannot be done in general terms, but only with reference to specified conditions—a matter which is frequently overlooked. Vogel's general statement (*loc. cit.*) that the relative stabilities of the polythionic acids should decrease in the order di-, tri-, tetra-, and penta- has no meaning, nor has Foerster and Centner's statement (*loc. cit.*, p. 56) that pentathionate is much less stable than tetrathionate.

The hydrolysis of the unsymmetrical form of trithionic acid has been dealt with on p. 1421, but the mechanism of the hydrolysis of the symmetrical form, which finally yields sulphite and thiosulphate, has not been considered. Since no sulphate is formed, it seems clear that in the first step the hydroxyl group becomes attached to the central sulphur atom, and not to a terminal one, yielding a molecule of sulphonic acid and an unstable intermediate compound which is to be regarded as thiopermonosulphuric acid :

$$\begin{matrix} OH\cdot SO_2 \\ H \end{matrix}\!\!\begin{matrix} \vdots \\ \vdots \end{matrix}\!\!\begin{matrix} S\cdot SO_2\cdot OH \\ OH \end{matrix} \longrightarrow H\cdot SO_3H + OH\cdot S\cdot SO_2\cdot OH$$

Further hydrolysis of the thiopermonosulphuric acid yields sulphoxylic acid and another molecule of sulphonic acid: $OH\cdot S\cdot SO_2\cdot OH + H_2O \longrightarrow S(OH)_2 + H\cdot SO_3H$. The sulphoxylic acid is then oxidised to sulphurous acid by another molecule of thiopermonosulphuric acid which is itself reduced to thiosulphate : $S(OH)_2 + OH\cdot S\cdot SO_2\cdot OH \longrightarrow H_2SO_3 + H_2S_2O_3$. The final result of the hydrolysis in alkaline solution is represented by equation (*a*) on p. 1446.

If this picture of the mechanism of the hydrolysis is correct, it should be possible to produce trithionate from sulphoxylic and sulphurous (sulphonic) acids. We attempted such a synthesis by boiling a solution of sodium formaldehydesulphoxylate (1 mol.) and sodium pyrosulphite (1½ mols.), but were unable to obtain any definite or conclusive results.

The hydrolysis of tetra- and penta-thionic acids is explicable along similar lines. The fact that pentathionate on treatment with sodium carbonate loses one atom of sulphur to form tetrathionate (Raschig, *op. cit.*, pp. 273—304), not two to form trithionate, suggests that in alkaline solution tetrathionate has the straight-chain structure, although it would seem to pass readily into the other form, $OH\cdot SO_2\cdot S(\cdot S)\cdot SO_2\cdot OH$, since sulphite converts it into trithionate. Hydrolysis of the straight-chain form would yield 1 mol. of thiosulphate and 1 mol. of thiopermonosulphuric acid, which would then give rise to thiosulphate and sulphite, as already indicated. Complete alkaline hydrolysis of tetrathionate would thus take place in accordance with equation (*b*) on p. 1446.

In the case of pentathionic acid, the sulphur atom dropped in the very first step of all (equation XIII) suffices to convert a molecule of sulphite into thiosulphate, so that in this case complete alkaline hydrolysis yields nothing but thiosulphate [equation (*c*), p. 1446].

Acid hydrolysis of pentathionic acid may be expected to follow a different course. If the hydroxyl group becomes attached to the central sulphur atom, as in the case of trithionic acid, the first step would yield an intermediate product which can be regarded as

dithiodithionic acid. This would, no doubt, be very unstable and might be expected to break up into sulphur and thiopermono-

$$OH{\cdot}SO_2{\cdot}S(:S_2){\cdot}SO_2{\cdot}OH \xrightarrow{H_2O} \underset{\text{sulphonic acid}}{H{\cdot}SO_2{\cdot}OH} + \underset{\text{dithiodithionic acid}}{OH{\cdot}S(:S_2){\cdot}SO_2{\cdot}OH}$$

sulphuric acid, which would then react further as indicated on p. 1447. It is possible that an intermediate compound $OH{\cdot}S(\cdot S){\cdot}SO_2{\cdot}OH$ might similarly be formed by acid hydrolysis of the unsymmetrical form of tetrathionic acid, $OH{\cdot}SO_2{\cdot}S(\cdot S){\cdot}SO_2{\cdot}OH$.

The influence of hydrogen-ion concentration on the relative stability of tri-, tetra-, and penta-thionic acids is not easy to forecast in any detailed manner. Reactions (XII) and (XIII) will only be dependent upon hydrogen-ion concentration in so far as the relative strengths of the three acids differ. Precise information on the strengths of these acids is lacking, although we know that they are all strong acids.

The strength might be expected to diminish in the order penta-, tetra-, tri-, in view of the fact that the content of "negative" sulphur diminishes in this order. If this is correct, decrease of acidity should tend to favour reactions (XII*a*) and (XIII*a*). The accepted statements (Debus, Raschig, *locc. cit.*) that alkali causes the formation of tetrathionate and sulphur from pentathionate, however, contradict this. It follows therefore that, either pentathionic acid is the weakest of the three acids, which is possible, or else that its decomposition into tetrathionic acid and sulphur is only apparent—that is to say, reaction (XIII*b*) does not occur directly at all, but only as the final result of a more or less complex series of changes [*e.g.*, slight hydrolysis in conjunction with reactions (XV*b*) and (VIII*a*)], some part of which is definitely favoured by decrease of acidity. In any case it is certain that the proportions of tri-, tetra-, and penta-thionic acids which can exist in a solution depend, among other things, upon the hydrogen-ion concentration, increase and decrease of which favour the formation of penta- and tri-thionic acid, respectively. The effect of change of acidity is so great that the separation of sulphur on addition of alkali is almost as delicate a test for pentathionate as is the ammoniacal silver nitrate test.

Experimental.

Expt. A. (Theory, p. 1403.)—Solutions containing known amounts of sodium formaldehydesulphoxylate, sodium hydroxide, and lead acetate were heated to boiling for a short time and allowed to cool. The mixture of lead sulphide and metallic lead was filtered off and

washed, finally with alcohol, dried as quickly as possible at 100°, and weighed. It was then converted into lead sulphate and weighed again. The following results were obtained in three experiments :

	I.	II.	III.
Sodium formaldehydesulphoxylate (g.) ...	2·4	2·4	1·2
N/2-Lead acetate (c.c.)	5	5	5
2*N*-Sodium hydroxide (c.c.)	10	2	10
Molecular ratio, Pb/PbS, in precipitate ...	1·82	2·27	2·69

Sufficient water was added in the second and third experiments to make the total volume the same as that of the mixture used in the first experiment. The sodium formaldehydesulphoxylate used in this and following experiments had the composition NaCl, 10; Na_2SO_4,10H_2O, 6·1; Na_2CO_3,10H_2O, 21·1; CH_3O_3SNa, 62·8%. Chloride, sulphate, sulphoxylate, and total sodium were estimated, and carbonate (proved qualitatively) was calculated. The sulphoxylate was determined by the methods of Helwig (*Amer. Dyestuff Reporter*, 1920, **7**, ii, 12) and Hollingsworth Smith (*J. Amer. Chem. Soc.*, 1921, **43**, 1307), which gave the same results.

Expt. B. (Theory, p. 1405.)—A bright silver coin (92·5% Ag) was digested for 1 hour with sulphur, 1 c.c. of 0·3*N*-potassium dichromate, 1 c.c. of 2*N*-phosphoric acid, and about 20 c.c. of water. Very little sulphide attached itself to the coin; most remained mixed with the sulphur.

Loss of weight of coin = 0·0079 g.
Ag_2S produced = 0·0078 g.
Sulphate formed, as $BaSO_4$ = 0·0063 g.
} Molecular ratio, $Ag_2S : BaSO_4 = 1·17$.

Expt. C. (Theory, p. 1405.)—10 C.c. of a solution containing 0·2 g. of the sodium formaldehydesulphoxylate (= 0·1256 g. pure sulphoxylate) were mixed with 10 c.c. of 2*N*-sodium hydroxide, 5 c.c. of 0·5*N*-lead acetate, and 5 c.c. of 2*N*-barium chloride. After simmering for ½ hour in an atmosphere of purified coal gas, the mixture of lead sulphide, metallic lead, and barium sulphate was filtered off. The lead and lead sulphide were extracted with warm dilute hydrochloric acid, and the barium sulphate was weighed; 0·0146 g. was obtained, of which 0·0088 g. was due to sulphate present in the sulphoxylate used. Decomposition of sulphoxylate in accordance with a reaction $2H_2SO_2 \longrightarrow H_2S + H_2SO_4$ would yield 0·1242 g. of barium sulphate; 0·0058 g. is only 4·6% of this, and no importance can be attached to it.

Expt. D. (Theory, pp. 1403, 1405.)—(I) 20 C.c. of 1·25*N*-hydrochloric acid containing 0·315 g. of pure sulphoxylate were digested for 80 mins. in a small flask connected to two wash-bottles containing

N/10-iodine and a third containing N/40-thiosulphate. A slow current of purified coal gas passed through the apparatus. The iodine reduced was 82% of that required by a reaction $2H_2SO_2 \longrightarrow S + H_2SO_3 + H_2O$, which is a combination of reactions (I) and (II). After the precipitated sulphur had been filtered off, any sulphate formed during the decomposition was precipitated and weighed as barium sulphate; only 0·0163 g. was obtained, and as 0·022 g. was to be expected from the sulphate present in the sulphoxylate used, it is clear that no sulphate had been formed during the hydrolysis. The filtrate from the barium sulphate gave a reaction for pentathionate, and the formation of this and other thionic acids would account for only 82% of the calculated amount of sulphurous acid being obtained. The weight of sulphur precipitated in this experiment was difficult to estimate exactly owing to the presence of some trithioformaldehyde, but it also corresponded to about 82% of that demanded by the above equation. Another experiment, similar to the above, in which some lead acetate was added to the reacting solution gave practically identical results. No metallic lead or lead sulphide was precipitated and 0·0185 g. of barium sulphate was obtained.

(II) 10 C.c. of sulphoxylate solution (= 1 g. crude or 0·628 g. pure sulphoxylate), 20 c.c. of 1% arsenious oxide solution, and 10 c.c. of concentrated hydrochloric acid were boiled in a current of purified coal gas until the arsenious sulphide had coagulated, and then for a further 15 mins. to drive out sulphur dioxide. The sulphide was filtered off and weighed. The filtrate after considerable dilution and treatment with barium nitrate gave a very small precipitate of barium sulphate on standing [Found: As_2S_3, 0·1444 g. Calc. (from the weight of sulphoxylate used on the basis of reaction II): 0·1447 g. Found: $BaSO_4$, 0·0226 g. Calc. (for sulphate present in the sulphoxylate used): 0·044 g.].

Expt. E. (Theory, p. 1405.)—To a mixture of 20 c.c. of 1% arsenious oxide solution and 10 c.c. of concentrated hydrochloric acid were added 2 c.c. of 2N-thiosulphate. After the mixture had been boiled to expel sulphur dioxide, the precipitate, which consisted mainly of arsenious sulphide, was filtered off and weighed. Sulphate in the diluted filtrate was precipitated as barium sulphate (Found: As_2S_3, 0·0654 g.; $BaSO_4$, 0·3908 g.).

Expt. F. (Theory, p. 1408.)—100 C.c. of a solution containing 1·2289 g. of sodium hydrosulphite (of 88·7% purity) and 0·3750 g. of sodium carbonate were left exposed to the air at room temperature, and the unoxidised hydrosulphite was determined at intervals by Hollingsworth Smith's method (*loc. cit.*): k is the value of the expression $1/t \cdot \log_e a/(a - x)$.

t (mins.).	% $Na_2S_2O_4$ present.	$k \times 10^4$.	t (mins.).	% $Na_2S_2O_4$ present.	$k \times 10^4$.
0	88·7	—	80	54·9	60·0
10	82·4	73·4	140	39·4	58·1
20	80·6	47·8	260	16·5	64·8
40	69·6	60·9			

The rate of oxidation and the actual value of k will depend on the exact conditions of exposure, which were, however, approximately constant during the experiment.

Expt. G. (Theory, p. 1414.)—Analyses are given in Table I of a number of old sulphurous acid solutions, none of which had deposited any visible sulphur. Sulphurous and sulphuric acids were determined by iodine titration followed by estimation of total sulphate. Polythionic acids were estimated in a separate portion, from which sulphur dioxide had been expelled either by boiling or by means of an air current.

The method we have used for analysing mixtures of polythionic acids depends on one of the tests given by Takamatzu and Smith (J., 1880, **37**, 608), *viz.*, the addition of silver nitrate to the neutral or acid solution. The general reaction may be expressed $Ag_2S_xO_6 \longrightarrow Ag_2S + (x - 3)S + 2SO_3$, whence the molecular ratios of silver sulphide to free atomic sulphur precipitated are, for trithionate 1 : 0, for tetrathionate 1 : 1, and for pentathionate 1 : 2. Since colloidal and precipitated sulphur react slowly with silver nitrate to form silver sulphide, a standard solution of silver nitrate should be used in only very slight excess. Decomposition of the silver polythionates is rapid at temperatures near 100°, so it is best to heat the solution nearly to this temperature before adding the silver nitrate. The silver sulphide–sulphur precipitate, which filters easily, is well washed, finally with ammonia or ammonium carbonate solution. (This is to remove sulphuric acid, which otherwise is obstinately retained and causes charring of the filter paper on drying.) The precipitate is dried at 100° and weighed. A portion is then weighed into a glass ignition tube and heated until all free sulphur (if present) is driven off. Brilliant, black, crystalline silver sulphide remains and is weighed. This method, although simple and expeditious, gives surprisingly reproducible results, whilst it enables the presence of very small amounts of free sulphur to be detected with certainty owing to the dark colour of the distillate. Although the ratio Ag_2S : S may be found to be 1 : 1, this does not prove the presence of pure tetrathionate unless it has been shown that pentathionate is absent, which can be most readily done by the well-known ammoniacal silver nitrate test.

It is to be noted that after sulphur dioxide had been expelled by an air current at the ordinary temperature, both tri- and tetra-

thionic acids were present, but after the sulphur dioxide had been boiled off only trithionic acid was found. We satisfied ourselves that these sulphurous acid solutions contained neither colloidal sulphur, thiosulphate, nor pentathionate. Only the $1\frac{3}{4}$-year old solution seemed definitely to contain thiosulphate. After the sulphur dioxide had been boiled off, both tri- and tetra-thionic acids were found in this case.

Expt. H. (Theory, p. 1416.)—Table II epitomises a series of experiments in which solutions of the concentrations stated were boiled for 2 minutes in a small conical flask, 20 c.c. being used in each experiment. Hydrochloric acid was used. The mouth of the flask was covered with a filter paper moistened in the centre with one drop of 2*N*-lead acetate solution. The stains of lead sulphide produced were compared and preserved.

In the more concentrated thiosulphate solutions, sulphur dioxide was evolved as well as hydrogen sulphide, which accounts for the fact that the latter appears to reach a maximum with *N*/100-acids, as shown in cols. 2, 3, and 4 of the table. Although the two gases can coexist in gaseous mixtures for considerable periods of time, lead acetate is not darkened when sulphur dioxide is largely in excess. The non-appearance of hydrogen sulphide under the conditions represented above the sloping line suggests that its production is due to a molecular rather than to an ionic reaction.

Abbreviations:

0, no sulphur separated.

Ⓢ, sulphur appeared and later disappeared.

S, sulphur was permanently precipitated.

$\boxed{S}$ or $\boxed{H_2S}$, the substance appeared to have reached a maximum in respect to the *vertical column*.

H_2Sf, a *faint* stain due to hydrogen sulphide.

Expt. I.—(i) (Theory, p. 1418). 5·86 G. of hydrated sodium thiosulphate, 1 c.c. of 0·2*N*-sodium hydroxide, and 5 c.c. of water were boiled for 5 mins. and cooled; addition of sodium plumbite then gave an immediate brown coloration.

(ii) (Theory, p. 1418). 20 C.c. of an aqueous solution containing 1·4 g. of hydrated sodium thiosulphate and 20 c.c. of 2*N*-sodium hydroxide were heated to boiling for 50 mins. in an atmosphere of purified coal gas, then acidified with hydrochloric acid and boiled in coal gas to decompose thiosulphate and drive off sulphur dioxide. Sulphate present in the solution was then estimated as barium sulphate: 0·0030 g. was obtained (mean of three experiments) after subtracting (α) the barium sulphate (0·0020 g.) due to sulphate formed during the decomposition of the thiosulphate with acid, and (β) sulphate, silicate, etc. (0·0083 g.), derived from the action of alkali on the glass. Both corrections were determined separately.

A similar solution after boiling for 50 mins. in coal gas was treated with 5 c.c. of 0·5*N*-lead acetate solution. This gave an immediate brown colour, and after short heating lead sulphide coagulated and was weighed as sulphate. In another experiment the lead acetate was added before the boiling with alkali. The two results were identical (Found: $PbSO_4$, 0·0443 g.). This lead sulphate represents sulphide formed by reaction (IX), but corresponds to only 5·8% of the original thiosulphate. The sulphate also formed is derived from the hydrolysis of a small proportion of the trithionate formed in the main reaction.

(iii) (Theory, p. 1419). 1·4 G. of hydrated sodium thiosulphate, dissolved in 20 c.c. of 8·4*N*-caustic soda and boiled for 50 mins. in coal gas, gave the merest trace of sulphide on treatment with lead acetate. On large dilution with water no further precipitate appeared.

(iv) (Theory, p. 1419). 10 C.c. of 2*N*-caustic soda, 2·5 c.c of 2*N*-sodium sulphite, and 20 c.c. of 0·0072*N*-hydrogen sulphide were digested in coal gas for 1 hour at the b. p.; 1 c.c. of 0·5*N*-lead acetate solution was then added. An immediate black precipitate was formed which was filtered off and weighed as lead sulphate. A blank experiment using 2·5 c.c. of water instead of the sodium sulphite was also carried out (Found, from sulphite mixture: $PbSO_4$, 0·0273 g.; from blank: $PbSO_4$, 0·0260 g.).

(v) (Theory, p. 1419). 20 C.c. of 2*N*-caustic soda, 5 c.c. of 2*N*-sodium sulphite, and 1 c.c. each of 2*N*-sodium thiosulphate and 2*N*-sodium sulphide were boiled for 50 mins. in coal gas, and then treated with 5 c.c. of 0·5*N*-lead acetate. The lead sulphide precipitated was converted into 0·2886 g. of sulphate, whereas a blank experiment without sulphite and thiosulphate gave 0·2903 g.

(vi) (Theory, p. 1418). This experiment was similar to the last, but 2 c.c. of 2*N*-sodium sulphate were used instead of the sulphite, and double the quantity of thiosulphate (*i.e.*, 2 c.c.) was used; 0·2885 g. of lead sulphate was obtained, again showing that no disappearance of sulphide had occurred during the boiling. Some thiosulphate was added, as it was thought that, if sulphide would not act directly on the sulphate, it might possibly react with thiosulphate to form trithionate, which would then react with the sulphide to form thiosulphate.

We could get no indication of any thiosulphate formation when hydrogen sulphide was allowed to act upon sodium sulphate either at the ordinary temperature or at 100°. Numerous experiments were made under various conditions of concentration, etc.

(vii) (Theory, p. 1418). 0·2988 G. of lead thiosulphate was boiled with 20 c.c. of 2*N*-sodium hydroxide, in which it dissolved, in an atmosphere of hydrogen. There was no trace of darkening or precipitate after 50 mins'. boiling. 0·8250 G. of lead thiosulphate, when boiled in hydrogen with 25·9 c.c. of 0·2*N*-sodium hydroxide (*i.e.*, the equivalent amount of alkali), became cream-coloured, but showed no sign of sulphide formation after 10 mins'. boiling.

When lead thiosulphate is boiled with less than the equivalent amount of alkali, decomposition is rapid and large amounts of trithionate are obtained, but a considerable proportion of the trithionate is decomposed into sulphide and sulphate, with consequent neutralisation of the alkali used—in fact, the reaction mixture becomes slightly acid. The black precipitate obtained was shown to be a mixture of lead sulphide and sulphate with sometimes a little unaltered thiosulphate, a trace of which may also remain in the solution. The filtrate from the lead sulphide and sulphate precipitate was analysed for thiosulphate and trithionate, one portion being titrated with *N*/100-iodine, and the trithionate and thiosulphate in another portion being obtained from the weight of silver sulphide given on treatment with silver nitrate. The results of two such experiments are given in Table III.

TABLE III.

	I.	II.
PbS_2O_3 (g.)	0·9012	0·7126
H_2O (c.c.)	10	10
NaOH	1 c.c. 2*N*.	5 c.c. 0·2*N*.
Ag_2S from trithionate (g.)	0·1680	0·1507
Ag_2S from thiosulphate (g.)	0·0135	0·0163

In both experiments, the mixture was boiled for 5 mins. in an atmosphere of hydrogen. In the second experiment, the mixture was left over-night after the boiling before filtering.

(viii) (Theory, p. 1418). Even under weakly acid conditions, some trithionate can survive during the decomposition of lead thiosulphate: 1·3974 g. of lead thiosulphate, 5 c.c. of 2·175*N*-acetic acid, and 20 c.c. of water were boiled for 5 mins.; sulphur dioxide was given off, and the black residue contained considerable free sulphur. The filtrate contained trithionate capable of giving with silver nitrate 0·0897 g. of silver sulphide, and thiosulphate equivalent to 0·0368 g. of silver sulphide (the thiosulphate was obtained by titration with *N*/100-iodine—some sulphurous acid may have been present, in which case the value for trithionate would be correspondingly greater).

Expt. J. (Theory, p. 1420.)—Freshly precipitated and washed manganese sulphide, obtained from the hydrated sulphate, was gently boiled in a narrow-mouthed, conical flask, closed by a funnel, with a solution of 10 g. of ammonium sulphate in about 50 c.c. of water, until all the sulphide had reacted, *i.e.*, for 3—5 hours. In Expts. I, III, and IV, 1·1 g. of $MnSO_4,4H_2O$ was used; in Expt. II, 2·2 g. Hydrogen was passed through the flask in which Expt. IV was carried out, but even so, indications of yellow ammonium sulphide were seen at the end of the exit tube inside the flask—a sign of slight oxidation. The sulphide used in Expt. I had undergone more oxidation during its preparation than the other samples. The filtrates from the small amounts of higher oxide of manganese (very small in Expt. III) were analysed by titrating one portion with *N*/100-iodine, and weighing the silver sulphide obtained with silver nitrate from another portion. The silver sulphide was shown to contain no free sulphur, and in amount it agreed very closely with that required by the iodine titration, showing that it was derived from thiosulphate, not trithionate:

	I.	II.	III.	IV.
Ag_2S weighed (g.)	0·1290	0·0662	0·0144	0·0048
Ag_2S calc. from iodine titration	(Not titrated.)	0·0669	0·0139	0·0050

A series of experiments in which hydrogen sulphide was passed through boiling strong solutions of ammonium magnesium and ammonium nickel sulphates gave entirely negative results, no trithionate or thiosulphate being formed.

Expt. K. (Theory, p. 1421.)—The following is a typical experiment: Hydrogen sulphide was passed through a mixture of 5 c.c. of concentrated sulphuric acid and 3 c.c. of water for 70 mins. No sulphur was precipitated. The gas was then displaced from the solution by a very rapid current of hydrogen, and the solution was diluted rapidly to 100 c.c.; this caused an immediate opalescence due to sulphur. Some of the diluted solution, when tested with

ammoniacal silver nitrate, gave a faint coloration such as would be expected from the sulphur cloud; the paleness indicated that all the hydrogen sulphide had been removed. The silver sulphide from half of the solution amounted to 0·0029 g. and the $N/100$-iodine titration indicated that one-third was derived from trithionate and two-thirds from thiosulphate. The cloud of sulphur formed on dilution is attributed to formation and decomposition of thiosulphate owing to the large addition of water having caused hydrolysis of trithionic acid originally present. In other experiments, it was noted that traces of hydrogen sulphide continued to be removed by the current of hydrogen from the original strong acid after several hours. This suggests a slow reversal of reaction (X) by the water present. The thiosulphate found in the solutions after dilution had probably been formed by hydrolysis from trithionate, partly during the removal of hydrogen sulphide by the current of hydrogen, and partly during the dilution.

Expt. L. (Theory, p. 1423.)—0·4884 G. of potassium trithionate and 20 c.c. of $5N$-hydrochloric acid were gradually heated to boiling. Sulphur appeared at about 50°. Boiling was continued until no more sulphur dioxide was liberated—about 25 mins. in all. The liberated sulphur weighed 0·0335 g. and a further 0·0032 g. separated on dilution owing to decomposition of pentathionic acid. This small quantity was filtered off after being boiled for 1 hour to cause coagulation. Sulphate present in the filtrate gave 0·4817 g. of barium sulphate, whereas if 1 mol. of trithionate gave 1 mol. of sulphate, the weight would have been 0·4216 g.

Expt. M. (Theory, p. 1423.)—Potassium trithionate solutions of the concentrations given in Table IV (p. 1452) were left at room temperature for the stated periods and then analysed. Our polythionate estimations (B. and D.) were made by the silver nitrate method (see Expt. G), whereas Kurtenacker and Kaufmann (K. and K.) used volumetric methods.

It is evident that N-hydrochloric acid had hastened the hydrolysis to a later stage in 28 days than had $N/10$-sulphuric acid in 42 days. Obviously our experiment (iv) represents the latest stage of the four —again confirming our contention that pentathionic acid is the last polythionic acid to be produced. Kurtenacker and Kaufmann also expected this, but had not reached it in (iii).

Expt. N. (Theory, p. 1425.)—Four mixtures of sodium thiosulphate and hydrochloric acid of the composition stated in Table V, (i), (ii), (iii), and (iv) were made by adding 1 c.c. of M-sodium thiosulphate to 10 c.c. or 21 c.c. of hydrochloric acid of appropriate strength in small, tightly-corked flasks. After the stated intervals of time, the whole mixture was titrated with $N/10$-iodine, a separate

mixture being used for each titration. The amount of iodine required at zero time was, of course, 10 c.c. in each case. In these experiments, since excess of acid was used, it can be safely assumed that decomposition of thiosulphate was complete when the iodine titration had reached its limiting value. The amount of decomposition at earlier stages was calculated by simple proportion. Holleman's three experiments, in which equivalent amounts of thiosulphate and acid were used, were also repeated (Expts. *a*, *b*, and *c*). At the time stated, a known quantity of *N*/10-iodine was added and the excess was then titrated with *N*/10-thiosulphate. After 1 min. we obtained similar results to his, but we followed up the experiments in order to determine the maximum values of the titre so that the velocity coefficient might be calculated in the manner indicated on p. 1428. For this purpose, the sulphate present in the titrated solution was also determined. In experiments (*a*) and (*b*) the sulphate was determined at each stage (and is given in the table as g. of barium sulphate) in order to get a direct measure of the amount of decomposition to compare with that calculated by simple proportion from the iodine titre and the sulphate formed at the stage of maximum iodine titre.

In all these experiments, which were carried out at 17°, the initial concentrations shown are those which obtained after mixing. Time, *t*, is given in minutes, unless otherwise stated. The number of mols. of thiosulphate decomposed is given by *x*; and *k* is the bimolecular velocity coefficient calculated from $k = x/ta(a - x)$.

Expt. O. (Theory, p. 1430; Fig. 1.)—Mixtures were made of 1 c.c. of 0·05, 0·1, 0·25, 0·5, or 1·0*M*-sodium thiosulphate with 10 c.c. of hydrochloric acid (or, in the cases indicated, phosphoric acid) of the *molecular* normalities shown on the abscissæ of Fig. 1, where the results are given in the form of curves. As ordinates are plotted

the times (in mins.) required for the first appearance of visible sulphur, which could not, of course, be determined with very great accuracy. The actual normalities of thiosulphate and of acid in the mixture would be 10/11ths of those indicated. The experiments were done at room temperature (about 17°).

Expt. P. (Theory, p. 1432.)—Four separate mixtures were made, each containing 1 c.c. of each of the specified constituents: (1) 0·1*M*-Thiosulphate, 0·5*N*-hydrochloric acid, water: Sulphur deposition began 90 secs. after mixing. (2) 0·1*M*-Thiosulphate, 0·5*M*-potassium tetrathionate, 0·5*N*-hydrochloric acid: This remained absolutely clear for 24 hours after mixing. It then gave a strong reaction for pentathionate. The original tetrathionate contained only a faint trace of pentathionate. (3) 0·5*M*-Thiosulphate, 0·5*M*-sulphuric acid, water: Sulphur deposition started in 15 secs. and was soon very heavy. (4) 0·5*M*-Thiosulphate, 0·5*M*-potassium tetrathionate, 0·5*M*-sulphuric acid: Faint sulphur deposit after 2 mins. It was only slight after 10 mins. Concentrations are stated in molecular normalities in all cases. Since we made these experiments, similar ones have been recorded by Foerster and Centner (*loc. cit.*, pp. 64, 68).

Expt. Q. (Theory, p. 1432.)—0·203 G. of iodine in 20 c.c. of alcohol was mixed with 0·216 g. of potassium trithionate in 20 c.c. of water, and hydrogen sulphide was then passed in very slowly until the iodine was decolorised. Some sulphur was deposited, which was filtered off, washed, dried, and found to weigh 0·0153 g. To the filtrate was added 0·265 g. of lead nitrate in 20 c.c. of water. After standing for 5 hours, the lead iodide was filtered off and washed once. The filtrate from this iodide was warmed with 5 c.c. of 0·4*N*-silver nitrate and the precipitated mixture of silver sulphide and iodide and free sulphur was dried, weighed, and gently heated in an ignition tube. In this way it was found to contain 0·0104 g. of free sulphur. It represents the tetrathionate formed by direct addition of sulphur. The iodine used in the experiment would have liberated 0·0256 g. of sulphur, so that 40·6% was absorbed. In a second experiment using twice as much trithionate, 60·2% of the sulphur was absorbed.

Expt. R. (Theory, p. 1434.)—One c.c. of 0·05*M*-sodium thiosulphate and 10 c.c. of 0·25*N*-hydrochloric acid gave a deposit of sulphur in 9½ mins. When this mixture was neutralised by caustic soda after 7 mins., no precipitation of sulphur occurred either then or after ½ hour. In a second experiment, 1 c.c. of lanthanum nitrate solution was added after 7 mins., but no precipitate occurred until after 13 mins. On the other hand, neutralisation of the above mixture after 9 mins. caused an immediate opalescence and so also did addition of 1 c.c. of lanthanum nitrate solution after 9 mins.

When 1 c.c. of 0·1*M*-thiosulphate and 10 c.c. of 0·25*N*-hydrochloric acid were used, sulphur separated 5 mins. after acidification. Similar mixtures were neutralised with sodium hydroxide 2 mins. and 3 mins. after acidification. No sulphur had separated after an hour, but a precipitate formed when the neutralisation was effected after 4 or 4½ mins.

One c.c. of 0·1*M*-thiosulphate and 10 c.c. of 2·163*N*-hydrochloric acid deposited sulphur in 4 mins. 10 secs. To a similar mixture, 3 c.c. of 8*N*-caustic soda were added 3 mins. after acidification. An immediate opalescence was produced. This faded and disappeared after 2 mins. The solution was finally alkaline. One c.c. of 0·1*M*-thiosulphate and 10 c.c. of 5*N*-hydrochloric acid gave a deposit of sulphur in 15 mins. A similar mixture was carefully neutralised with 8*N*-caustic soda in presence of phenolphthalein within a few minutes of preparation. No immediate precipitation of sulphur occurred, but a faint opalescence appeared 13½ mins. from the start, and disappeared after a further minute. A somewhat similar result was obtained with 0·5*M*-thiosulphate and 5*N*-hydrochloric acid.

Expt. S. (Theory, p. 1435.)—In the following experiments 1 c.c. of *M*-thiosulphate and 10 c.c. of 10·5*N*-hydrochloric acid were mixed. (In the first experiment, 10 c.c. of 9*N*-acid were used.) The mixtures were left at room temperature for the times specified (in Table VI) in tightly-corked, small flasks. They were then titrated with 0·1*N*-iodine. In the first four experiments this was done in the concentrated mixture, without using starch and in presence of the precipitated sodium chloride. In the case of Expts. 2, 3, and 4, owing to the large amount of sulphurous acid present, the yellow iodide–sulphur dioxide complex was formed. Addition of a little water towards the end of the titration broke this down and enabled the end-point to be determined sharply. The solutions were then raised to boiling point to coagulate sulphur, which was filtered off and weighed. The filtrate was diluted considerably and reheated, and sulphate present was precipitated and weighed as barium sulphate. This sulphate is due to oxidation of sulphurous acid by iodine, but may be partly due to hydrolysis of thionic acids during the heating, etc. In Expt. 5 the solution was diluted with 50 c.c. of water before being titrated with iodine.

TABLE VI.

Expt.	Time elapsed before titration.	*N*/10-Iodine (c.c.).	$BaSO_4$ (g.).	Sulphur deposited (g.).
1	10 mins.	12·5	0·0714	—
2	2 hours	12·1	0·1082	0·0206
3	21 ,,	11·1	0·1559	0·0290
4	23·5 ,,	10·7	0·1663	0·0326
5	23·5 ,,	10·2	0·1175	0·0242

In the mixture used in Expt. 1, sulphur began to appear after 11 min. 50 sec.; some was seen just before the end of the titration with iodine. In the other experiments, most of the sulphur separated during the titration (owing to the consequent dilution) and subsequent heating, indicating that it originated from pentathionate.

If we assume that the reduction of iodine is due to sulphurous acid and thiosulphuric acid (or $H_2S_4O_5$) only, we can make the following deductions. In Expt. 1, 63·7% of thiosulphuric acid had remained unchanged (as $H_2S_4O_5$, in our opinion), and 30·6% had decomposed according to reaction (VIII). This assumes that all the barium sulphate had resulted from sulphurous acid and that no hydrolysis of polythionate had occurred. In Expt. 2, again assuming no hydrolysis of polythionate, 28·3% of thiosulphuric acid (as $H_2S_4O_5$) had remained, whilst 46·4% had decomposed according to reaction (VIII).

In Expts. 3, 4, and 5 it appears that no thiosulphuric acid remained in the cold solution, and if that is correct, the determinations show that: (α) In (3), 55·5% had decomposed according to reaction (VIII), and none remained undecomposed. Of the polythionate present in the cold mixture an amount corresponding to 0·0264 g. of barium sulphate had been decomposed during the boiling.

(β) In (4) and (5), 53·5% and 51%, respectively, had decomposed according to reaction (VIII). In (5), the barium sulphate obtained was equivalent to the iodine used, showing that no hydrolysis of polythionate had occurred during the boiling of the diluted solution; but in (4), where the boiling lasted longer than in (3), polythionate corresponding to 0·0414 g. of barium sulphate had been decomposed.

It should be noted that actually more thiosulphuric acid will have decomposed according to reaction (VIII) than is shown by the residual sulphurous acid, for some of the latter will have reacted with hydrogen sulphide, formed by reaction (IX), to yield sulphur (reactions II*b* and I*b*). The amount of thiosulphuric acid which has reacted to form polythionate cannot therefore be obtained by deducting from the original amount that remaining undecomposed and that which has decomposed in accordance with reaction (VIII).

Expt. T. (Theory, p. 1436.)—(i) An aqueous solution of methylene-blue was prepared containing 0·64 g. per litre (= 1/500th g.-mol. $C_{16}H_{18}N_3SCl$). One c.c. of 0·1*M*-sodium thiosulphate was added to 10 c.c. of hydrochloric acid, which was either 10*N*, 5*N*, or 2·5*N*. With each strength of acid two mixtures were made. To one, 24·5 c.c. of the methylene-blue solution were added, and to the other 25·5 c.c., the mixtures being in tightly-corked flasks filled with carbon dioxide. In each case, the solutions containing 24·5 c.c.

of methylene-blue were bleached, whilst those containing 25·5 c.c. retained a pale blue colour. The thiosulphate used in the experiment could reduce 25 c.c. of the methylene-blue solution according to the equation given on p. 1435.

Another bleaching experiment was done in a slightly different way, using a solution which was 0·1*M* with respect to thiosulphuric acid without any excess of other acid, obtained by mixing equal volumes of 0·2*M*-sodium thiosulphate and 0·4*M*-hydrochloric acid; on shaking this solution with solid methylene-blue in an atmosphere of carbon dioxide, it was found to bleach exactly the amount calculated from the equation, but no more.

0·32 G. of methylene-blue was dissolved in 100 c.c. of water and the solution placed in a separating funnel filled with carbon dioxide; 2 c.c. of *M*-sodium thiosulphate were added, followed by 10 c.c. of 2·5*N*-hydrochloric acid. The mixture was well shaken, and the colour disappeared completely in ½ hour; 9·84 c.c. of 2·564*N*-sodium hydroxide were then added, this being the amount required to produce neutrality after due allowance for the fact that 1 mol. of hydrochloric acid is liberated from methylene-blue for each mol. of the *leuco*-compound produced, whilst, on the other hand, each mol. of tetrathionate formed corresponds to the neutralisation of 2 mols. of hydrochloric acid. Immediately on addition of the alkali a white, flocculent precipitate was thrown out, which dissolved at once in ether. The ethereal extract was separated and the ether distilled in a current of carbon dioxide, leaving the *leuco*-methylene-blue as long, colourless crystals. These do not melt, but decompose on heating. They slowly turn blue owing to oxidation. The *leuco*-compound is strongly basic and cannot be extracted from acid solution by ether, although it is freely soluble in absence of acid. Bernthsen (*Ber.*, 1883, **16**, 1025; *Annalen*, 1885, **230**, 147) prepared it by reduction of methylene-blue with hydrosulphite ($Na_2S_2O_4$) followed by ether extraction.

Expt. U. (Theory, p. 1437.)—The times taken for the disappearance of the blue colour from mixtures of thiosulphate, hydrochloric acid, and methylene-blue were carefully noted, the thiosulphate being added last of all and the timing starting from then. These times are given (in secs.) under *t* in Table VII; they are the average of two or more concordant readings and are subject to an experimental error of at least 5%. The temperature was 15° throughout, and the same weight of methylene-blue (*viz.*, 0·0064 g.) was used in each experiment.

The total volume in each experiment was 21 c.c., 1 c.c. of *N*-, 0·5*N*-, or 0·2*N*-thiosulphate being added to 20 c.c. of 10*N*-, 5*N*-, 2·5*N*-, 1·25*N*-, 0·625*N*-, or 0·5*N*-hydrochloric acid containing the

methylene-blue. The resulting normalities are shown in the table. (In this experiment, $N = \frac{1}{2}M$ for thiosulphate.)

TABLE VII.

Times of disappearance of colour from 0·0064 *g. of methylene-blue in solutions containing thiosulphate and hydrochloric acid of concentrations given in horizontal and vertical columns, respectively.*

	Conc. of HCl.	Column 1. 0·0476*N*-$H_2S_2O_3$. *t.*	Column 2. 0·0238*N*-$H_2S_2O_3$. *t.*	Column 3. 0·00952*N*-$H_2S_2O_3$. *t.*
a.	9·50*N*	41	104	450
b.	4·75*N*	20·3	61·4	250
c.	2·38*N*	21·6	61·8	265
d.	1·19*N*	37	117	840
e.	0·594*N*	78	230	1740
f.	0·475*N*	90	330	2160

The amounts of thiosulphate used in columns 1, 2, and 3 are, respectively, 8, 16, and 40%, since 0·0064 g. of methylene-blue has been shown to react with 40% of the weight of thiosulphate in column 3.

Aqueous solutions of methylene-blue can be kept without change of concentration or behaviour for more than a year. The solutions in 10*N*- and in 5*N*-hydrochloric acid, when freshly made, react with thiosulphate to give colourless solutions, but if they are kept for 3 days before mixing with thiosulphate, the reaction ceases before the solution is colourless, a green tint remaining. Dilute solutions of hydrochloric acid will dissolve only a portion of the methylene-blue, even although left for many days. All experiments with concentrations lower than 10*N*-hydrochloric acid were carried out by mixing an aqueous solution with appropriate amounts of acid just before the start, and usually it was found that no "salting out" of methylene-blue occurred in the short time the experiment lasted. When "salting out" does occur, it may begin soon after the addition of thiosulphate, and if so the experiment must be started afresh.

The following table gives the figures in Expts. *d*, *e*, and *f* (of Table VII) relatively to the 37-minute value for *d* 1, which is taken as unity, on the assumption that the variations are inversely as the square of the thiosulphate concentrations and also as the first power of the hydrochloric acid concentrations.

	(1.)	Theory.	Ratios.	(2).	Theory.	Ratios.	(3).	Theory.
d.	1	1	(1)	3·16	4	(1)	22·7	25
e.	2·108	2	(2·14)	6·75	8	(2·07)	47·0	50
f.	2·43	2·5	(2·82)	8·93	10	(2·56)	58·3	62·5

Expt. V. (Theory, p. 1439.)—One c.c. of 0·0628*M*-sodium formaldehydesulphoxylate was added to 10 c.c. of 10*N*-hydrochloric acid,

and the times taken to bleach successive amounts of a methylene-blue solution containing 0·00064 g. per c.c. were noted. The sulphoxylate should have been able to bleach 31·4 c.c. of the methylene-blue if oxidation gave sulphite alone.

25 C.c. were bleached in 133 mins.; 27 c.c. (total) were bleached in 172 mins.; 29 c.c. (total) in 215 mins.; 31 c.c. (total) in 285 mins.; 33 c.c. (total) in 415 mins. The reaction was then complete.

Expt. W. (Theory, p. 1443.)—Polythionic acids were formed in thiosulphate solutions which had been acidified under varying conditions. The polythionates were not estimated individually, but on the basis of the S/Ag_2S ratio, as explained in Expt. G. Before the polythionates can be satisfactorily determined by this method, it is necessary to remove sulphurous acid or to render it inactive towards silver nitrate. In most cases this was done by boiling, which, unfortunately, has two undesirable effects: some polythionate is hydrolysed, and at the same time higher polythionates are formed at the expense of lower ones. These two effects are the more pronounced the greater the acidity of the solutions.

In a few experiments formaldehyde was added (compare Kurtenacker and Bittner, *Z. anorg. Chem.*, 1924, **141**, 297). This enables the polythionates to be determined directly by the silver nitrate method without any previous boiling. In another case, sulphur dioxide was removed by means of a brisk air current before the silver nitrate reaction was carried out.

When considered collectively, the experiments recorded in Table VIII show that trithionic acid is formed in the earlier stages of the decomposition, but that time, acidity, and boiling all tend to shift the balance in favour of pentathionic acid.

In Table VIII the columns numbered I—IX are given by the following key:

I. Normality of thiosulphate (*i.e.*, referred to $\frac{1}{2}Na_2S_2O_3$).
II. Nature and normality of acid used (referred to $1H_3PO_4$ or $\frac{1}{2}H_2SO_4$).
III. Precipitated sulphur (mg.).
IV. Silver sulphide (mg.).
V. Mg. of sulphur mixed with silver sulphide.
VI. Molecular ratio, S/Ag_2S.
VII. Molecular ratio of trithionate to tetrathionate (taken as 100).
VIII. „ „ „ pentathionate „ „ „ „.
IX. Ratio of sulphur, %, in polythionate to that in original thiosulphate.

Expt. X. (Theory, p. 1443.)—Solutions of sulphurous acid and hydrogen sulphide of known strength were prepared. Mixtures of

these in different proportions were made and kept in tightly-corked flasks for various times. Excess of sulphur dioxide and hydrogen sulphide was then removed by boiling, and the polythionic acids present were estimated by the silver nitrate reaction (Table IX).

Summary.

(1) The hydrolysis of sulphur probably occurs in accordance with the equation $S_2 + 2H_2O \rightleftharpoons H_2S + (HO)_2S$.

(2) Sulphoxylic acid is very unstable either in acid or in alkaline solution, and readily yields hydrogen sulphide and sulphurous acid. The mechanism of this change and its bearing on the initial step in the Wackenroder reaction are discussed.

(3) The cause of the yellow colour of certain simple sulphur compounds is attributed to the presence of a sulphur atom with a ten-electron sheath.

(4) The decomposition of hydrosulphurous acid, $H_2S_2O_4$, is discussed.

(5) The autoxidation of sulphurous acid is considered.

(6) The main part of the paper deals with the decomposition of thiosulphuric acid, and it is shown that this decomposition can occur in three different ways.

(7) One mode of decomposition yields hydrogen sulphide and trithionic acid. This is considered to be an essential step in the Wackenroder reaction also, and trithionic acid is regarded as the primary thionic acid both in the thiosulphate decomposition and in the Wackenroder reaction.

(8) The objections to the usual view that pentathionic acid is the primary thionic acid are dealt with.

(9) It is shown that, in all probability, thiosulphates never decompose directly into sulphide and sulphate, but that the sulphate results from trithionate formed first of all.

(10) Experiments are recorded which suggest that the decomposition of thiosulphuric acid into sulphurous acid and sulphur is probably a bimolecular reaction involving a sulphur unit S_2.

(11) A new mode of decomposition of thiosulphuric acid into an anhydro-acid, $H_2S_4O_5$, is described. The new acid reduces methylene-blue and is thereby oxidised to tetrathionic acid.

(12) The structural formulæ of the polythionic acids and their behaviour on hydrolysis have been considered, and some new points of view put forward.

UNIVERSITY OF READING. [*Received, April 8th,* 1927.]

CXCVIII.—*The Reaction between Manganese Salts and Sodium Hypochlorite in the Presence of certain other Salts.*

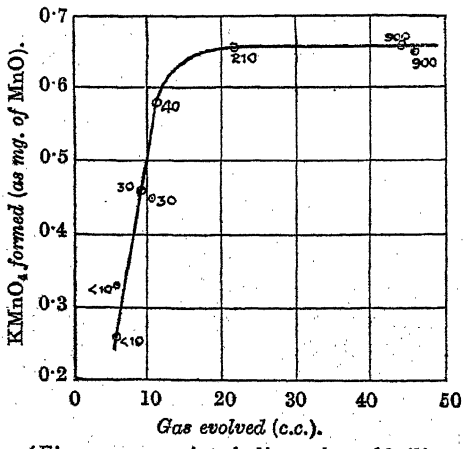
By Bertram Eastwood Dixon and John Ledger White.

From a solution of a manganese salt sodium hypochlorite precipitates hydrated manganese dioxide, and, on prolonged boiling, a small quantity of sodium manganate or permanganate is formed. If the reaction takes place in the presence of copper salts, however, the copper is precipitated and permanganate is the main product. The latter reaction was studied by Duyk (*Ann. Chim. anal.*, 1907, **12**, 465), who gave no data, but stated that the reaction was complete for small quantities of manganese. Heslinga (*Chem. Weekblad*, 1922, **19**, 274) used bromine water in alkaline solution in place of hypochlorite, and stated that the reaction was suitable for qualitative purposes only.

It has been found that a small amount of sodium permanganate is formed even when special precautions are taken to purify both the manganese salt and the sodium hypochlorite, so the manganese dioxide itself appears to be capable of catalysing the reaction. When present in quantities roughly equivalent to that of the manganese salt, the salts of several metals, notably copper, cobalt, nickel, and molybdenum (as molybdate), possess the property of greatly increasing the amount of permanganate formed in this reaction, and the present communication is a study of the effect of variations in the conditions of the experiment on the conversion of manganese salt into permanganate.

Experimental.

Influence of Time.—Of the oxygen available from the hypochlorite, some is utilised in the formation of permanganate, whilst the bulk is evolved as gas. The relations were observed between time of heating, permanganate formation, and evolution of gas at a temperature of 100°.



The reactants were mixed at 100° by sharply shaking a small tube, which contained measured amounts of manganese- and copper-salt solutions, and which stood normally in an upright position inside the reaction tube containing the hypochlorite. After being heated for a definite time, the reaction tube was immersed in an ice-bath, the volume of gas evolved was measured, and the permanganate estimated colorimetrically. Only at 100° is the suspension of copper oxide sufficiently agitated, without the use of a stirrer, to exert a constant and maximum influence on the reaction. But since the

reaction has been chiefly studied at this temperature, no attempt has been made to carry out the above experiment at any other temperature. The results were as follows, *all weights of manganese salts and permanganates being expressed, both here and later, as mg. of* MnO:

Time of boiling (secs.)	<10	<10	30	30	40	210	900	900
Volume of gas (c.c.)...	5·4	5·4	10·7	9·4	11·2	21·7	43·8	45·6
$KMnO_4$.....	0·26	0·33	0·45	0·46	0·58	0·66	0·66	0·65

These results are shown graphically in Fig. 1, and it is evident that, at these concentrations, the maximum amount of permanganate is formed at the end of about 3 minutes' boiling, and after the evolution of one-third of the total oxygen.

FIG. 1.

(*Figures near points indicate time of boiling in seconds.*)

Effect of Alkali.—On filtering the above reaction mixtures, it was noticed that the solutions sometimes had a slight bluish tint which made colorimetric comparison with permanganate solution impossible. This was very marked when the bulk of the hypochlorite had been decomposed and the ratio of alkali to hypochlorite had greatly increased. On keeping indefinitely, the solution turned greenish-blue in colour, and a brown precipitate formed. When the filtrate from this solution was treated with acid, the original pink colour was restored, with co-precipitation of manganese dioxide. The colour was found to be due to the formation of a little manganate by the action of sodium hydroxide on the permanganate.

Heslinga (*loc. cit.*) stated that the presence of iron was prejudicial to the reaction, since it caused the colour of the solution to change to bluish-violet, probably through the formation of unstable potassium ferrate. It was found, however, that (1) the bluish-violet colour was observed when no iron was present, (2) this colour formed more readily as the concentration of alkali increased, and (3) the brown precipitate contained manganese, but no iron.

Of the reagents usually employed to convert manganate to permanganate, sodium bicarbonate was found to be the only one

suitable in this case, provided that sufficient hypochlorite was also present.

Extent of Reaction.—Another series of tests was carried out to discover how far the oxidation of the manganese to permanganate was quantitative, starting with different quantities of reactants.

Approximately equivalent measured amounts of manganese and of cobalt or copper salt were poured into a conical flask, and the solution was diluted to 50 c.c. To the warm solution, 10 c.c. of 5*N*-sodium hypochlorite (total alkalinity 0·1*N*) were added gradually, the flask being shaken simultaneously, and the mixture was heated. After reaching brisk effervescence, the solution was boiled for 3 minutes, a further 5 c.c. of hypochlorite were added, and the solution was again heated until it effervesced freely. After filtration through pure asbestos, the solution was cooled, made up to a known volume, and estimated colorimetrically.

II. $KMnO_4$ formed :									
A. Using cobalt.	0·30	0·45	0·91		1·25		1·42		1·80
	0·30	0·46	0·93				1·44		
		0·45					1·47		
B. Using copper.		0·73	1·33	1·64	1·62	2·21	2·39	3·00	3·83
				2·00	1·87	2·50	2·58	3·06	
					2·21	2·50			
					1·98				

From the results obtained it is seen that, when cobalt is used, the ratio of permanganate formed to that theoretically possible decreases in a regular manner as the amount of manganese salt used increases. In the case of copper, however, although the amount of permanganate formed approached the theoretical more closely than when cobalt was used, the results obtained were erratic. Occasionally, the manganese was completely converted into permanganate, and it was noticed that this happened only when the standard manganese solution (in this case prepared from permanganate) was slightly acidic. It was found impossible, however, to reproduce these conditions, as a very slight excess of acid over the alkali present in the hypochlorite caused decomposition to set in, whereas a deficiency of acid did not favour complete oxidation of manganese.

These indications that low alkalinity is a critical factor in the reaction find support on theoretical grounds. Kauffmann ("Bleichlaugen und Bleichverlauf," *Z. angew. Chem.*, 1924, **37**, 364) states that the activity of sodium hypochlorite is due to free hypochlorous acid, and that the condition of higher instability occasioned by a minimal alkali content is also that of enhanced activity. Again, assuming that it is peroxide of copper that catalyses the reaction

(and later observations seem to warrant this assumption), an appreciable hydroxyl-ion concentration would hasten its decomposition.

In view of the difficulty experienced in establishing and maintaining approximate neutrality during the course of the reaction by means of mineral acid, use was made of the solution of the double carbonate of sodium and copper (Aldridge and Applebey, J., 1922, **121**, 238), which has a very slight alkalinity. Owing to the buffer action of this solution, the addition of the alkaline hypochlorite does not appreciably alter the p_H value of the solution.

2 C.c. of a solution containing 100 g. of anhydrous sodium carbonate and 40 g. of sodium bicarbonate per litre were warmed to 50°, and 3 c.c. of copper sulphate solution (containing 1 g. of CuO per litre) were added. Into this solution was poured quickly a measured quantity of manganese salt solution, the liquid shaken, and, before any signs of turbidity appeared, 5 c.c. of 5*N*-sodium hypochlorite were added from a burette, whilst the flask was shaken. The liquid was diluted to 50 c.c., gently heated until freely effervescing, and then boiled for 3 minutes. Filtration through an asbestos–glass wool filter was followed by the addition of 1 c.c. of hypochlorite and 0·5 c.c. of saturated sodium bicarbonate solution. The solution was then cooled, made up to a known bulk, and the permanganate estimated colorimetrically.

	I.	II.	III.	IV.	V.	VI.	VII.
Manganese salt present	1·02	2·04	3·07	4·00	4·00	4·00	5·11
Permanganate formed	1·08	2·09	3·17	4·01	3·93	4·02	5·16

If the hypochlorite is not added immediately after the manganese salt has dissolved in the double sodium copper carbonate solution, the solution becomes turbid, and the amount of permanganate subsequently formed is decreased, as shown by the following figures (VIII—XII).

	VIII.	IX.	X.	XI.	XII.	XIII.	XIV.
Manganese salt taken	2·04	2·04	3·06	3·07	3·07	4·00	4·00
Permanganate formed	1·86	1·73	2·80	2·85	2·81	3·79	3·89

A somewhat lower result for permanganate was also obtained if only 1 minute's boiling (instead of the usual 3 minutes) was given after reaching the stage of free effervescence (Nos. XIII and XIV).

When the modified procedure described above was applied to cobalt, considerably less permanganate was formed and appreciable quantities of cobalt remained in solution, rendering colorimetric estimation difficult, owing to the difference in tint between the standard and the sample.

The filtrates I—VII were tested for copper. They were evapor-

ated to dryness and the residues were dissolved in dilute acid, any copper present being separated as sulphide and estimated colorimetrically as copper pyridine thiocyanate (Spacu, *Bul. Soc. Stiinte Cluj*, 1922, **1**, 284). Only traces of copper were found, and these did not affect the tint of the permanganate.

			IV.	V.	VI.	
Mn salt taken	Nil.	Nil.	4·00	4·00	4·00	13·32
Cu salt taken (as mg. CuO)...	3·12	3·12	3·12	3·12	3·12	1·04
Cu salt in filtrate (as mg. CuO)	0·03	0·01	0·08	0·08	0·06	0·03

When sodium hypochlorite is added to the double copper carbonate solution alone, the solution acquires a deep yellow colour, and gradually deposits a buff precipitate, which, on heating, is converted into a dense black precipitate. This behaviour emphasises another advantage of the use of the double copper carbonate in the reaction under study, *viz.*, the introduction of the copper into the reaction mixture in a form which is soluble and not readily precipitable. It was found that, if the copper had once become separated as a brown flocculent precipitate (*e.g.*, by the method described on p.1471, and in the presence of considerable alkali), the dense black precipitate phase did not occur, and the amount of permanganate formed was far from theoretical, nor could it be appreciably increased by further treatment of the residue. This is in agreement with the work of Müller (*Z. anorg. Chem.*, 1907, **54**, 417) on the formation of copper peroxide by the action of hypochlorite on copper oxide, who found that he could obtain the yellow peroxide only by the use of a clear blue alkaline *solution* of copper oxide. When a *suspension* of cupric hydroxide in alkali was used, he could not observe the formation of either the yellow copper peroxide or the black copper oxide phase.

When the method described above was applied to larger amounts of manganese (above 8 mg. MnO), the quantity of permanganate formed did not reach the theoretical value (XV—XIX).

	XV.	XVI.	XVII.	XVIII.	XIX.
Manganese taken	13·33	13·07	13·33	13·33	13·33
Permanganate formed	12·00	12·23	11·82	12·23	11·68

It was thought that this might be due to the premature decomposition of the buffer solution by loss of carbon dioxide before the comparatively large quantity of manganese had been converted to permanganate. To retard this loss as far as possible, the experiments were repeated, a stream of carbon dioxide being passed through the solution during the heating. At the end of 3 minutes' heating, and without check in the passage of the gas, a further 10 c.c. of sodium hypochlorite were added from a burette. After

a further 2 minutes' heating the solution was filtered, and the permanganate estimated as before (XX—XXIII).

	XX.	XXI.	XXII.	XXIII.
Manganese taken	9·84	9·84	13·33	13·33
Permanganate formed	9·62	9·84	13·22	13·30

By this modified method practically all the manganese was converted to permanganate, as in the case in which smaller quantities of manganese were taken. Owing to the difficulty of estimating colorimetrically permanganate corresponding to more than 15 mg. of MnO, the method was not applied to amounts greater than this.

Reversibility of the Reaction.—When known amounts of permanganate were heated with approximately equivalent quantities of copper as double carbonate and with hypochlorite, no decrease in the amount of permanganate could be detected colorimetrically, and the precipitates, when tested by the bismuthate process, indicated only traces of manganese. It appears, then, that the reverse reaction is negligible in the case of copper, although when cobalt is substituted for copper an appreciable amount of permanganate is reduced.

Ratio of Manganese to Copper.—The most effective ratio of copper to manganese is not so well defined as is the case with other factors, and varies considerably according to the circumstances. For moderate amounts of manganese (1—5 mg. MnO), the presence of the equivalent quantity of copper leads to the best results, but with larger amounts of manganese the presence of approximately equivalent quantities of copper is not favourable to complete precipitation of the copper. Again, a large surface area of catalyst results in a relatively rapid decomposition of hypochlorite without perceptibly hastening the permanganate formation. This would have the effect of rendering the curve (Fig. 1) less steep, and delaying the attainment of the maximum value. With moderate amounts of manganese and very small quantities of copper, permanganate formation is incomplete, *e.g.*, 4·22 mg. MnO and 0·10 mg. CuO yielded permanganate equivalent to 3·70 mg. MnO. The precipitate was separated, washed, and heated with more hypochlorite, yielding a further 0·36 mg., and a third treatment of the precipitate gave 0·05 mg.

Increase in the ratio of cobalt to manganese shows a marked tendency to decrease the amount of permanganate formed.

Limit of Delicacy for Detection of Manganese.—The minimal quantity of manganese that could be detected by this method appeared to depend on the amount of permanganate capable of producing a visible tint: Manganese equivalent to 0·002 mg. MnO

was converted to the theoretical amount of permanganate. For this purpose only 0·5 c.c. of sodium hypochlorite and 0·2 c.c. of sodium copper carbonate solution were used; a larger quantity of hypochlorite tended to mask the permanganate colour with a yellowish tint.

Mechanism of the Reaction.—It is evident that there is a pronounced difference between the functions of the copper oxide and of the cobalt oxide in this reaction:

(1) The hydroxyl-ion concentration, which is so critical a factor in the case of copper, appears to be comparatively unimportant in the case of cobalt, although large concentrations of alkali are prejudicial to permanganate formation.

(2) Other conditions being favourable, moderate amounts of manganese salts can be completely oxidised to permanganate in the presence of copper, independent of the amount of manganese present. When cobalt is used, however, the proportion of permanganate formed decreases in a regular manner with increasing amounts of manganese.

(3) The form and the mode of action of the precipitates of cobalt and copper differ in several respects. That of cobalt is flocculent, finely divided, and difficult to filter, and promotes copious evolution of oxygen from the hypochlorite throughout the reaction. The copper precipitate, at first flocculent, soon passes into a dense black residue, easily separated, and becomes considerably less active as regards hypochlorite decomposition after the formation of the permanganate has taken place.

(4) The cobalt, when used in the form of the double sodium carbonate, cannot be completely separated from the solution by boiling, as is the case with moderate quantities of copper.

It is suggested that the following probably represents the course of the main reaction, and is in agreement with the facts described in the foregoing pages. The first effect of the hypochlorite is to form copper peroxide and hydrated manganese dioxide. The oxidation of manganese dioxide to permanganate, which can proceed in the presence of manganese alone, is greatly accelerated by the copper peroxide, which gives up its active oxygen, possibly through the intermediate formation of an unstable compound of copper and manganese,* and is reconverted to the cupric form. At this stage

* Some evidence for the existence of such an unstable intermediate compound is afforded by the following observations. If the manganese and copper salts are separately warmed with hypochlorite before mixing, and the combined solutions heated with a further quantity of hypochlorite, the amount of permanganate formed is much less than that obtained by the action of hypochlorite on the mixed salts.

much of the hypochlorite has been decomposed, and the hydroxyl-ion concentration, due to the alkali which is necessarily present in the hypochlorite solution, becomes an important factor. The excess of hydroxyl ions has an inhibitive effect on the formation of fresh copper peroxide, and the main reaction is arrested. If, however, the carbonate–bicarbonate mixture is used, (i) its buffer action renders the influence of the alkali negligible, and (ii) owing to the delayed precipitation of the copper, much of the earlier part of the reaction takes place in the liquid phase, and the oxidation of the manganese proceeds to completion.

BATTERSEA POLYTECHNIC. [*Received, March 28th*, 1927.]

CXCIX.—*The Activation of Wood Charcoal by Progressive Oxidation in Relation to Bulk Density and Iodine Adsorption.*

By ALBERT BRAMAH PEARCE PAGE.

PROGRESSIVE oxidation of wood charcoal alters its sorptive capacity, but a systematic study of this alteration requires a stock material, the properties of which do not vary much from one charge to the next. To make a standard charcoal from a pure chemical compound, it may be sufficient to fix the conditions of carbonisation, but this is not true for wood charcoal, on account of the heterogeneity of wood. Accordingly, in the present work, the conditions of carbonisation were fixed only approximately, exact similarity of every quantity of charcoal taken for subsequent treatment being ensured in the following way.

The wood was carbonised in the form of cubes, which were so small that there were a very large number in a furnace charge. Since these cubes were roughly mixed and the conditions of carbonisation fixed approximately, it is likely that the charcoal from the different charges was fairly uniform. Each of these charges of charcoal was then most thoroughly mixed with all the other charges according to a definite plan, thus rendering it extremely probable that any one portion taken for subsequent treatment was a representative sample.

The standard charcoal was oxidised at various temperatures by a slow stream of air or of an oxygen–nitrogen mixture rich in nitrogen. This mode of oxidation was chosen because (*a*) it was a natural development from earlier rough experiments with crucibles more or less open to air; (*b*) it was readily controlled by varying the proportion of oxygen in the gas stream, and it allowed all the

important variables to be fixed; and (*c*) it seemed likely to lead to the most simple series of reactions.

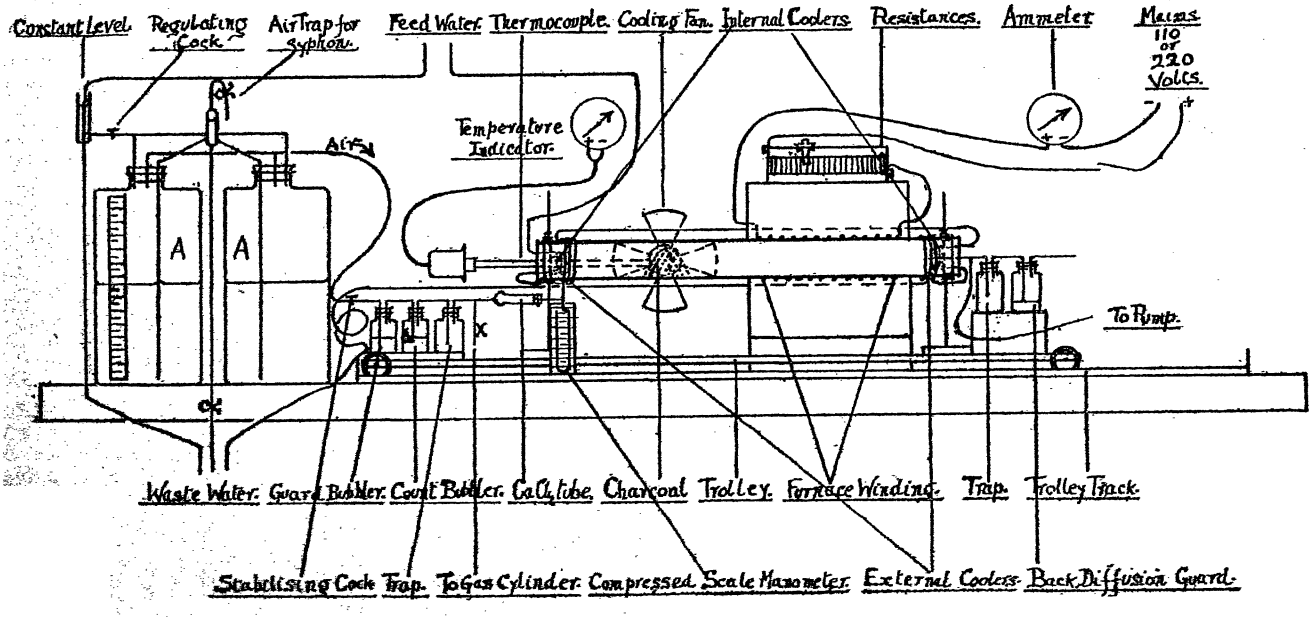
The labour and time involved necessitated the examination of the treated charcoals by simple methods. Those chosen as being the most informative were the "bulk density" test and the determination of the removal of iodine from solution in benzene. These two simple tests were applied to a very large number of charcoals, all made from the standard stock.

Experimental.

Preparation of Stock Charcoal.—Birch wood, cut into rough ½-inch cubes, was carbonised in a horizontal silica tube closed with asbestos wool. The tube was kept in a well-lagged electric furnace for 4 hours, after which it was withdrawn, allowed to cool for about ½ hour, and then unloaded. The furnace kept the interior of the tube at 400° in the absence of any charge. The charcoals obtained from 64 charges—each of which was bottled separately—were thoroughly mixed according to a plan which will be apparent from the following description for the first 8 charges. Each of the original charges 1, 2, 3, . . . 8 was divided into 8 equal parts a, b, c, . . . h. Parts 1a and 2a were mixed, giving 1.2(a). Similarly the mixed parts 1.2(b), etc., and 3.4(a), 3.4(b), up to 7.8(a), (b) . . . (h) were obtained. Then the parts 1.2(a) and 1.2(b) were themselves mixed, giving 1.2(a.b), the corresponding parts from the other charges being similarly treated. Repetition of this process gave the four mixed charges 1.2(a.b.c . . .h), 3.4(a.b.c . . . h), 5.6(a.b.c . . . h), and 7.8(a.b.c . . . h), which were now called (1.2), (3.4), (5.6), and (7.8). Each of these was divided into 16 equal parts, which were then mixed as before to give, after several mixings, the two mixed charges (1.2.3.4) and (5.6.7.8). Each was divided into 32 equal parts, which were then mixed in the same manner to give eventually the mixed charge (1.2.3.4.5.6.7.8). The mixed charge (1.2.3 . . . 64), when sieved free from dust, was the stock charcoal, the oxidation of which has been studied.

Conditions of Heat Treatment.—(i) *Temperature.* The temperature of the charcoal during heat treatment was taken as that given by a platinum–rhodium couple the junction of which was immediately over the pile of charcoal. Occasional regulation of a long and well-lagged wire resistance furnace prevented fluctuations of more than 5° from the required value.

(ii) *Atmosphere.* Mixtures of oxygen and nitrogen at atmospheric pressure were passed at known rates over the charcoal. The oxygen contents (by vol.) of mixtures 1, 2, 3, and 4 were,



respectively, 21, 10, 2, and 0·5%, the first being air, and the other three being supplied in cylinders by the British Oxygen Co., Ltd. —these were analysed in a Bone–Wheeler apparatus. In a short experiment, the effect of the oxygen in the 0·5% mixture appeared to be negligible. There was no reason, therefore, to use pure nitrogen.

The rate indicator was a sulphuric acid bubbler with a jet ground off square. It was protected on both sides, and the complete train was calibrated, yielding a curve showing the rate of delivery of gas in litres per hour corresponding to the number of bubbles per minute. The bubbler was quite suitable for the slow rate of 0·7 litre per hour which was nearly always used. Regulation of the rate of mixtures 2, 3, and 4 was obtained by the main needle valve. This required altering every 2—4 hours. Mixture 1 (air) was taken under a pressure of a few inches of water from the two 15-litre bottles A,A (Fig. 1). Rate regulation was effected by the cock shown, whilst the "stabilising cock" served as a steadying resistance to ensure even bubbling. The actual volume of air used was read from a scale on one of the bottles, which showed the combined contents of the bottles for various water levels.

(iii) *Time of treatment.* To define the time of treatment, the charcoal must be both heated and cooled quickly. The long horizontal containing tube (Fig. 1) was carried on platforms which formed a trolley running beyond the furnace at either end. To perform an experiment, the trolley was pushed to the left (as in the figure) and the cooling fan switched on. The weighed charge (27 g.) was loaded into the tube and pushed into a conical heap in the position shown. The tube was closed with water-cooled bungs, lubricated with glycerol, one carrying the thermo-couple, and the other the exit tube, which led to the trap and guard bubbler, and to the pump. The gas entered by a T-piece connected also to a closed manometer which was used in the preliminary displacement of air by three alternate evacuations and fillings with gas. The bubbling rate was adjusted and the cooling fan switched off. The voltage across the furnace was raised from its normal value to that of the main, *viz.*, 220 volts. The trolley was pushed to the right, so as to bring the charcoal into the middle of the furnace. The annular space between the containing tube and the furnace was closed at both ends with asbestos wool. In about 15 minutes the current was altered to that needed to maintain the desired temperature. The treatment was considered to have begun when the temperature had risen to within 10° of that required, and to have ended at the moment the trolley was run back to the left and the cooling fan switched on. Within 5 or 10 minutes, the

Diagram of Heat Treatment Apparatus

Fig. 1.

temperature indicated had fallen to 400°. At this temperature, activation is very slow. At 50° the treated charcoal was raked into a tared beaker and weighed.

(iv) *Other variables.* Variable conditions, such as size and shape of charcoal particles and disposition of apparatus, affecting the circulation of gas among the particles, were maintained roughly constant. Doubtless such irregular results as were obtained were partly due to these variations, which would be most marked when but little charcoal remained unburnt.

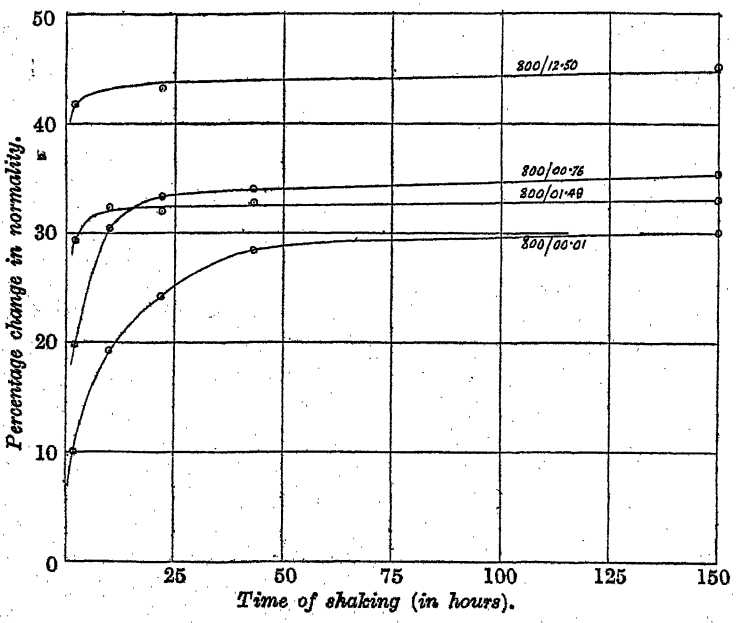
Examination of the Treated Charcoals.—After the selection of 12 representative cubes, the remainder were broken up to give a maximum yield of particles between 10 and 20 to the inch. Each block was cut into $\frac{1}{10}''$ sections, across the grain. The charcoal retained by the "10" sieve after this treatment was placed a little at a time in a flat mortar and tapped lightly. Most of it lay on its end grain and so split into small cubes instead of the usual thin strands or powder. The charcoal which passed the "20" sieve was ground in a glass mortar to yield equal quantities of "100—200" and "less than 200" charcoal. The "10—20" size, intended for gas adsorption, has not yet been used. The "100—200" size proved convenient for "bulk-density" tests. The "less than 200" size was used for sorption from solution.

Determination of bulk density. About 6 c.c. of the "100—200" charcoal spread over the bottom of a flat weighing-bottle remained over calcium chloride in a vacuum desiccator for about 12 hours. It was then weighed and transferred from glazed paper by a brush to a narrow test-tube of 7 c.c. capacity, graduated in tenths of a c.c. This tube was held vertically at one end of a horizontal arm which was pivoted at the other end, $21\frac{1}{4}''$ away. The arm carried a pin, bearing on a cam driven at 100 r.p.m. by a shunt motor, and so shaped that the arm and tube were gently raised and then given a clear drop of 1″ at every revolution. After 15 minutes, *i.e.*, 1500 "taps," the tube was removed and the "bulk volume" of the charcoal read to 0·02 c.c. after carefully levelling the surface by striking the tube gently at the side with the finger. The tube, replaced in the "tapper," was given a further 500 taps, and the volume read again. Agreement worse than 0·01 or 0·02 c.c. indicated incomplete drying or sieving, and hence the need for a complete redetermination. The weight of the charcoal (in mg.) divided by the bulk volume (in c.c.) gives the bulk density.

Determination of activity or sorptive capacity. The iodine used was purified in the usual way and tested by titration against sodium thiosulphate solutions standardised against pure recrystallised potassium dichromate. The benzene was purified according to

Richards and Shipley (*J. Amer. Chem. Soc.*, 1914, **36**, 1825; 1919, **41**, 2002). The solutions of iodine in benzene were estimated by direct titration with sodium thiosulphate in presence of aqueous potassium iodide. As seen by a "daylight" lamp, the disappearance of the pink colour from the benzene layer was quite sharp even with *N*/100-solutions. Fifty or 100 determinations were made at a time by the following method. Soft-glass test-tubes were cleaned, dried, numbered, and weighed, and about 0·25 g. of charcoal was weighed roughly into each. After drying in a vacuum desiccator, the tubes were quickly stoppered with compressed cotton wool, which was not removed until a rider adjustment sufficed to complete the weighing. The weighed tubes were placed in a numbered rack and each was drawn out. After solution had been added in the proportion of 100 c.c. per g. of charcoal, the tubes were sealed with a hand blow-pipe. After being shaken for a definite period, each tube was tapped so as to remove charcoal and solution from the tip and then put in its place in a numbered rack. Soon the suspended charcoal settled, the tip was cracked off, and the clear solution decanted and titrated.

Nomenclature. All the treated charcoals are numbered as follows. First, a number expressing the temperature at which the charcoal was treated, *e.g.*, 500, 600 . . . 900; secondly, separated from it by a stroke (/), a number, of four digits, expressing in litres the total volume of oxygen, at atmospheric pressure and room temperature, passed over the charcoal at the standard rate of 0·7 litre per hour, *e.g.*, /00·01 or /12·30. Thus, a charcoal treated at 0·7 litre per hour for 10 hours at 600° with gas containing 2% of oxygen would be labelled 600/00·14. If a rate other than 0·7 litre per hour were used, a special note is added, *e.g.*, 500/02·38 (14 l./hr.).



Properties of the Treated Charcoals.—(1) *Appearance.* Every block appeared shrunken. The following general statements may be made: (*a*) For 2 or 3 litres of oxygen or less, the charcoal was harder and, although still definitely black, had acquired a slight lustre. This was most pronounced at high temperatures. (*b*) For 4 or 5 litres of oxygen or more, the charcoal seemed softer. (*c*) At 500° and 600°, the charcoal burnt away much as sticks in a bonfire with a large, loose, white ash. When separated from this, and cut or powdered, the charcoal was sooty black. The three heavily oxidised charcoals treated at 600°, 600/10·29, 600/14·33, and 600/20·58, were very soft and broke up to an intensely black soot. (*d*) At 800° and 900°, the charcoal burnt away without much separation of loose ash. The cubes compacted and decreased in size until there remained a tiny grey cube; this was very fragile, but

was sometimes removable from the tube, and must have been nearly all ash. The heavily oxidised charcoals were soft but not sooty. Those treated at 900° were noticeably flaky. (*e*) The 700° charcoals seemed intermediate between those mentioned in (*c*) and (*d*).

(2) *Rate of sorption of iodine from benzene solution, and the ageing effect.* In all the experiments with freshly treated charcoal the duration of shaking was 22 hours. According to Davis (J., 1907, **91**, 1663), McBain (*Trans. Faraday Soc.*, 1919, **14**, 202), and others,

FIG. 2.

Rate of sorption of iodine from N/10-*solution in benzene by four different charcoals.*

adsorption should be complete in a shorter time, and absorption not noticeable until after a much longer time. Some peculiar isotherms for charcoals prepared at 600°, 700°, and 800° with little oxygen threw doubt on this. Accordingly, it was decided to determine the rate of sorption from *N*/10-solution by the four typical charcoals 800/12·50, 800/01·49, 800/00·76, and 800/00·01. The results are plotted in Fig. 2.

The distinction between *ad*- and *ab*-sorption is not clear. Although the order of figures is the same at 22 as at 150 hours' shaking, yet the absolute values are very different. In particular, the figure for charcoal 800/00 01 at 22 hours is 6% low. Evidently the /00·01

charcoals are exceptional. The contention of Herbst that a slow rate of sorption is due to a high density is not upheld. Other factors must be more important, for the bulk densities of 800/00·01, /00·76, and /01·49 are about the same. McBain's "cleaning" of the surface is possibly one such factor. There is an undoubted ageing effect which may account in part for the slow rate of sorption. It will be seen from the general tables that the sorption from $N/5$- and $N/10$-solution, after shaking for 150 hours with charcoals which have aged, is less than that brought about by shaking for 22 hours with freshly treated charcoals. But this ageing effect cannot account entirely for the slow rate, for the sorption from $N/20$-solutions is about the same, whilst from $N/50$-solutions it is greater when brought about by shaking for 150 hours with aged charcoals than for 22 hours with fresh charcoals. This would probably be even more marked at higher dilution. The ageing effect is irregular, for although the individual isotherms for aged charcoals with long shaking are smoother than the others, yet the isotherms for a series of charcoals are related for the short period and unrelated for the long period. There is no evidence indicating the cause or nature of the effect. It may possibly correspond, in part, to the formation of a stable carbon–oxygen complex from the catalytic carbon surface and adsorbed oxygen (see Rideal and Wright, J., 1925, **127**, 1347).

(3) *Influence of the rate of passage of gas.* This can be deduced from the general tables (for eight charcoals), but is of little interest. It is noteworthy, however, that, for a given percentage yield, the charcoals prepared with a fast gas stream are less active than those with a slow stream. It is possible that at the fast rate either some of the active carbon may be removed mechanically, or, since there may be more oxygen available at any instant, more of the active carbon formed (or freed) is burnt away or perhaps covered with a "Langmuir film" of firmly attached oxygen.

(4) *Significance of the total amount of oxygen.* It was soon found that the properties of charcoals treated at any one temperature with a gas stream of 0·7 litre per hour depended almost solely on the *total* amount of oxygen passed, and if this was kept constant, they varied comparatively slightly with the joint alteration of time of treatment and oxygen concentration. This is shown in Table I.

TABLE I.

	Activity towards $N/10$-solutions.	
Name of charcoal.	Charcoal treated 4 hours in 2% O_2.	Charcoal treated 16 hours in 0·5% O_2.
400/00·06	7·4	8·0
600/00·06	39·9	40·0
900/00·06	4·9	5·6

the change in activity when the total oxygen is constant being within the limits of experimental error. At the same time, during long experiments there was probably some distillation, and the effect of the change of oxygen concentration from 21% in Mixture 1 to 0·5% in Mixture 4 cannot have been entirely negligible.

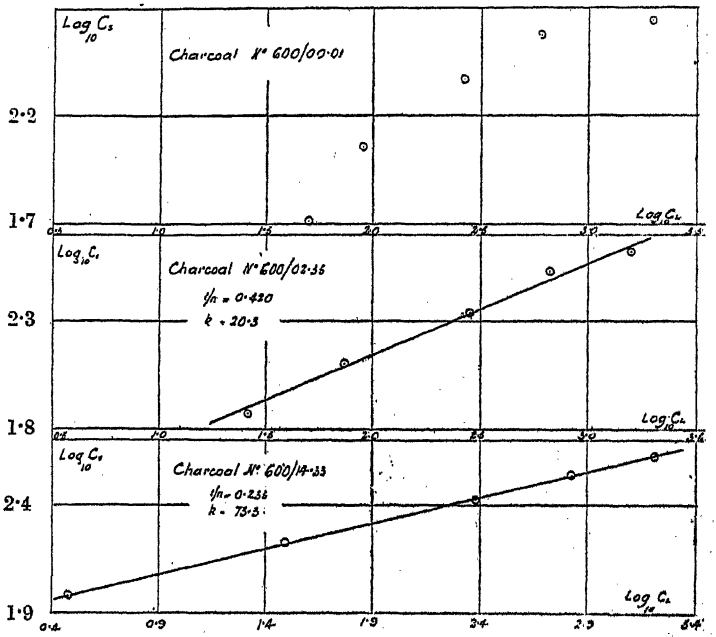
(5) *Effect of temperature change and variation in the total amount of oxygen.* The yield of charcoal treated at any one temperature falls off directly with increase in the total volume of oxygen passed. There is a tendency for it to fall less quickly when but little char-

FIG. 3.

Variation of bulk density with degree of oxidation of charcoal.

coal remains unburnt, and less quickly at low than at high temperatures. These changes can be seen by plotting the data given in the main tables.

The Bulk-density Curves.—In Fig. 3 is shown the variation of bulk density with oxidation at 500°, 600°, and 900°. It will be seen that the bulk density of charcoals treated at 500° is nearly constant and independent of the amount of oxygen used. That of charcoals treated at 600° and 900° falls off regularly with oxidation. With excessive oxidation the bulk density of the charcoals treated at 600° eventually rises after passing through a minimum. This rise is probably due to a very high ash content, most of the carbon having been burnt away. Associated with it is a low



activity towards $N/10$-iodine solution. The irregular fluctuations of the bulk density of slightly oxidised charcoals are probably fortuitous. The curve for charcoals treated at 700° is similar to the 600° curve. The 800° curve flattens at the highest degree of oxidation used and would probably rise with further oxidation.

Sorption of Iodine from Benzene Solution.

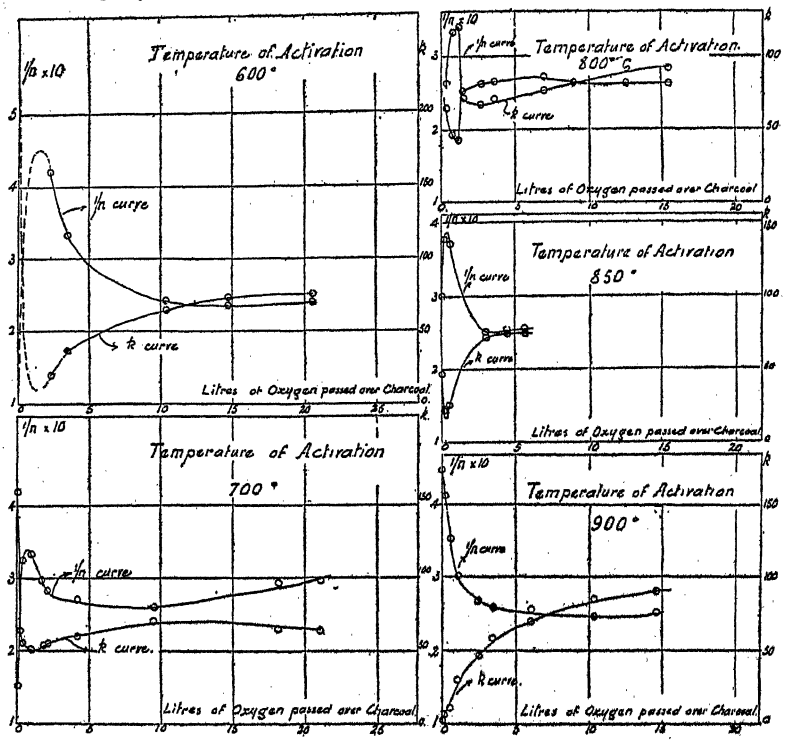
(i) *The "Freundlich" Constants.*—To characterise the activity of each treated charcoal, adsorption isotherms have been obtained

FIG. 4.

Typical logarithmic adsorption isotherms for charcoals treated at 600°.

with iodine in benzene solution. The concentrations used were $N/5$, $N/10$, $N/20$, $N/50$, and $N/100$ with 22 hours' shaking, and $N/5$, $N/10$, $N/20$, and $N/50$ with 150 hours' shaking. The concentration in the solid phase, C_S, is expressed in terms of c.c. of $N/100$-solution containing the iodine adsorbed per g. of charcoal; and that in the liquid phase, C_L, is similarly expressed per 100 c.c. of solution. No account has been taken of the removal of the benzene by the charcoal. Curves were drawn showing the change of $\log_{10} C_S$ with $\log_{10} C_L$ for each charcoal. Most of these curves are fair straight lines, and from them have been calculated the constants in the Freundlich equation ($C_S = kC_L^{1/n}$), k being the

concentration in the solid phase when that in the liquid is equal to unity, and $1/n$ the slope of the line. The three curves in Fig. 4 are representative of those obtained from experiments with 22 hours' shaking. With 150 hours' shaking, there was, on the whole, considerably closer approximation to the straight line. The curve for charcoal 600/00·01 is an extreme example of the curvilinear form obtained with very slightly oxidised charcoals treated at temperatures below 850°. Most of the charcoals treated at 500° give similar curves. The other two curves are fair samples of the bulk; that of charcoal 600/02·35 is the first of the 600° curves from which constants have been calculated.



The interpretation of the changes in these constants (k and $1/n$) depends, in the first place, on the following considerations. For any one isotherm, $1/n$ is a characteristic constant and depends only on the ratio of the units chosen for C_S and for C_L. Its variation, from one isotherm to another, is not even dependent on the particular value of this ratio, provided this is kept constant. On the other hand, k depends on the magnitude of the units chosen. Further, since two isotherms will cross each other at concentrations higher or lower than C_L = one unit, according to the magnitude of the unit, therefore the *relative* value of k for the two isotherms will also change. Now C_L is expressed in very small units, so that it happens that the crossing point of most of the isotherms is at liquid concentrations higher than $C_L = 1$. (This can be seen by plotting, and follows also from the reciprocal variation of the constants from one isotherm to another, which is most marked—see curves in Fig. 5.) Hence a change in the value of k, accompanied as it is by a reciprocal change in the value of $1/n$, actually indicates a change in sorption at low concentrations, whilst the magnitude of $1/n$ indicates the extent to which the sorption falls off at higher concentrations compared with simple proportionality.

(ii) *Variation of the Constants with Temperature and Total Amount of Oxygen.*—For 22 hours' shaking, the variation of k and $1/n$ with the volume of oxygen passed over the charcoal at 600°, 700°, 800°, 850°, and 900° is shown by the curves in Fig. 5. The scales of plotting are, of course, arbitrary; therefore, the maxima and minima and the points of inflexion are the only characteristic features. The curves for 600° are traced no nearer to the zero oxygen axis than 2·35 litres of oxygen, because the shape of the isotherms of the less oxidised charcoals did not permit the evaluation of the constants. The values for the slightly oxidised charcoals at 700° and 800° are from lines on the logarithmic graphs drawn through points derived from measurements with $N/5$-, $N/10$-, and $N/20$-solutions, the experiments in which the shaking was pro-

longed to 150 hours having shown that the systems with the more dilute solutions were probably far short of equilibrium. Very few of the 500° charcoals give isotherms from which constants can be calculated even after the long period of shaking. This slowness in attaining equilibrium was one of the important points brought out by the experiments with long shaking. The other was the clear demonstration of the ageing effect. Unfortunately, as previously

FIG. 5.

Change of Freundlich constants with degree of oxidation of charcoal.

mentioned, the irregularity of this effect has concealed the relations of the constants obtained from these experiments with 150 hours' shaking.

The reciprocity of the k and $1/n$ curves shows, as already stated, that, in general, the isotherms cross one another at concentrations higher than $C_L = 1$, *i.e.*, higher than $C_L = 0{\cdot}0001N$. On comparing all the isotherms, many crossing points will be found between $C_L = 0{\cdot}0002N$ and $0{\cdot}193N$, *i.e.*, within the range which includes $N/10$-, $N/20$-, and $N/50$-solutions, one of which is frequently used

for determining activity (compare Ruff, *Z. angew. Chem.*, 1925, **38**, 1164; Berl and Wachendorff, *Koll. Z.*, Special No., April, 1925, pp. 36—40). From this it follows that determinations of activity made at only one concentration are, in general, misleading.

The curves obtained by plotting k and $1/n$ as ordinates against volumes of oxygen as abscissæ are steepest near the zero oxygen axis. There is a family resemblance between the curves at the five temperatures. On the zero oxygen axis, the highest value of k is probably at 600°, as indicated by the dotted line suggested for the shape of the 600° curve over the range where no figures are obtainable. From 600° the initial value of k decreases continuously with temperature to a very low value at 900°. The subsequent fall of k with increasing value of oxygen also varies with temperature in the same sense from 600° to 850° inclusive. At 850°, the fall is small, whilst at 900° it is non-existent; k, at that temperature, increases continuously with the volume of oxygen from its very low initial value to about the same as that attained by the 800° curve. This continuous increase in k, which forms the whole curve at 900°, corresponds to the only clearly marked feature of the curves at the other temperatures after the initial fall in the k values has been passed. The curves at 700° and 800° certainly have a more complicated form, but it cannot be decided whether this is due chiefly to experimental error or not. It is rather remarkable that these derived curves, expressing the properties of so variable a substance as charcoal, should show resemblances as clearly as they do. The $1/n$ curves exhibit somewhat similar resemblances.

The extent of the variation of $1/n$ is surprising when it is recalled that the charcoals which show it have all been prepared from the same stock charcoal; for the magnitude of $1/n$ expresses, as already stated, the extent to which sorption falls away at high concentrations from simple proportionality, and must indicate a change in type or disposition of surface rather than the mere enlargement which might be expected to result from progressive oxidation.

Strictly, since k and $1/n$ are characteristic of the whole system and not of the charcoal alone, it is difficult to interpret their changes in terms of changes in the charcoal. (It may be recalled that Firth, *Trans. Faraday Soc.*, 1921, **16**, 434, found that the constants for the system iodine–*benzene*–charcoal differed from those for the system iodine–*chloroform*–charcoal.) Besides this difficulty, there is the solvent correction, which is uncertain, although of little importance at the low concentrations used. If, however, the constants k and $1/n$ are conceded to be relatively characteristic of the charcoal, then the following suggestions may be put forward to account for their variation.

Theory of the Variation of the Freundlich Constants.—The changes from one charcoal to another, which may be responsible for the observed variation of k and $1/n$, will first be considered. Since the solution wets the charcoal there must be a definite attraction between the two. Further, the equilibrium concentration of iodine in the bulk of the solution is less than that at the solution–charcoal interface; hence, there is a decrease of surface energy accompanying adsorption, and more energy is liberated in the adsorption of iodine by the charcoal than in the adsorption of benzene. This will hold whatever be the mechanism of the adsorption, whether the attracting field of force above the charcoal surface is uniformly distributed over the surface or localised at active spots, whether it extends for only one molecular diameter or for many, or whether it varies so that in effect only every x atoms of carbon can attract one adsorbed molecule. An increase of available surface per gram of charcoal would merely increase the value of k.

A change in the value of $1/n$ would entail either (i) a change in the field of force, involving the creation of, or an alteration in, an interference effect between the adsorbed molecules; or (ii) a change in the relative importance of two or more types of attraction.

It is easy to see that (i) might be brought about either by a molecular rearrangement of the surface producing a change in the closeness of packing of the adsorbed molecules or by a change in the disposition of the available surface producing locally, according to the size and shape of the capillaries, a change in the closeness of packing.

Since adsorption depends on the specific attraction of the carbon in charcoal, it follows that if there is more than one type of carbon, as Chaney assumed (*i.e.* presumably, more than one type of crystal lattice), then a change in the proportions of these types would bring about change (ii) above.

Rideal and Wright (*loc. cit.*) distinguish three types of surface, and it may be that investigation of the charcoals on the lines of their method would have furnished a satisfactory characterisation. The attempt, however, has been made to interpret the results obtained in the present investigation on the basis of change (i) above.

A brief summary of the variations of k and $1/n$ is of use in considering the corresponding variations in the charcoal: (i) $1/n$ varies from one charcoal to another; (ii) k and $1/n$ vary reciprocally, as a rule; (iii) k and $1/n$ always vary simultaneously; (iv) the k and $1/n$ curves for 600°, 700°, 800°, and 850° charcoals can most readily be built up from simple curves of two quantities, one of which decreases, whilst the other increases with oxidation. Now

bulk density decreases with oxidation, except that with excessive oxidation it has been shown for charcoals prepared at 600° and 700° to increase again after passing through a minimum. Philip, Dunnill, and Workman (*loc. cit.*), and others, have correlated bulk density with activity, and have suggested that with decrease of bulk density there is an *increase of available surface* which accounts for the observed increase in activity. This view seems reasonable, and is further supported by the present work if we exclude for the moment those charcoals prepared with very little oxygen, *i.e.*, less than 1 or 2 litres, at temperatures below 900°. In particular, the view is supported by the decreasing sorption (from $N/10$-solution *) which accompanies increasing bulk density of the most highly oxidised charcoals prepared at 600° and 700°. If this view is accepted, then both the increase of k and the decrease of $1/n$ receive a reasonable explanation. We have only to picture, along with the increase of the extent of surface, a change in the disposition which would increase the packing effect. This packing effect would obviously be more important at high than at low concentrations, so its increase would lead to a decrease of $1/n$. It is easy to see that if the oxidation increased the surface by rendering more and more capillaries available, then in these capillaries a packing effect would not be unlikely.

In seeking a quantity likely to *decrease* with oxidation, in order to suggest a change in the charcoal responsible for the changes in the first part of the k and $1/n$ curves, the rapidity of these changes must be borne in mind. The quantity must alter so as to bring about a large change at 600° and 700°, a smaller change at 800° and 850°, and none at all at 900°; further, its alteration must bring about these changes over a range of oxidation, over which other quantities, such as bulk density and yield, vary very little. It is suggested that this quantity must be the effective number of attracting centres per unit of surface. It may also be described as a particular configuration of the surface giving *in effect* a large number of active centres, and may correspond to what Chaney describes as a particular modification of carbon in an "active" state. We may readily imagine that this quantity would have quite different values, initially, at different temperatures, as is required, varying from a low value or zero at 900° to a maximum at 600°. It is not difficult to see that the effect of oxidation might well be to decrease this quantity rapidly, either by the removal of the active centres (or the "active carbon") or by the formation of a firm "Langmuir adsorption compound." Since the bulk

* There was not sufficient charcoal left after oxidation to determine the sorption from solutions of other concentrations.

density of the unoxidised charcoals is high, therefore the available surface is probably small, so that the large number of active centres involves a large number of these centres per unit area, and therefore favours a large packing effect, giving a low value of $1/n$ and a high value of k. The rapid decrease in the number of active centres with oxidation causes a corresponding decrease in k and increase in $1/n$.

* In *N*/8-solution. † 16 Hours. ‡ 7 Litres per hour. § 14 Litres per hour.

It must be admitted that the evidence for these changes from one charcoal to another with oxidation is not decisive. Further work is needed which should be sufficiently accurate to permit an examination of the k and $1/n$ curves in detail—an examination not warranted by the accuracy of the present work, which has, however, fixed the general shape of the curves with considerable certainty.

Summary.

A large quantity of wood charcoal has been prepared and mixed so as to give a substantially uniform product.

Some 80 samples have been oxidised by oxygen–nitrogen mixtures under regulated conditions. The following properties of the oxidised charcoals have been determined: Appearance, bulk density, percentage yield, sorptive capacity for iodine in benzene solution, and rate of sorption.

Sorption isotherms have been determined for 22 and for 150

hours' shaking for each oxidised charcoal over a range of concentration from $N/100$- to $N/5$-iodine in benzene.

An ageing effect has been observed.

The isotherms are mostly parabolic. Their Freundlich constants have been plotted against degree of oxidation of the charcoal for five different temperatures. A study of these curves has led to suggestions explaining the changes in the charcoal with progressive oxidation. These suggestions are based on the views of Philip, Dunnill, and Workman, and of Chaney.

I wish to thank Professor J. C. Philip, F.R.S., for suggesting the research, and for his subsequent help and encouragement.

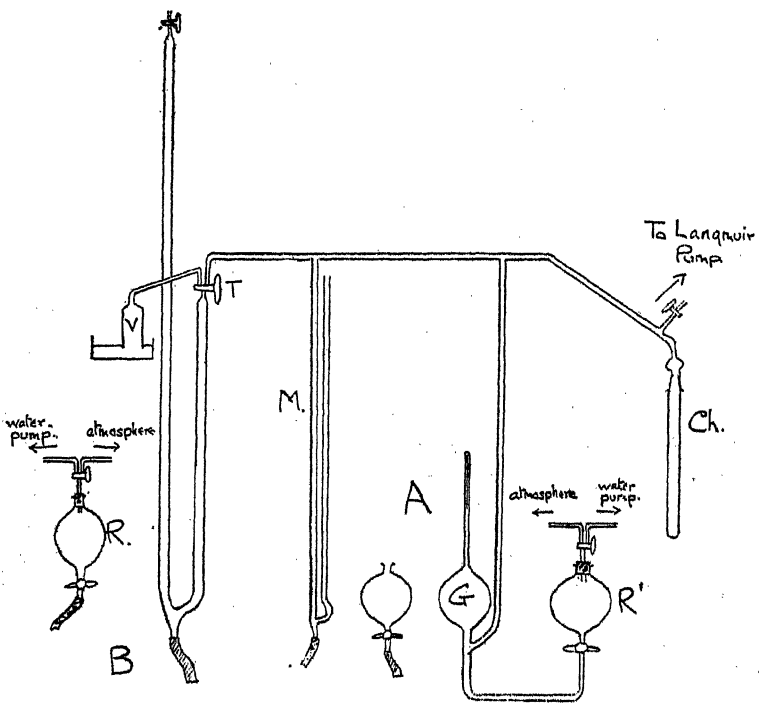
IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY,
SOUTH KENSINGTON, S.W. 7. [*Received, April 4th*, 1927.]

CC.—*The Heat of Adsorption of Gases by Charcoal.*

By SIDNEY JOHN GREGG.

AN examination of the literature dealing with the theories of the adsorption of gases by charcoal showed that one particular experimental quantity—the heat of adsorption—is especially important in testing them; and since the relevant data are very scanty, the following series of experiments was undertaken in order to measure this quantity, together with the more usual ones, equilibrium pressure and amount adsorbed. Measurements were therefore carried out at 0° with the aid of a Bunsen ice calorimeter, and also at 40° using the same calorimeter filled with phenol instead of ice. The adsorption of eight different gases on a standard charcoal was studied, and also the adsorption of a given gas on several different charcoals.

EXPERIMENTAL.



The apparatus (Fig. 1) consists of two main parts, the gas burette, B, and the adsorption system, A, sealed together and mounted on a board, which can slide vertically, thus allowing the charcoal tube, Ch, to be lowered into the calorimeter.

The gas burette is a modification of that used in the Bone–Wheeler gas-analysis apparatus. The gas to be measured is drawn from the reservoir, V, where it is stored over mercury, into the shorter limb of the burette *via* the three-way tap, T. Since a Torricellian vacuum (produced by previous sweeping out of the air) exists above the mercury in the longer limb, the pressure of the gas in the shorter limb is given directly by the difference of mercury levels in the two limbs. The volume of the gas is known from the calibration figures

for the shorter limb, and its temperature is also known, so that the quantity of gas can be calculated. It can then be admitted to the adsorption system by means of the tap T.

The adsorption system consists of an ordinary open tube manometer, M, a McLeod gauge, G, and the charcoal tube, which is joined to the rest of the apparatus by a ground glass joint. The McLeod gauge is joined to its mercury reservoir, R′, by an all-glass connexion, the raising or lowering of the mercury levels in this case, as also with

FIG. 1.

the gas burette, being accomplished by applying atmospheric pressure or a water-pump vacuum, respectively, to the space above the mercury in the reservoir.

The ice calorimeter is of the usual type, but is fitted with an outer jacket which can be evacuated by means of a Langmuir pump. A simple Geissler tube connected with this jacket gives a ready means of testing the vacuum from time to time, and whenever this falls much below *X*-ray hardness, the jacket must be re-evacuated. This jacket, in conjunction with a very large and amply lagged bath of ice (diameter, 14 inches; depth, 16 inches) from which the water

was frequently siphoned off, made it possible normally to obtain a leak of only 0·02 or 0·03 calorie per hour, though on occasions it rose much higher than this.

The desirability of measuring the heat of adsorption at a temperature other than 0° led to the attempt to use other working substances in the Bunsen calorimeter. Owing to the difficulty of keeping a thermostat sufficiently constant at the m. p. of anethole (19·5°), this substance was not satisfactory (compare Grassi, *Atti R. Accad. Lincei*, 1913, **22**, I, 304), but ultimately phenol was found to be a fairly suitable substitute. For accurate working, the normal heat leaks from the surroundings of the calorimeter should be constant enough to produce a small and steady creep of the mercury meniscus in the capillary in one direction; actually, it was found that a bath showing no variation on a Beckmann thermometer still gave unsteady heat leaks, and even in the best cases the mercury meniscus oscillated in the capillary over a range of some 0·6 cm., so that the readings are always uncertain to at least this extent. This is, unfortunately, an appreciable fraction of the movement due to the heat of adsorption itself, which was usually of the order of 10 cm. at each reading. In order to achieve even this degree of success, it was necessary to have very rapid stirring of the bath, to employ a large thermo-regulator, and to cover the top of the bath to minimise irregular evaporation.

Calibration of the Calorimeters.—The standard figure 1 cal. $\equiv$ 0·001132 c.c. was adopted for the ice calorimeter. The phenol calorimeter was calibrated by an electrical method, a known quantity of electrical energy being passed through a heating coil immersed in mercury, contained in the reaction tube of the calorimeter. The coil was of nichrome wire, welded on to copper leads, and was rendered insulating by momentary heating in a Bunsen flame, whereby a coating was formed on it such that on immersion in mercury it suffered no reduction in resistance. A voltmeter was connected across the terminals, and a known current passed for a definite period, the change in volume of the phenol being read on the capillary. A mean of several determinations gave 1 cal. $\equiv$ 0·00169 $\pm$ 0·00002 c.c. Finally, the temperature of operation was found to be 40·35° by immersing a standard thermometer in mercury contained in the reaction tube.

Charcoals.—A stock of charcoal was prepared by heating small cubes of birch wood in a large silica test tube in an electric furnace for 4 hours at about 400°. Four different samples were then prepared by activating separate charges of the stock at different temperatures in a very slow stream of nitrogen (containing 0·5% of oxygen). Details of these are :

Charcoal No.	I	II	III	IV
Time of activation (hrs.)	3	4	4	3
Temp. of activation	600°	800°	500°	450°

Manipulation.—The charcoal was dried in a vacuum desiccator for 5 hours, and 3—5 g. were accurately weighed into the charcoal tube, which was then placed in position on the adsorption apparatus and surrounded by an electric furnace. The charcoal was then evacuated by a mercury condensation pump for 24 hours, its temperature being maintained at 400°, as read by a pyrometer whose junction was in contact with the bottom of the charcoal tube. At the end of this time the pressure was of the order 0·0001 mm., and on cooling, it always became so low as to be unreadable. By means of the sliding board, the charcoal tube was now lowered into the reaction tube of the calorimeter, into which mercury was poured in order to facilitate heat conduction from the charcoal to the calorimeter during the subsequent measurements; to prevent heat losses by convection from the top of the reaction tube, the space between this and the charcoal tube was covered with a piece of plasticine. As soon as the movement in the capillary became constant, the first charge of gas was admitted, and readings of the pressure were taken every few minutes until two consecutive readings were identical, showing that equilibrium had been reached. When the calorimeter was working well, it was possible to use the heat readings as a check on the attainment of equilibrium, for when the creep became the same as before the admission of gas, one could assume that equilibrium had been reached.

The sorption curve was obtained by adding successive small quantities of gas from the burette, as outlined above, whilst, in order to obtain the desorption curve, the burette was opened to the adsorption system, thus enlarging the volume of the dead space. After a minute or so, the burette was shut off, the volume of gas withdrawn was read, and the attainment of equilibrium awaited.

In most cases, fresh samples of charcoal were used for each experiment. In a few instances, however, the supply of fresh charcoal was insufficient, and on these occasions, samples of charcoal that had been used for previous experiments had to be employed; in order to reduce the activating effect in such cases to a minimum, the charcoals were freed from gas at a lower temperature than before, *viz.*, at 150°, and in some cases even at room temperature. Nevertheless, as will be explained later, a small activating effect was still present, the charcoal being slightly altered during each removal of gas.

Calculations.—In calculating volumes of gas, correction is made for the deviation from Boyle's law, and the volume which would be

occupied ideally by the gas at *N.T.P.* thus obtained. To calculate the amount of gas v_a that has been adsorbed up to a given reading, the amount v_u remaining unadsorbed in the dead space is subtracted from the total amount v_i which has been admitted to the system; in calculating v_u, it must be remembered that part of the dead space is at room temperature and part at that of the calorimeter. In order to obtain the heat of adsorption corresponding to a given charge of gas, a correction must be made for the heat communicated to the calorimeter by the gas when changing from room temperature to 0° or 40·35° as the case may be. This correction is $v_c s(t_1 - t_2)$, where s is the specific heat of the gas per c.c. at constant volume, and v_c is the amount of gas that has been changed from the temperature of the atmosphere, t_1, to that of the calorimeter, t_2.

Degree of Accuracy.—No attempt has been made to attain to any great degree of accuracy for two main reasons: (i) Charcoal itself is such an indefinite substance, and is so difficult to obtain in a perfectly homogeneous condition, that excessive accuracy in the measurements would be superfluous; and (ii) the accuracy attainable with the ice calorimeter is not so high as to justify great accuracy in the measurement of the other two quantities. A rough estimate of the probable error of the respective measurements is as follows:

Pressure: Never greater than $\pm$ 1%, and for higher pressures (10 cm. or more), of the order $\pm$ 0·2%.

Amount adsorbed: Between $\pm$ 0·5% and $\pm$ 1·0%.

Heat: Very variable, but of the order $\pm$ 2% for the ice-, and $\pm$ 5% for the phenol-calorimeter.

Note on the Purity of the Gases.—In these experiments, the fact that hysteresis (see "Discussion") was absent, was assumed to prove that the gas was pure, since the presence of air as an impurity immediately produced the phenomenon. The author has since recognised that this is inadequate evidence of purity, however, for the work of Lorenz and Wiedbrauck (*Z. anorg. Chem.*, 1925, **143**, 268) indicates that only when gases differ widely in physical properties do they interfere with each other's adsorption. Hence the absence of hysteresis does not necessarily indicate the absence of impurities similar in physical properties to the gas in question; such impurities, however, would have but a very slight effect on the adsorption measurements.

Results.

The following quantities are given for each reading:

x = total number of g.-mols. of gas adsorbed per g. of charcoal ($= v_a/22414\,w$, where w is the weight of charcoal).

p = equilibrium pressure (cm. of Hg).

Q = integral heat of adsorption per g. of charcoal, $= \Sigma h$, where h is the amount of heat evolved per g. of charcoal at a given reading.

In the curves, desorption points are denoted by a small tail attached to the circle, etc., which surrounds the point, thus ⊙.

Preparation of gas. Propionitrile was dropped on sodium wire in an evacuated apparatus (see Stähler *et al.*, " Arbeitsmethoden der Anorganischen Chemie," 1926, IV, p. 93), and the ethane passed in succession through tubes containing the following reagents : potassium hydroxide solution, solid potassium hydroxide, concentrated sulphuric acid, and phosphorus pentoxide. It was then solidified and redistilled in high vacuum. The presence of hysteresis showed that the gas was not pure, although Cardoso and Bell (*J. Chim. physique*, 1912, **10**, 498) endorse the method as giving pure ethane.

Remark. The attainment of equilibrium at some readings required several hours, again indicating that the gas was not pure.

Preparation of gas. A mixture of 50 c.c. each of concentrated sulphuric acid and absolute alcohol was placed in a distilling flask, and a little sand (previously washed with concentrated hydrochloric acid and ignited) was added. A mixture of 50 c.c. of concentrated sulphuric acid with 25 c.c. of absolute alcohol was slowly added from a dropping funnel, the flask being warmed. The whole apparatus was previously evacuated. The ethylene was passed successively through tubes containing solid potassium hydroxide, concentrated sulphuric acid, and phosphorus pentoxide; it was then solidified and redistilled in a vacuum.

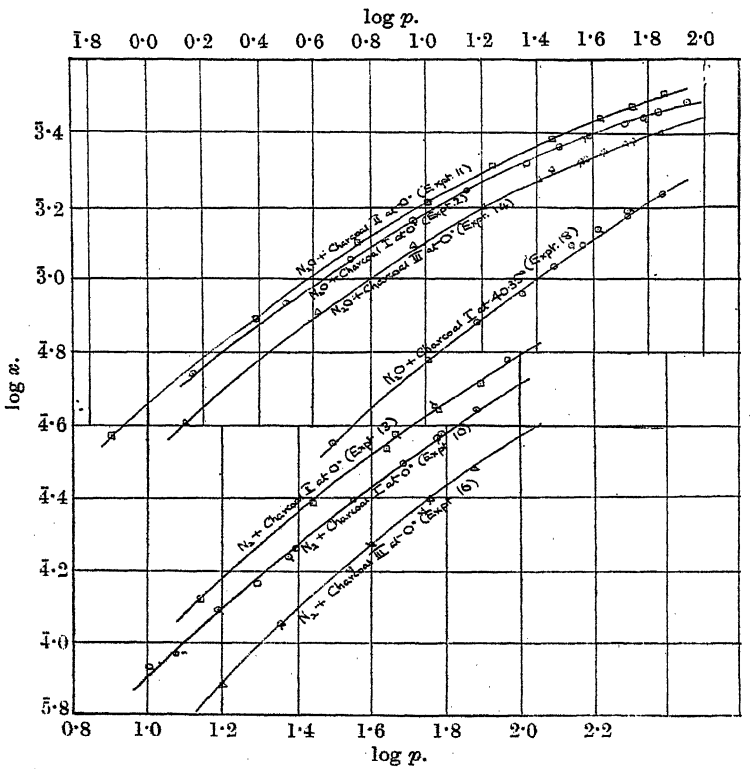
Charcoal. This had been previously used for Expt. 6, and was freed from gas at 150°.



Discussion.

During the earlier stages of the work, great trouble was experienced from the occurrence of "hysteresis," which is a well-known phenomenon in adsorption work; the desorption curve, obtained by withdrawing the gas from the charcoal, does not retrace the sorption curve, the charcoal always retaining more gas for a given pressure on the curve of desorption than on that of sorption. Furthermore, the time required to attain equilibrium is much shorter (of the order of one hour) during desorption than during sorption, in which the pressure may continue to fall for several days. In agreement with Patrick (*J. Amer. Chem. Soc.*, 1920, **42**, 946) and others, the trouble was found to be due to traces of non-condensable gas in the system; for when the gas to be adsorbed was liquefied and then distilled in high vacuum, and when the charcoal was thoroughly evacuated, the sorption and desorption curves could be made to agree, and the time for equilibrium in both cases became normal at about one hour. Only with ethyl chloride was this treatment ineffective, for no matter how carefully the gas was prepared, considerable hysteresis was observed; hence adsorption experiments with this gas were abandoned.

As has been shown by many previous workers, neither the p–x nor the log p–log x curve possesses a simple analytical form; the shape of the latter curve does not even appear to bear any simple relationship to the nature of the adsorbed gas, though it must be remembered that it is difficult to give criteria for selecting comparable parts of the curve for different gases; thus, while the sulphur dioxide curve

at atmospheric pressure is approaching the point of saturation, the curve for a permanent gas like nitrogen is still in its early stages. On the other hand, the log p–log x curves undergo a regular variation with the change of charcoal, for the order of the curves for the charcoals I, II, and III is the same for the three widely different gases nitrogen, nitrous oxide, and sulphur dioxide—charcoal II always having the greatest adsorption for a given pressure, charcoal

FIG. 2.

I the next, and charcoal III the smallest. This is illustrated for nitrogen and nitrous oxide by the curves in Fig. 2.

Q and x are connected by the simple relation $Q = kx^n$, where k and n are constants at constant temperature, a result obtained also by other workers (*e.g.*, Lamb and Coolidge, *J. Amer. Chem. Soc.*, 1920, **42**, 1146). The index n is roughly characteristic of the gas which is adsorbed, for, as will be seen from Table I, it remains approximately constant when one gas is adsorbed on different charcoals, and varies from gas to gas for the same charcoal. The

rule is only a rough one, however, for in some cases quite a large difference is obtained for the same gas. This is illustrated by sulphur dioxide with charcoals I and IV (Expts. 7 and 17, respectively).

FIG. 3.

The data available are too limited to decide whether any simple rule holds for the variation of k; for the nitrous oxide experiments, the log Q–log x curves are in the same order as the corresponding isotherms—charcoal II having the largest k, charcoal I the next, and charcoal III the smallest (see Fig. 3). It is difficult, however, to pronounce judgment upon the apparently anomalous order of the sulphur dioxide curves, for they lie so close together that a small experimental error would alter their relative order; it is possible that

FIG. 4.

such an error may be present in the experiment with charcoal II, for the abnormally high value of n in this case throws doubt on the accuracy of the curve.

*It is here appropriate to note the effect of the adsorption of one gas upon the subsequent adsorption of the same or a different gas by a given charcoal. In Fig. 4 are plotted the log Q–log x curves for ethylene on charcoal I, Expt. 9 being carried out with fresh charcoal, and Expt. 9*a* after pumping out the gas from the used charcoal at room temperature and without intermediate exposure to the atmosphere. The curves for Expts. 1 and 1*a* represent a similar

pair for nitrous oxide, and the curve for Expt. 3 was obtained with charcoal I that had been previously saturated with ammonia and evacuated at room temperature. It will be seen that a small de-activating effect is indicated in the heat curves in each case, the value of k being slightly decreased, though the corresponding log p–log x curves show no such effect.

The heat of adsorption should now be compared with the latent heat of condensation of the adsorbed gas. For this purpose, one must use the differential heat of adsorption, $dQ/dx = knx^{n-1}$, *i.e.*, the heat evolved per g.-mol. of gas, since this is the quantity comparable with the latent heat; and this must relate to a fixed value of x in each case.

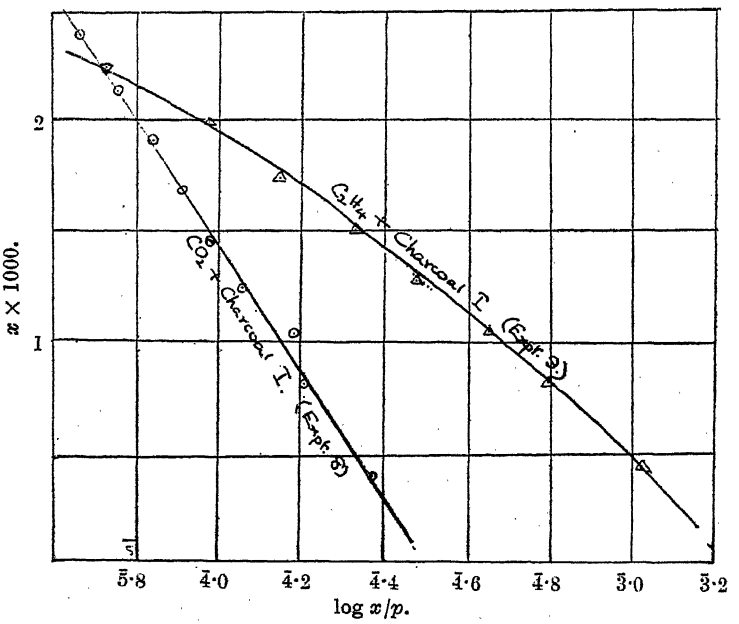
Since n is always less than unity, the differential heat of adsorption decreases as the concentration increases, but its value can be calculated for a given value of x within the range of the experiments, *e.g.*, $x = 1000 \times 10^{-6}$ g.-mol. per g. of charcoal. From Table II it will be seen that this differential heat is in each case 2—3 times as large as the latent heat of condensation of the vapour at 0° (calculated by the Clausius–Clapeyron equation); this agrees with the results of Lamb and Coolidge (*loc. cit.*) for several organic vapours.

TABLE II.

Heats of adsorption and latent heats of condensation.

Gas.	Molecular latent heat (cal.).	dQ/dx (cal.) for $x = 1000 \times 10^{-6}$.
Sulphur dioxide	6,160	11,460
Ethylene	2,050	6,620
Acetylene	2,580	8,100
Carbon dioxide	2,570	6,930
Nitrous oxide	2,510	7,180
Nitrogen (Charcoal II)	—	4,740

(The charcoal used in the first five cases was No. I.)



It is further of interest to compare the heat of adsorption of nitrous oxide at 0° with that at 40·35°, these temperatures being, respectively, below and above the critical temperature (35—39°). Whilst it must be borne in mind that, owing to the difficulty of working the phenol calorimeter, the measurements at 40·35° give little more than the order of magnitude of the heat of adsorption, yet it will be seen that the values of k and n at the two temperatures are not very different, showing that at a given concentration x, the integral heat of adsorption and the differential dQ/dx at the respective temperatures are also not very different.

This approximate constancy, with reference to temperature, of the heat effect of adsorption is confirmed by the fact that the value of the differential heat of adsorption calculated from the van't Hoff

isochore, on the assumption that it remains constant between 0° and 40·35°, is close to the experimental value. In the isochore $d \log_e K/dT = -H/RT^2$, where K is the equilibrium constant and H is the heat of reaction, K may be replaced by p, and integration then gives $\log_e p_1/p_2 = H(T_2 - T_1)/RT_1T_2$, where p_1 and p_2 are the equilibrium pressures at temperatures T_1 and T_2, respectively, for a given value of x, so that H becomes the differential heat of adsorption for the same value of x.

The values of $\log p$ for nitrous oxide on charcoal I at 0° (Expt. 2) and 40·35° (Expt. 18) are, respectively, 0·605 and 1·372 when

FIG. 5.

$x = 1000 \times 10^{-6}$; putting $T_1 = 273$, $T_2 = 313{\cdot}35$, and $R = 1{\cdot}98$, H is calculated to be 7442 cals. per g.-mol. per g. of charcoal. This is close to the value 7180 cal. obtained from the formula $dQ/dx = knx^{n-1}$ by using the experimental values of k and n for nitrous oxide at 0° on charcoal I (Expt. 1).

Although the p–x curve cannot be represented by any simple mathematical equation, the results agree fairly well with an equation of the form $\log x/p = A_0 - A_1x$, which has been deduced thermodynamically by Williams (*Proc. Roy. Soc.*, 1919, **96**, *A*, 287) and from kinetic theory by Henry (*Phil. Mag.*, 1922, **44**, 689). Thus on plotting $\log x/p$ against x (see Fig. 5), a straight line is obtained for

carbon dioxide, acetylene, nitrous oxide, carbon monoxide, or nitrogen with charcoal I; but deviations from the rectilinear occur in other cases, *e.g.*, ethylene and nitrogen with charcoals II and III, and also in Homfray's results (*Z. physikal. Chem.*, 1910, **74**, 129) for ethylene and nitrogen, and Richardson's (*J. Amer. Chem. Soc.*, 1917, **39**, 1828) for carbon dioxide. Furthermore, on plotting the results for sulphur dioxide from the present measurements, and also those for ammonia from Richardson's, the curves are not even approximately rectilinear. In general, however, it may be said that the Williams–Henry equation does reproduce moderately well the adsorption measurements at 0° for those gases which are far removed from their condensation point at *N.T.P.*; but, as it is hoped to show elsewhere, this fact is insufficient evidence for the validity of either Williams's or Henry's fundamental assumptions.

The values of the constants A_0 and A_1 for those cases where the equation holds are given in Table III. The equation put forward by Iljin (*Physikal. Z.*, 1925, **26**, 497) extends to the adsorption of

gases by charcoal the results obtained by Szyszkowski (*Z. physikal. Chem.*, 1908, **64**, 385) for the surface tensions of aqueous solutions of certain fatty acids. Szyszkowski found that if σ_0 is the surface tension of pure water, and σ that of a solution of the fatty acid of concentration c, then

$$\sigma_0 - \sigma = \beta \log (c/\alpha + 1),$$

where α is a constant decreasing as the length of the carbon chain in the acid increases, and β is a constant characteristic of the solvent. Applying this to charcoal adsorption, Iljin puts $\sigma_0 - \sigma = Q/S$, where S is the area of the adsorbing surface of the charcoal, the heat of adsorption thus being taken as a measure of the free energy of adsorption; c must be replaced by p, so that $Q = \beta S \log (p/\alpha + 1)$, which is more convenient for plotting if written as $Q = B \log (p + \alpha) - B \log \alpha$, where $B = \beta S$. Then, if Iljin's equation holds, the graph of $\log (p + \alpha)$ against Q should give a straight line intercepting the $\log (p + \alpha)$ axis at $\log \alpha$. The correct value of α is obtained by plotting with successive values of α, differing by small increments, until two consecutive values are reached such that one

gives a curve convex to one axis, and the next a curve convex to the other axis; the required value of α is then taken as the mean of these two values. Plotting the present results in this way, it was found that the best straight line was one that did not in general intercept the log $(p + \alpha)$ axis at log α (see, *e.g.*, Fig. 6), so that the results only fit a modified Iljin equation of the form $Q = B \log (p/\alpha + 1) + A$, where A is usually a positive quantity, but is occasionally negative. The results for sulphur dioxide do not agree with the equation at all, for even with $\alpha = 0$ (its minimal value, since it is essentially positive), a curved line is still obtained; this is true also of Titoff's results for ammonia (*Z. physikal. Chem.*, 1910, **74**, 641) which Iljin quotes as fitting his equation.

* H = Homfray; T = Titoff; G = Gregg; R = Richardson; P = Patrick (*J. Physical Chem.*, 1925, **29**, 421).

The value of α at a given temperature is roughly characteristic of a gas, varying considerably from one to another. This makes it possible to deduce the approximate value of α even when no heat measurements are available. For since $Q = kx^n$, we may put $kx^n = B \log (p + \alpha) - B \log \alpha$; and since n is never far from unity, the graph of log $(p + \alpha)$ against x also gives a nearly straight line; or, alternatively, the values of α necessary to give a straight

line with the measurements of Q and x, respectively, are quite close to one another, as shown by the figures for α derived by the two methods (Table IV). In this table, the gases are arranged in order of decreasing α, and it will be seen that they then stand in order of increasing a and b (the van der Waals constants), so that a complete parallelism exists between α, on the one hand, and a and b, on the other. (In the table, the suffix indicates whether the value is derived from the Q- or x-curve.) Moreover, the fact that the value of α decreases as the value of b (which is a measure of the size of the

FIG. 6.

molecule) increases, is analogous to Szyszkowski's result for the surface tension of solutions, in which he found that α decreases with increasing length of the hydrocarbon chain. This indicates that there is a close analogy between adsorption at a charcoal–gas interface and that at a water–gas interface, but it is difficult to pursue the analogy further.

Unfortunately, it is impossible to calculate B except by using heat measurements, for the equation $kx^n = B \log (p/\alpha + 1) + A$ shows that a knowledge of k is necessary for obtaining B. It will be seen that, in contrast to Szyszkowski's results, B does not remain constant for a given charcoal, though its variation is much less than

that of α. The non-constancy is possibly due to the fact that Q is not a true measure of the free-energy change; furthermore, the true analogue to Szyszkowski's β is not B, but B/S, and the adsorbing surface S of the charcoal may vary in an unknown way from gas to gas.

It is hoped to discuss more fully elsewhere some of the current theories of adsorption in the light of both the present results and those of other workers.

Summary.

1. Measurements are described of the heat of adsorption, the equilibrium pressure, and the amount adsorbed, for eight gases on a standard charcoal at 0°, with the aid of Bunsen's ice calorimeter. A few experiments were also carried out at 40·35° using a phenol calorimeter, and in some cases the charcoal was replaced by other standard samples.

2. The phenomenon of hysteresis has been traced to the presence of some non-condensable gas in the adsorption system, as other workers have found.

3. For the integral heat of adsorption Q, the relationship $Q = kx^n$ has been found to hold, where x is the amount adsorbed and k and n are constants; n is roughly characteristic of the gas and lies between approximately 0·9 and 1·0; k is slightly decreased by previous adsorption and subsequent elimination of the same or another gas.

4. The Williams–Henry equation, $\log x/p = A_0 - A_1x$, where p is the equilibrium pressure and A_0 and A_1 are constants at constant temperature, is fairly satisfactory for all except the readily condensable gases.

5. With similar limitations, the relationship between p and Q is expressed fairly well by a modified Iljin equation of the form $Q = B \log (p/\alpha + 1) + A$. A close parallelism exists between the value of α and the corresponding values of the constants a and b in van der Waals's equation, a fact which recalls the results of Szyszkowski for the surface tension of aqueous solutions.

In conclusion, the author desires to thank Professor J. C. Philip, F.R.S., for his kindly help and advice during the whole of this work; and also the Department of Scientific and Industrial Research for a grant which enabled him, as student-in-training, to carry out the experimental part of this work at the Imperial College of Science and Technology.

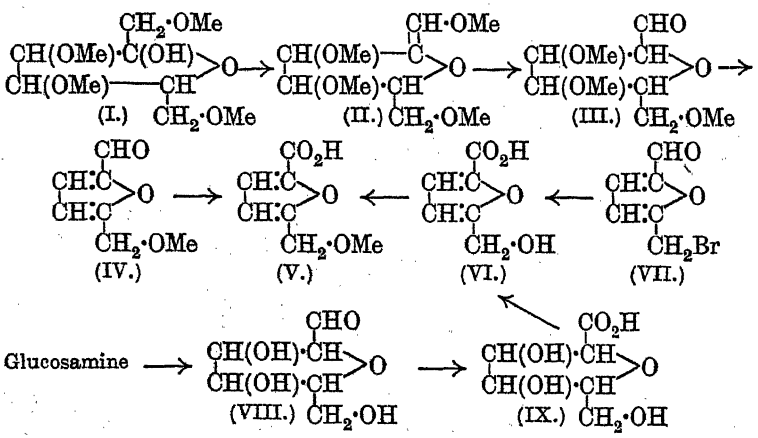
CCI.—*The Constitution of the Disaccharides. Part XIII. The γ-Fructose Residue in Sucrose.*

By WALTER NORMAN HAWORTH, EDMUND LANGLEY HIRST, and VINCENT STANLEY NICHOLSON.

THE γ-fructose residue in sucrose was isolated by one of us in the form of tetramethyl γ-fructose (Haworth, J., 1915, **107**, 12; 1920, **117**, 199). This unstable sugar was characterised by its dextrorotation and by the ease with which it decolorised aqueous permanganate, but further study has revealed a remarkable and unexpected behaviour. In contact with dilute hydrochloric acid at 80°, or on digestion with acetic anhydride in presence of sodium acetate, this methylated ketose undergoes changes involving loss of three of its methoxyl groups as methyl alcohol. This circumstance explains many of the discordant results quoted in the literature of this sugar, and serves also to emphasise the danger attaching to the acceptance of preconceived ideas of the properties of methylated sugars.



When 8% hydrochloric acid was used, more than a third of the product was collected as a typical aldehyde, having an odour like that of benzaldehyde and distilling at about 54°/0·07 mm. It was optically inactive, restored the colour to Schiff's reagent, reduced Fehling's solution, and decolorised permanganate instantly. The aldehyde was characterised by its giving crystalline derivatives; an *oxime*, m. p. 103—104°, and a *semicarbazone*, m. p. 166—167°. Its molecular composition, $C_7H_8O_3$, was recognised by this means, and its general properties suggested its relationship to furan.

The action of hot mineral acid on free sugars containing exposed hydroxyl groups, *e.g.* the pentoses, was already recognised as involving condensation with elimination of water, leading to the formation of furfural or similar products; but in the special case now under review, the hydroxyl positions in fructose are methylated, leaving only the reducing group exposed.

In a previous paper (Haworth and Hirst, J., 1926, 1858), reference was made to the tendency of tetramethyl γ-fructose to pass into furan derivatives during oxidative degradation, and it was there suggested that many of the anomalies attending the constitutional study of this sugar might be attributed to this behaviour. The present results extend and confirm this observation. It was also indicated that an explanation of this behaviour was to regard tetramethyl γ-fructose as a substituted hydrofuran (I), and this provisional formula is strongly supported by the series of transformations which are now recorded.

It is necessary to proceed with caution in the structural interpretation of these observations, and we have relied essentially on the isolation of crystalline products which in the last resort have been compared with substances of known constitution described in the literature. Evidence of the identity of the final products obtained by the conversion of tetramethyl γ-fructose into furan derivatives by contact with hydrochloric acid is now furnished.

The aldehyde, originating as already described, was identified as *ω-methoxy-5-methylfurfural* (IV), since it gave on oxidation with permanganate (compare Frankland and Aston, J., 1901, **79**, 515) *ω-methoxy-5-methylfuran-2-carboxylic acid* (V), m. p. 72—73°, the constitution of which was confirmed by comparison with the crystalline acid isolated from two known sources: ω-bromo-5-methylfurfural (VII) (Fenton and Gostling, J., 1899, **75**, 429) gave on hydrolysis and oxidation *ω-hydroxy-5-methylfuran-2-carboxylic acid* (VI), m. p. 165—167°, the constitution of which had been previously determined by conversion of the crystalline bromide into furan-2 : 5-dicarboxylic acid (dehydromucic acid), identical with that obtained from mucic acid (Hill and Jennings, *Amer. Chem. J.*, 1893, **15**, 159; Hill and Sawyer, *ibid.*, 1898, **20**, 169). When the ω-hydroxy-5-methylfuran-2-carboxylic acid (VI) isolated by these methods was methylated with methyl iodide and silver oxide, we obtained an ester which on hydrolysis gave the crystalline ω-methoxy-5-methylfuran-2-carboxylic acid (V), m. p. 72—73°, identical with that which we had isolated as a transformation product of tetramethyl γ-fructose.

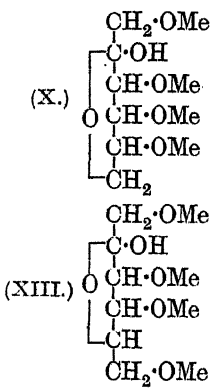
No simple explanation suffices to interpret the transformation of tetramethyl γ-fructose to this furan derivative. On the hypothesis that this sugar contains already a substituted hydrofuran ring (I),

a reasonable explanation of the series of conversions is given in the formulæ above. On this interpretation, the first stage of the transformation from tetramethyl γ-fructose (I) to ω-methoxymethylfurfural (IV) is the elimination of water by removal of the reducing hydroxyl group along with hydrogen of the methylated primary alcohol residue in the first terminal position. This would give the compound (II), containing a methoxymethylene residue which, hydrolysing with ease to the hydroxymethylene group, thereafter functions as an acidic residue, the compound now being an enolic form of the aldehyde (III), and there can be little doubt that the introduction of an aldehyde group follows a course similar to that which is here represented. It may be that the compound (III) is readily formed from tetramethyl γ-fructose and may frequently be present in this sugar as an impurity. It is indeed a variety of trimethyl chitose, and the realisation of this has led us to investigate the transformation of glucosamine into chitose by the methods described by Fischer. This further extension of our work has readily afforded us an alternative means of identifying our products (IV) and (V).

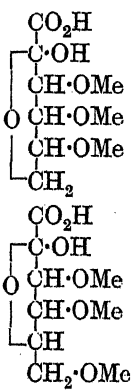
Thus, it has already been shown by Fischer that glucosamine is converted by nitrous acid into chitose (VIII), and that the latter on oxidation with bromine passes into chitonic acid (IX). During acetylation in the presence of acetic anhydride and sodium acetate, chitonic acid lost two molecules of water and passed into ω-acetoxy-5-methylfuran-2-carboxylic acid, which on hydrolysis gave ω-hydroxy-5-methylfuran-2-carboxylic acid (VI). We have confirmed this series of transformations leading from glucosamine, and the final product (VI) was identical with the compound we had obtained as described above by interconversion from (VII). Finally, the specimen of hydroxymethylfurancarboxylic acid obtained from glucosamine gave on methylation ω-methoxy-5-methylfuran-2-carboxylic acid (V) identical with that obtained from tetramethyl γ-fructose.

Thus a cycle of inter-relationships has been established between γ-fructose derivatives on the one hand and glucosamine, chitose, and chitonic acid on the other. The allocation of the butylene oxide formula (I) to tetramethyl γ-fructose, representing this sugar as a substituted hydrofuran, therefore receives the same experimental sanction as the formulæ ascribed by Fischer (Fischer and Tiemann, *Ber.*, 1894, **27**, 138; Fischer and Andreae, *Ber.*, 1903, **36**, 2587) to chitose and to chitonic and chitaric acids. The results now indicated afford definite proof of the presence in tetramethyl γ-fructose of two terminal methoxy-groups, $-CH_2 \cdot OMe$. These serve to distinguish the structural representation of this sugar from

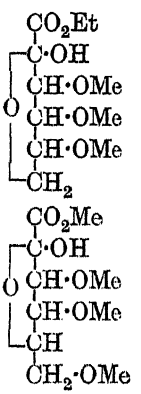
the amylene oxide type which is normal crystalline tetramethyl fructose (Haworth and Hirst, *loc. cit.*).



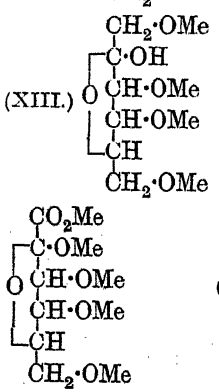
There now remains to be considered the evidence arising from the oxidation of tetramethyl γ-fructose (*a*) with nitric acid and (*b*) with permanganate. The latter degradation will be dealt with in a later paper, but we have again investigated the nitric acid method of oxidation employed by Haworth and Linnell (J., 1923, **123**, 294), and have conducted this work alongside a similar investigation on the normal crystalline tetramethyl fructose.



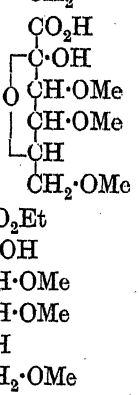
Previous knowledge of the behaviour of nitric acid towards aldoses had established a predilection in favour of the view that the reducing group of sugars was the first to suffer attack in the presence of such an oxidising medium. That such is not the case, however, with ketoses has been made abundantly clear by Haworth, Hirst, and Learner (this vol., p. 1040). It was, for example, shown that the first product of oxidation of normal crystalline tetramethyl fructose (X) was a trimethoxy-lactol acid (XI), giving a crystalline ethyl ester (XII) and a crystalline methyl ester; and the latter gives a higher methylated homologue (crystalline), which is converted into a crystalline amide by the agency of ammonia.



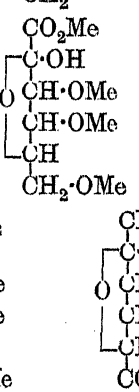
With the insight and experience gained by investigation of this simpler example of the oxidation of a fructose derivative, we have now applied similar methods to the examination of the initial oxidation product of tetramethyl γ-fructose obtained by Haworth and Linnell by the use of dilute nitric acid. These authors recorded the isolation of an oxidation product giving the analysis: C, 50·5; H, 7·3; OR (calc. as OMe), 47·3%. This product was considered to be, on the basis of its analytical data and its general behaviour, a trimethoxy-δ-valerolactone, $C_8H_{14}O_5$ (Calc.: C, 50·5; H, 7·4; OMe, 48·9%). We have since isolated this product many times and in yields representing more than 70% of the tetramethyl γ-fructose employed and have confirmed these analytical figures repeatedly.



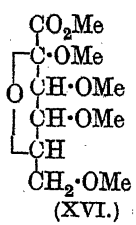
In view, however, of the exceptional behaviour of tetramethyl γ-fructose towards dilute mineral acids, it seemed to us reasonable to suspect that, although the same oxidation product appeared to be constantly formed, the analytical data might be influenced by the presence of traces of the transformation product (III), (IV), or (V), arising in the way we have demonstrated in the earlier part of this paper. If so, it appeared to us that Haworth and Linnell's oxidation product might be analogous in composition and structure to the initial product of oxidation of normal tetramethyl fructose, that is, that the supposed lactone $C_8H_{14}O_5$ might be the ethyl ester of a trimethoxy-lactol acid, $C_{11}H_{20}O_7$ (XVII), isomeric with (XII),



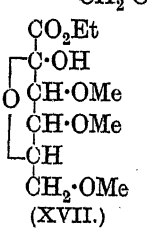
for which the calculated figures are: C, 50·0; H, 7·6; OR (as OMe), 47·0%. This has indeed proved to be the case. The product, resembling a lactone in many of its properties, is unstable to alkali through retaining the free reducing group of the original sugar, and the titration data are for this reason slightly higher than those required for the lactol ester $C_{11}H_{20}O_7$, and may readily be interpreted to satisfy the lactone formula $C_8H_{14}O_5$. We have isolated the corresponding methyl ester (XV) in yields of 75%, but in this case also the carbon value is slightly high owing to the presence of furan derivatives or their intermediate compounds as impurity. That this substance is not a lactone is, however, shown by its conversion into the higher homologue (XVI) of the lactol methyl ester by further methylation. This product no longer reduced Fehling's solution, was comparatively stable towards alkali, and gave a titration value approximating closely to that required by this constitution. Treatment of this methylated product with methyl-alcoholic ammonia gave a crystalline amide (XVIII), m. p. 100—101°, the complete analysis of which established the molecular weight of the original ester, identifying it as being structurally analogous to the product of oxidation obtained under similar conditions from normal crystalline tetramethyl fructose.



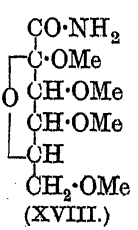
(X.)



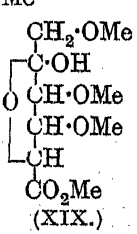
(XI.)



(XII.)



(XIII.)



(XIV.)

(XV.)

(XVI.)

(XVII.)

(XVIII.)

(XIX.)

The possibility has not escaped us that the methyl ester, $C_{10}H_{18}O_7$, might also be formulated as in (XIX), representing the carboxyl

group in position 6 instead of in position 1 as given in formula (XV), but there are many indications which favour the latter structure. In the first place, the oxidations of both the normal and the γ-form of tetramethyl fructose proceeded on exactly parallel lines and led to analogous products. The oxidation of the normal sugar is definitely shown not to affect position 6 (Haworth, Hirst, and Learner, *loc. cit.*). Again, the action of hydrochloric acid on tetramethyl γ-fructose has in the present paper been shown to lead readily to an attack on the $-CH_2 \cdot OMe$ group in position 1. In both cases the vulnerable position towards the action of nitric acid may be expected to be that of the group in position 1. The further oxidation of these products will form the subject of a future communication.

It seems probable that oxidation products similar to the above lactol esters have also been isolated by other workers in the course of investigations on derivatives of γ-fructose, *e.g.*, in the oxidation of tetramethyl γ-fructose with nitric acid as conducted by McOwan (J., 1926, 1737). This author allocated formulæ based on the analytical data given by liquid specimens which were probably not homogeneous. Doubtless the compound represented by (XV) was also obtained by the above author, who assigned to it the formula of a keto-ester containing a four-carbon chain, one of the alternatives suggested being that of a substituted acetoacetic ester.

The present constitutional position in regard to tetramethyl γ-fructose is that, as we have shown in the earlier part of this paper, this sugar cannot contain an amylene oxide ring, since there is present a $-CH_2 \cdot OMe$ group in each of the terminal positions. The remaining possibilities are that the oxide ring is butylene-, propylene-, or ethylene-oxidic, but the 2 : 3-oxide ring is excluded inasmuch as 3-methyl fructose gives rise to a γ-methylfructoside (Allpress, J., 1926, 1720), and the 1' : 2-oxide is excluded by the above results. We definitely favour the allocation of a butylene oxide formula, since this affords the simplest explanation of the peculiar transformations which tetramethyl γ-fructose undergoes, leading with the greatest facility to furan compounds, and secondly, because in the series of aldoses the γ-sugars which have been studied are butylene oxidic.

EXPERIMENTAL.

For the sake of brevity, numerous preliminary experiments are given in condensed form as follows:

Purity of Tetramethyl γ-Fructose.—Tetramethyl γ-fructose is acted upon both by acids and by alkalis, and in order to obtain a pure specimen, prolonged contact of the sugar even with dilute acid, especially at high temperatures, must be avoided. If suitable

precautions are not observed, the first distillation product may contain sufficient aldehydic material to give a pronounced colour to Schiff's reagent. Careful hydrolysis of heptamethyl sucrose (Haworth, J., 1915, **107**, 12; 1920, **117**, 199), the most convenient source, with 0·4% aqueous hydrochloric acid at 60° as originally recommended, followed by neutralisation of the acid with barium carbonate and extraction of the tetramethyl sugar with chloroform, yielded a product the physical constants of which were in agreement both with those previously recorded and with those of a specimen of tetramethyl γ-fructose which had been subjected to further rigorous purification. This was effected by means of bromine, which does not attack tetramethyl γ-fructose, but oxidises a methylated aldose (Haworth and Mitchell, *loc. cit.*). Tetramethyl γ-fructose in 20% aqueous solution was treated with half its weight of bromine for 16 hours at 35°. After removal of the bromine by aeration in the cold, the solution was neutralised with barium carbonate and the purified tetramethyl γ-fructose was extracted by chloroform and distilled. The final product was neutral to litmus, gave no colour with aniline acetate or Schiff's reagent, and had $[\alpha]_D^{16^\circ} + 31{\cdot}3^\circ$ ($c = 2{\cdot}015$) and $n_D^{13^\circ}$ 1·4513.

With regard to the method of purification recommended by McOwan (*loc. cit.*), who employed alkaline hypoiodite, it was found that the action of very dilute alkali ($N/30$) on tetramethyl γ-fructose resulted in changes such that the solution very quickly contained material which gave a positive test with Schiff's reagent. Further details of these experiments will be communicated shortly, but in the meantime the results are sufficiently striking to warrant the opinion that the use of alkali at any stage of the purification of the sugar should be avoided. Even with neutral hypoiodite the purest samples of tetramethyl γ-fructose give a figure corresponding to a content of 2·8% of tetramethyl glucose. Incidentally, it was found to be undesirable to use octamethyl sucrose as a source of tetramethyl γ-fructose, inasmuch as a specimen, obtained in this way, which had not been subjected to the bromine treatment gave on oxidation with nitric acid small quantities of *d*-dimethoxysuccinic acid and *i*-xylotrimethoxyglutaric acid, both of which were recognised as their crystalline diamides (for method of isolation, see Hirst, J., 1926, 350).

Oxidation of Tetramethyl γ-Fructose with Nitric Acid.—A series of oxidations was carried out with both concentrated (*d* 1·42) and dilute (*d* 1·2) nitric acid under various conditions of temperature and times of oxidation, the products being isolated both as esters (methyl and ethyl) and also by simple distillation without the use of alcohol at any stage of the experiment. Details of the methods

employed are given in earlier communications (Haworth and Hirst, *loc. cit.*) and it will be sufficient to give here a summary of the results.

I. *With nitric acid, d* 1·2. (Time, 20 hours at 60° or 9 hours at 90°.)

When the oxidation product was collected as an acid, *contact with alcohol being avoided*, distillation gave a strongly reducing syrup which was evidently a complex mixture of products. From this, crystals of the optically inactive acid $C_8H_{10}O_5$ (m. p. 88—89°; Haworth and Hirst, J., 1926, 1858) separated on standing. Fractionation of the remaining syrup failed to give any homogeneous material, and the colourless distillate, in addition to reducing Fehling's solution, was unstable when kept and became nearly black in the course of a few weeks.

When methyl alcohol was used for esterification, the distilled product invariably gave the strongly reducing methyl ester, $C_{10}H_{18}O_7$, of the acid the ethyl ester of which was obtained under different conditions of working by Haworth and Linnell (*loc. cit.*). The prolonged treatment with nitric acid required in this experiment led to the formation of a considerable quantity of oxalic acid.

II. *With nitric acid, d* 1·42. By the use of the stronger acid, the time required for the oxidation was curtailed, much of the decomposition caused by long contact with an acid medium thus being obviated. Isolation of the product as methyl ester now gave in larger yield (up to 75% of the weight of the sugar used) a methyl ester, the physical properties of which approximated to $n_D^{15°}$ 1·4500; $[\alpha]_D$ + 30° in water, and gave analytical figures in fairly close agreement with those required by a compound of formula $C_{10}H_{18}O_7$ (Found: C, 48·4; H, 7·6; OMe, 49·6. Calc.: C, 48·0; H, 7·2; OMe, 49·6%). Under similar conditions of oxidation but with the use of ethyl alcohol for esterification, equivalent yields of the substance described by Haworth and Linnell were obtained. The analytical figures formerly given were confirmed and found to correspond with those required by a substance of formula $C_{11}H_{20}O_7$.

The methyl ester was unstable to alkali and vigorously reduced Fehling's solution, accurate titration figures being therefore impossible to obtain. It was unstable even on being kept at the ordinary temperature in a desiccator, showed a progressive increase in the value of n_D amounting to + 0·004 approximately after 3 weeks, and became distinctly darker in colour.

Methylation of the Product $C_{10}H_{18}O_7$.—With the view of determining the nature of the reducing group present, the strongly reducing methyl ester $C_{10}H_{18}O_7$ was methylated with Purdie's reagents. The product on distillation gave a main fraction distilling at a bath

temperature of 165°/16 mm.; $n_D^{20°}$ 1·4392; $[\alpha]_D$ + 9° in methyl alcohol (Found: C, 49·9; H, 7·8; OMe, 57·0; CO_2Me, 24·0. $C_{11}H_{20}O_7$ requires C, 50·0; H, 7·6; OMe, 58·7; CO_2Me, 22·4%). It was now non-reducing. Amide formation was effected by dissolving the ester in methyl alcohol saturated with ammonia. No deposition of crystals occurred until the solvent had been evaporated; the residual syrup then crystallised. The long needles so obtained were drained on porous earthenware and washed with ether and light petroleum; they then melted at 95—100°.

Preparation of the Amide $C_{10}H_{19}O_6N$, m. p. 100—101°.—The results described up to this point were regarded as merely preliminary in view of the uncertainty attaching to any interpretation based solely on the examination of liquid substances. It had become apparent during the course of the experiments that the action of acid on the strongly reducing oxidation products, unless carefully controlled, led to profound and complex changes even during the processes necessary for the isolation and characterisation of the substances in question. Accordingly, another series of experiments was carried out in which the contact with acid was reduced to the minimum and the sensitive reducing group was protected as soon as possible by methylation. In this way substantial yields of the above-mentioned crystalline amide (m. p. 95—100°) were obtained, amounting to 40% by weight of the tetramethyl γ-fructose used.

Ten g. of tetramethyl γ-fructose were treated with 70 c.c. of nitric acid (*d* 1·420). Vigorous oxidation began at 70°; the temperature was thereafter gradually raised in the course of an hour to 92° and maintained for 1¾ hours. The nitric acid was then removed in the usual way at 50°/15 mm., the distillation with repeated addition of water being carried on for 5 hours only. Methyl alcohol was added, and distilled off to remove water, and the residual syrup was boiled for 4 hours with 70 c.c. of methyl alcohol. Removal of the solvent yielded a syrup which still contained a little nitric acid but was soluble in methyl iodide. The solution in methyl iodide was neutralised with silver oxide (3 g.), and methylation with silver oxide (30 g.) then proceeded under the usual conditions, the reaction being sufficiently vigorous in the cold to cause the solvent to boil. The product was purified by distillation, giving (*a*) 1·2 g., mainly methyl oxalate and solvent; (*b*) 4·4 g., bath temp. 161°/16 mm., $n_D^{15°}$ 1·4422; (*c*) 3·0 g., bath temp. 166°/16 mm., $n_D^{15°}$ 1·4442; and (*d*) 1·1 g., bath temp. 180°/16 mm., $n_D^{15°}$ 1·4470. There was no sign of decomposition at any stage of the distillation. Fractions (*b*) and (*c*) appeared to be essentially the same product or mixture of products.

Fraction (*b*) was a colourless, mobile syrup without action on Fehling's solution and was not decomposed to give coloured substances by hot alkali; $[\alpha]_D$ — 8° in methyl alcohol ($c = 2{\cdot}452$) (Found: C, 49·0; H, 7·5; OMe, 57·0; CO_2Me, 32·0%). The analytical figures revealed that the distillate was not a single substance, but amide formation proved that it consisted very largely of the methyl ester (methylated), $C_{11}H_{20}O_7$. A solution of 1·3 g. in 10 c.c. of methyl alcohol saturated with ammonia deposited no crystalline material after being kept for a week. The clear solution was then allowed to evaporate, whereupon the resulting syrup crystallised. The crystals were extracted with boiling light petroleum (b. p. 60—80°) and could easily be recrystallised from this solvent. The yield of pure recrystallised material was 0·5 g. In all, from 6·3 g. of fractions (*b*) and (*c*), 3·0 g. of pure recrystallised *amide* were obtained. It crystallised from light petroleum in tufts of interlacing needles resembling cotton-wool in appearance. It was very soluble in methyl and ethyl alcohols and water, less soluble in acetone, and slightly soluble in ether. M. p. 100—101°; $[\alpha]_D$ —76° in water ($c = 1{\cdot}099$) (Found: C, 48·0; H, 7·8; N, 5·4; N, by titration, 5·5; OMe, 47·7. $C_{10}H_{19}O_6N$ requires C, 48·2; H, 7·6; N, 5·6; OMe, 49·8%).

The residue, after extraction with light petroleum, contained some solid matter embedded in a stiff gum. The syrup was removed by extraction with benzene, and the powdery residue was recrystallised from alcohol containing light petroleum. M. p. 177—178°. This material was insoluble in the usual organic solvents except ethyl and methyl alcohols. It was readily soluble in water. Apparently it was not a pure substance, but the analytical figures indicated clearly that it represented the amide of that portion of the original oxidation product which was responsible for the low value of carbon and the high value of CO_2Me. Yield, 0·6 g. from 6 g. of ester (Found: C, 40·3; H, 6·2; N, 12·2; OMe, 39·1%).

The Action of Acetic Anhydride and Sodium Acetate on Tetramethyl γ-Fructose.—Tetramethyl γ-fructose (5 g.), anhydrous sodium acetate (5 g.), and acetic anhydride (50 g.) were heated together at 120° for 1½ hours and then at the boiling point of the mixture for another hour. The solution was then poured into water (4 vols.), and after a few hours the product was extracted with chloroform. Removal of the solvent left a syrup containing acetic acid, which was removed by keeping the mixture in a desiccator over potassium hydroxide. Distillation now gave a series of fractions with a wide range of boiling points and refractive indices, revealing the presence of a complex mixture of substances, the lowest-boiling fraction of which represented the most homogeneous portion. This (0·7 g.;

b. p. about 55°/0·01 mm.; $n_D^{13^\circ}$ 1·4985) was a colourless oil which darkened when kept and gave all the reactions of an unstable aldehyde. It had the odour of furfural, readily combined with phenylhydrazine to give a liquid phenylhydrazide, reduced Fehling's solution, gave Schiff's test for aldehydes, and produced an intense red colour with aniline acetate. It showed slight acidity towards litmus, but this was probably due to the presence of impurities. Analysis showed that the product was not a single substance (Found: C, 57·4; H, 6·6; OMe, 31·7%), but it was proved to be largely ω-methoxy-5-methylfurfural by the following series of reactions. Treated with semicarbazide hydrochloride and sodium acetate, a concentrated aqueous solution of the aldehyde immediately gave a precipitate of the crystalline semicarbazone, m. p. 166—167° after recrystallisation from alcohol. Similar treatment with hydroxylamine hydrochloride and sodium acetate gave the oxime as a mobile oil which readily crystallised. Recrystallised from light petroleum (b. p. 40—60°) containing a little ether, it was obtained in colourless, matted needles, m. p. 103—104°. Further details and analytical figures for these compounds are given in the following paragraph.

The Action of Hydrochloric Acid on Tetramethyl γ-Fructose. Preparation of ω-Methoxy-5-methylfurfural.—ω-Methoxymethylfurfural was more readily obtainable by the action of hydrochloric acid on tetramethyl γ-fructose. Tetramethyl γ-fructose was mixed with twice its weight of 8% hydrochloric acid and heated at 80°. The solution darkened and methyl alcohol distilled over, this being identified by the usual tests. After treatment in this way for 1½ hours, the solution was cooled and repeatedly extracted with chloroform. The extracts were neutralised with sodium carbonate, dried, and filtered. After removal of chloroform, a mobile syrup remained (70%), which was divided into two fractions by distillation: I, b. p. about 54°/0·07 mm., n_D 1·4908 (yield over 30%); II, b. p. up to 82°/0·04 mm., n_D 1·4597. Fraction I had a powerful aldehydic odour, restored the colour to Schiff's reagent, gave a red coloration with aniline acetate, and immediately decolorised neutral permanganate.

The *semicarbazone* was prepared and twice recrystallised from alcohol; it melted at 166—167° and was identical with that obtained by the action of acetic anhydride and sodium acetate on tetramethyl γ-fructose (Found: C, 48·7; H, 5·5; OMe, 15·4; N, 21·7. $C_8H_{11}O_3N_3$ requires C, 48·7; H, 5·6; OMe, 15·7; N, 21·3%). The *oxime* also was prepared; after recrystallisation from light petroleum and ether, it melted at 103—104° and was identical with that obtained and described in the previous section (Found:

C, 54·1; H, 5·9; N, 9·1; OMe, 18·8. $C_7H_9O_3N$ requires C, 54·2; H, 5·8; N, 9·05; OMe, 20·0%).

Fraction II contained some of the aldehyde already examined, and probably some unchanged tetramethyl γ-fructose and intermediate products.

In order to study the effect of more drastic treatment with mineral acid, the following experiment was carried out: The sugar (10 g.) was treated with concentrated hydrochloric acid (4 c.c.), the temperature being very gradually raised until at 80° a liquid began to distil. This was methyl alcohol. After remaining over-night at room temperature, the mixture was heated at 50°/0·1 mm. until the methyl alcohol and water had been removed, leaving a residue (6 g.). The bath temperature was then raised and, the first two drops being rejected, a fraction (4·4 g.) was obtained, b. p. 70—75°/0·4 mm., $n_D^{15°}$ 1·5060. A small, dark residue remained.

Refractionation of 3 g. of the above material gave (1) 0·3 g., b. p. below 50°/0·05 mm., $n_D^{15°}$ 1·5020; (2) 1·7 g., b. p. 53°/0·05 mm., $n_D^{15°}$ 1·5105; (3) 0·9 g., b. p. above 55°/0·05 mm., $n_D^{15°}$ 1·5078. The middle fraction was crude *ω-methoxy-5-methylfurfural* (Found: C, 58·3; H, 6·0; OMe, 24·1. $C_7H_8O_3$ requires C, 60·0; H, 5·7; OMe, 22·1%). The oxime (m. p. 103—104°) and the semicarbazone (m. p. 166—167°) were prepared by the methods given above and were identical with the corresponding derivatives of the aldehyde prepared by the action of acetic anhydride on tetramethyl γ-fructose. Mixed melting-point determinations of the corresponding oximes and semicarbazones gave no depression, the values being 103—104° and 166—167° respectively.

The analytical figures given by the aldehyde indicated that a small quantity of a more highly methylated substance was present, and attempts were made to obtain the pure aldehyde by regenerating it from the crystalline semicarbazone. Hydrolysis by dilute hydrochloric acid or by oxalic acid failed to give satisfactory results. The use of 18% hydrochloric acid appeared to liberate the aldehyde, but it changed at once to a dark, viscid mass which still retained the characteristic odour of the aldehyde.

Oxidation of ω-Methoxy-5-methylfurfural to give ω-Methoxy-5-methylfuran-2-carboxylic Acid.—The oxidation was carried out by Frankland and Aston's method (J., 1901, **79**, 515). Calcium hydroxide (1·5 g.) was made into a paste with water (5 c.c.), and the aldehyde (1 g.) was added; 13·6 c.c. of a solution of potassium permanganate containing 5·5 g. per 100 c.c. were then added, with constant stirring, during 30 minutes, the temperature being maintained throughout at 10° by addition of ice as required. The mixture was heated on the steam-bath and filtered hot, and the

precipitated manganese oxides were repeatedly washed with hot water. The united filtrates were evaporated to dryness under diminished pressure, and the acidified residue extracted with dry ether. The extract yielded a dark syrup, which was dissolved in a little water and carefully neutralised with dilute sodium hydroxide solution. Evaporation under diminished pressure gave the sodium salt, which, after being freed from some syrupy material by washing with ether, was clean and hard. A solution of it in a very slight deficiency of dilute hydrochloric acid was evaporated to dryness under diminished pressure, and the free organic acid extracted by dry ether. Removal of the ether gave a mobile syrup which crystallised when stirred. The solid was drained on porous earthenware and the pure *ω-methoxy-5-methylfuran-2-carboxylic acid* was obtained by recrystallisation from light petroleum; it melted at 72—73° after slight softening at 69° and was optically inactive (Found: C, 54·0; H, 5·1; OMe, 18·9. $C_7H_8O_4$ requires C, 53·9; H, 5·1; OMe, 19·9%. 0·1996 G. required 12·7 c.c. of *N*/10-NaOH for neutralisation. Calc. for $C_7H_8O_4$, 12·8 c.c.).

Preparation of ω-Methoxy-5-methylfuran-2-carboxylic Acid from ω-Bromo-5-methylfurfural.—The ω-bromomethylfurfural was prepared by Fenton and Gostling's method (J., 1899, **75**, 429), the following modification giving an improved yield. Fructose (15 g.) was covered with dry chloroform (250 c.c.) saturated with hydrogen bromide. The mixture was heated at 60—65° for one hour and then kept at room temperature over-night. The product (4·9 g.), after recrystallisation from ether, had m. p. 60—61°. The pure crystalline ω-bromomethylfurfural (7 g.) was simultaneously hydrolysed and oxidised by means of silver oxide (60 g.) suspended in boiling water (Fenton and Gostling, *loc. cit.*). Isolation of the ω-hydroxymethylfurancarboxylic acid yielded a light brown, crystalline solid as crude product (5·6 g.), recrystallisation of which from ethyl acetate gave material having m. p. 159—161°; this m. p. was raised to 165·5—167° (turning brown at 158°) by two further crystallisations from alcohol–toluene. Fischer and Andreae give m. p. 165—167° (turning brown at 157°). (Found: C, 50·5; H, 4·3. Calc.: C, 50·7; H, 4·2%).

Methylation of ω-Hydroxy-5-methylfuran-2-carboxylic Acid.—The acid (1 g.) was heated at 45—50° with methyl iodide (20 g.) and silver oxide (10 g.), addition of methyl alcohol (4 c.c.) being necessary to effect solution of the acid. Isolation of the product was followed immediately by a second methylation under similar conditions, the addition of only 1 c.c. of methyl alcohol now being necessary. For the third methylation no methyl alcohol was required. The product, on distillation, gave *methyl ω-methoxy-*

5-*methylfuran*-2-*carboxylate* (0·8 g.) as a colourless liquid, b. p. about 61°/0·05 mm., $n_D^{19.5°}$ 1·4938 (Found: OMe, 35·3. $C_8H_{10}O_4$ requires OMe, 36·5%).

ω-*Methoxy*-5-*methylfuran*-2-*carboxylic Acid*.—The above ester (0·2 g.) was warmed on the water-bath for 2 hours with a 1% aqueous solution of sodium hydroxide (10 c.c.). Hydrochloric acid was then added until the solution was acid to Congo-paper, and the product was isolated by extraction with ether. Evaporation of the solvent gave a colourless syrup which immediately crystallised. Recrystallisation from light petroleum (b. p. 40—60°) gave pure ω-methoxymethylfurancarboxylic acid, which, alone or mixed with a specimen prepared from tetramethyl γ-fructose, melted at 72—74° after softening slightly at 69°.

Preparation of ω-*Methoxy*-5-*methylfuran*-2-*carboxylic Acid from Glucosamine*.—Glucosamine hydrochloride (10 g.) was treated with nitrous acid to give chitose, and the latter, without being isolated, was oxidised by bromine to chitonic acid. The calcium salt of this, after being recrystallised from water (yield, 3·3 g. Found: Ca, 9·35. Calc.: Ca, 9·3%), was converted (2·8 g.) into ω-acetoxymethylfurancarboxylic acid by the action of sodium acetate and acetic anhydride. The product (1·9 g.), recrystallised from ether, had m. p. 115—118° (Found: C, 52·0; H, 4·7. Calc. for $C_8H_8O_5$: C, 52·2; H, 4·4%).

The acetyl compound was hydrolysed by means of baryta, and the free acid obtained melted, alone or mixed with ω-hydroxymethylfurancarboxylic acid prepared from ω-bromomethylfurfural, at 165—167°, colouring slightly at about 156°. The hydroxy-acid (0·5 g.) was heated with methyl iodide (10 g.), silver oxide (5 g.), and methyl alcohol (2—3 c.c.) at 45—50°; the methyl ester thus obtained was hydrolysed by means of *N*/4-sodium hydroxide (30 c.c.) for 2 hours on the water-bath, and the solution of the sodium salt was acidified. The ω-methoxy-5-methylfuran-2-carboxylic acid, after recrystallisation from ether, melted at 72—73°, alone or mixed with the specimens prepared from tetramethyl γ-fructose and from ω-bromomethylfurfural.

EDGBASTON.

[*Received, April 29th*, 1927.]

CCII.—*The Constitution of the Disaccharides. Part XIV. Melibiose and its Relationship to Raffinose.*

By WILLIAM CHARLTON, WALTER NORMAN HAWORTH, and WILFRED JOHN HICKINBOTTOM.

RAFFINOSE was the subject of a constitutional study in an earlier communication (Haworth, Hirst, and Ruell, J., 1923, **123**, 3125), wherein it was stated that completely methylated raffinose gives rise on hydrolysis to three methylated fragments: (1) normal tetramethyl galactose; (2) 2 : 3 : 4-trimethyl glucose*; (3) tetramethyl γ-fructose, and in the course of recent work these experimental results were confirmed. The constitution advanced for this trisaccharide, translated into terms of the revised formulæ for the constituent hexoses (Charlton, Haworth, and Peat, J., 1926, 89; Haworth and Hirst, *ibid.*, p. 1858), is formulated

(I.)

It was also stated that "from this determination of the structure of raffinose it may be inferred that the constitution of melibiose proposed by Haworth and Leitch (J., 1919, **115**, 809) receives substantial confirmation, but inasmuch as structural changes may occur in the resulting disaccharide when the fructose residue is eliminated from raffinose, it has been thought desirable to undertake a separate investigation of melibiose, which is now in progress."

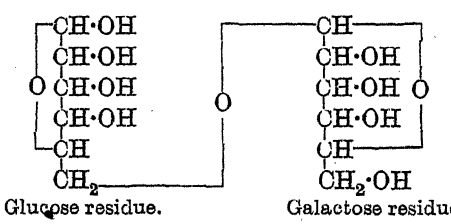
The results of that investigation are now presented, and they support the view that the glucose and galactose residues occurring in raffinose are identical with those in melibiose. During the isolation of hendecamethyl raffinose in the earlier work, a small quantity of a crystalline by-product was encountered, m. p. 78°, which was considered to be a completely methylated disaccharide, probably melibiose. This had been formed by partial hydrolysis of raffinose during the process of methylation. This crystalline substance when purified (m. p. 101—103°) gave on hydrolysis 2 : 3 : 4 : 6-tetramethyl galactose, and a liquid trimethyl glucose which on conversion into the glucoside gave the characteristic crystalline 2 : 3 : 4-tri-

* This formula was indexed as 2 : 3 : 5-trimethylglucose on the basis of the older formula for glucose.

methyl β-methylglucoside, m. p. 94°, identical with that previously isolated from methylated raffinose.

For the purpose of this comparison, we have again submitted hendecamethyl raffinose to hydrolytic cleavage, and have separated the trimethyl glucose fragment from the other methylated hexoses by extraction with chloroform. The tetramethyl derivatives of galactose and γ-fructose are removed by this solvent, as is also a small proportion of the trimethyl glucose, but the greater proportion of the trimethyl glucose remains in the aqueous solvent. Isolation of this residue and conversion into the glucoside gave again the characteristic crystalline 2 : 3 : 4-trimethyl β-methylglucoside, m. p. 93—94°. Finally, we have prepared melibiose from raffinose and have transformed this sugar into heptamethyl methylmelibioside, which is a crystalline compound. It has previously been described by Schlubach and Rauchenberger (*Ber.*, 1925, **58**, 1184) as forming needles, m. p. 98·5° (after twice crystallising from light petroleum). Ordinarily, the substance is found to melt at about this temperature, but two further crystallisations raised the melting point to 101—103°, and this specimen gave no depression of m. p. when mixed with the methylated melibiose isolated as a by-product during the methylation of raffinose (see above). On repeated crystallisation, however, the m. p. was raised to 106—107°, and the specific rotation was correspondingly diminished from $[\alpha]_D + 113°$ to $[\alpha]_D + 97·8°$ (in water).

It thus appeared that the material had been contaminated with what was probably an α-form of heptamethyl methylmelibioside; indeed a portion of the material was isolated (m. p. 122—123°).* As is usual, however, in the methylation of sugars with methyl sulphate and alkali, the major bulk of the product was isolated as the β-form. This was hydrolysed with dilute mineral acid and the mixture of tetramethyl and trimethyl hexoses was separated by taking advantage of the greater ease with which a tetramethyl hexose may be extracted from aqueous solution by chloroform. In this way this tetramethyl hexose was recovered from the solution in chloroform and was shown to contain crystalline 2 : 3 : 4 : 6-tetramethyl galactose, m. p. 71—73°; $[\alpha]_D + 149·4° \longrightarrow 116·9°$ (yield 50%). The portion remaining in the aqueous solution represented about 35% of the weight of the original methylated melibiose. The latter product was liquid, and was transformed into a mixture of the α- and β-methylglucosides by heating with methyl-alcoholic hydrogen chloride. This mixture of the two stereoisomeric



* A mixture of the α- and β-forms (m. p. 82°; $[\alpha]_D + 145°$) also gave on hydrolysis 2 : 3 : 4-trimethyl glucose, isolated as the β-methylglucoside, m. p. 94° (yield, 28%).

forms of the glucoside distilled completely and underwent spontaneous crystallisation immediately. Of the total yield of distillate, 13—15% by weight was collected as the characteristic 2 : 3 : 4-trimethyl β-methylglucoside, which on recrystallisation gave m. p. 92°. The liquid portion of the distillate doubtless contained a further quantity of this crystalline material.

Since the original distillate represented an equilibrium mixture of α- and β-forms, the former of which is liquid, it will be recognised that the whole of the product cannot be isolated as the crystalline β-variety. Proof of the identity of the glucoside was established by mixed melting-point determinations with specimens of the 2 : 3 : 4-trimethyl β-methylglucoside which had previously been isolated (*a*) from heptamethyl methylgentiobioside, (*b*) from methylated amygdalin, (*c*) from methylated raffinose, references to which preparations are given in the experimental section of this paper. Furthermore, a specimen of the crystalline 2 : 3 : 4-trimethyl β-methylglucoside has been specially prepared for the present comparison in the following way.

The 6-triphenylmethyl glucose (Helferich, Moog, and Jünger, *Ber.*, 1925, **58**, 872) was completely methylated with methyl iodide and silver oxide, and thereafter the triphenylmethyl residue was removed by hydrolysis. The specimen of 2 : 3 : 4-trimethyl β-methylglucoside obtained in this way was identical in all respects with the above material obtained from methylated melibiose.

(II.)

Glucose residue. Galactose residue.

The evidence adduced from these experimental results does not appear to be capable of any simple interpretation other than that in melibiose there is present a glucose residue which is attached through its (6) position to the reducing group of the galactose residue, and therefore the formula (II) previously advanced by Haworth and Leitch (J., 1918, **113**, 188) as modified by the introduction of the new oxide-ring formulæ for the hexoses (Charlton, Ha[illegible]orth, and Peat, J., 1926, 89) is fully supported.

In the interim Zemplén (*Ber.*, 1927, **60**, 923) has advanced new structural formulæ for melibiose and raffinose, differing from those which have been assigned by us to these sugars. The experimental evidence on which Zemplén bases his conclusions is the failure, which

he records, to isolate a phenylosazone from the galactoarabinose obtained by degradation of melibiose. Haworth and Long (this vol., p. 544) have already pointed out that an element of danger attaches to this method of proof, and indeed, the trimethyl hexose which would be expected on the basis of Zemplén's formula for melibiose would be 2 : 4 : 6-trimethyl glucose. Fortunately, we had a specimen of this sugar, and its glucoside, in our possession for the purpose of comparison, and it may be definitely stated that this sugar could not be isolated from the products of hydrolysis of methylated melibiose.

Discussion of Results.

The fact that melibiose is slowly attacked by the enzymes present in emulsin (Fischer and Armstrong, *Ber.*, 1902, **35**, 3144) has been widely interpreted in the literature as evidence for the classification of this sugar as a glucose β-galactoside. The specific enzyme for the hydrolysis of melibiose is, however, that occurring in bottom yeast, which is designated melibiase.

The observation of Helferich and Rauch (*Ber.*, 1926, **59**, 2655) casts doubt on the presence of a β-biose linking in this sugar, and these authors suggest that the configuration assigned may be incorrect. The following comparisons of the specific rotations may be considered in the discussion of this point.

	$[\alpha]_D$.		$[\alpha]_D$.
Maltose (β-glucose-α-glucoside)	+118°	Cellobiose (β-glucose-β-glucoside)	+16°
		Gentiobiose (β-glucose-β-glucoside)	−11
Melibiose	+124	Lactose (β-glucose-β-galactoside)	+35

Those disaccharides which possess indisputably a β-biose linking have low rotations as compared with maltose, which has an α-biose linking, and melibiose displays a rotation corresponding to that of maltose. Moreover, α-methylgalactoside has $[\alpha]_D$ + 178·8°, whilst the specific rotation of β-methylgalactoside is ± 0°. If melibiose were a glucose β-galactoside, its rotation, on the analogy of the relationship of lactose to gentiobiose, should be nearly zero, whereas if it were a glucose α-galactoside the rotation should be comparable with that of maltose, which is the case.

It has previously been remarked (Haworth and Leitch, J., 1919, **115**, 813) that there is some resemblance to maltose in the behaviour of melibiose, and this resemblance may be due to a stereochemical rather than a structural relationship.

On Hudson's method of representation (*J. Amer. Chem. Soc.*,

1916, **38**, 1566) the rotations of the disaccharides could each be divided into three parts as follows :

	[α]D, β-form.	[α]D, β-form octa-acetate.
1. Lactose β-galactose<glucose< Ga − L_1 + R_1 ...	+ 35°	− 4°
2. Cellobiose β-glucose<glucose< G − L_1 + R_1.....	+ 16	−15
3. Maltose α-glucose<glucose< G + L_1 + R_1	+118	+63

From (2) and (3) by subtraction L = 51 for the β-forms of the sugar, and this value is in excellent agreement with the value L = 50 for the lactonyl grouping in the simple glucosides and galactosides (recalculated for mol. wt. 342 for disaccharides). Furthermore, Hudson has pointed out that the value + 19° for (β-lactose–β-cellobiose) agrees excellently with his calculated value + 18°.

As further confirmation of these relationships, we may consider lactose and maltose.

By subtraction
$$118 - 35 = G - Ga + 2L$$
$$83 = G - Ga + 102$$
$$\text{or } Ga - G = 19$$
(Hudson's calc. value = 18.)

In view of the above, it would appear possible to take the value L = 51 and use it in the case of melibiose, at least as a very fair approximation.

If the rotation of melibiose be compared with that of gentiobiose, we have the following possible cases :

	[α]D, β-form.
1. Melibiose an α-biose α-galactose<glucose< Ga + L + R_2 ...	+124°
2. Gentiobiose β-glucose<glucose< G − L + R_2	− 11
3. Melibiose a β-biose β-galactose<glucose< Ga − L + R_2.....	+124

(*a*) Melibiose as an α-biose.

From (1) and (2) the difference in rotation between the β-forms of melibiose and gentiobiose = 135 or Ga − G + 2L. From Hudson's observed values for the experiment, Ga − G = 19, and L calculated as above and confirmed = 51.

Hence calculated diff. = 121,
observed ,, = 135.

(*b*) If melibiose is a β-biose, from (2) and (3) the difference in rotation = Ga − G.

Hence calculated diff. = 19,
observed ,, = 135.

Therefore presumably melibiose must be an α-biose.

Similar calculations based on the observed figures for the octa-acetates of the disaccharides, gentiobiose, melibiose, and the synthetic 6-glucosido-β-galactose of Helferich and Rauch (*loc. cit.*),

also favour the presence of an α- rather than a β-biose linking in melibiose, and the agreement between the observed and the calculated value for the expression Ga′ — G′ (107 and 113) is also fairly close, whereas the calculated figure for melibiose as a β-biose is 11.

Occasion may here be taken to correct a misprint in the paper by Haworth, Hirst, and Ruell (*loc. cit.*), where the m. p. of 2 : 3 : 4-trimethyl β-methylglucoside is given as 74° instead of 94°. That this is a typographical error is seen from the context, since this product was described as being identified by a mixed m. p. determination with the same product from amygdalin biose (gentiobiose), described in the paper immediately preceding it in the Journal (Haworth and Wylam, *loc. cit.*), where the m. p. is given as 94·5°. Again, the m. p. 94°, and not 74°, is given in the abstract of Haworth, Hirst, and Ruell's paper published about the same date (*J. Soc. Chem. Ind.*, 1923, **42**, 1139); and is also given as 94° in the preliminary notice of papers to be read at the meeting on November 15th, 1923. These facts appear to have escaped the knowledge of Irvine and Macdonald (J., 1926, 1507), who on the basis of this misprint criticise the formula we have applied to raffinose.

Experimental.

Melibiose was obtained from raffinose by fermentation of the latter with top yeast containing a small quantity of malt sprouts as recommended by Hudson (*J. Amer. Chem. Soc.*, 1915, **37**, 2734), and the resulting disaccharide was identified as melibiose by the melting point and specific rotation of the octa-acetate.

Methylation.—To melibiose (22 g.), dissolved in 100 c.c. of water, 56 c.c. of sodium hydroxide solution (30%) and 38 c.c. of methyl sulphate were added at 30° over a period of 3 hours. By cautious and simultaneous addition of these reagents the solution was not permitted to become alkaline until the sugar had been deprived of its reducing activity. Thereafter 28 c.c. of the alkali were added, the temperature was raised to 70°, and the remaining portions of the reagents (making in all 196 c.c. of 30% sodium hydroxide and 107 c.c. of methyl sulphate) were admitted slowly. For example, lots of 14 c.c. of alkali and 7·6 c.c. of methyl sulphate were simultaneously admitted during a period of 25 minutes, with vigorous stirring. Finally, the solution was heated at 100° for an hour, then cooled, stirring being continuous during the separation of sodium sulphate. Over-night, more sodium sulphate separated. This was filtered off and washed with chloroform, and the filtrate was extracted four times with more chloroform. The latter extracts yielded 15 g. of syrupy product. The aqueous residues were neutralised, evaporated,

and extracted with alcohol, and the portion of partly methylated melibiose which was more soluble in water was thus recovered (10 g.).

The combined products were again submitted to the action of methyl sulphate and alkali, and to ensure complete methylation the products from this treatment were twice methylated with Purdie's reagents.

The material isolated by following this procedure was a viscid syrup which crystallised almost completely on nucleation with a specimen of heptamethyl methylmelibioside which had been isolated during the earlier experiments on the methylation of raffinose. The crude solid (yield, over 20 g.) was recrystallised from light petroleum several times (Found: OMe, 54·3. Calc., 54·7%). The initial m. p. of the crude methylated melibiose, 85—90°, was raised considerably by repeated crystallisation from light petroleum, and after four or six such recrystallisations the crystals had m. p. 101—103° and showed $[\alpha]_D$ + 113·8° in water ($c = 1·22$). Ordinarily, this might have been regarded as a pure specimen of heptamethyl β-methylmelibioside, and Schlubach and Rauchenberger (*Ber.*, 1925, **58**, 1184) describe the substance as melting at 98·5°. This material gives correct analyses, but it seemed to us doubtful whether it was stereochemically pure. By recrystallising this five times, the crystals showed a higher melting point, 106—107°, and a diminished rotation, $[\alpha]_D$ + 97·8° in water ($c = 1$), + 85·0° in ethyl alcohol ($c = 1·1$) (Found: C, 52·8; H, 8·5; OMe, 53·5. Calc.: C, 52·9; H, 8·4; OMe, 54·7%). It was thus evident that the purification had resulted in the removal of the α-stereoisomeride, and elsewhere we describe what appears to be the α-variety, m. p. 122—123°.

Hydrolysis.—A solution of 2 g. of heptamethyl methylmelibioside in 150 c.c. of 5% hydrochloric acid was heated at 95—100°. The rotations in a 1 dm. tube showed $[\alpha]_D$ 1·34° (initial); 1·22° (1 hr.); 1·21° (2½ hrs.); 1·18° (4 hours); 1·18° (5½ hours). The solution was neutralised with silver carbonate, filtered, and treated with charcoal to remove traces of silver, and the concentrated filtrate was extracted five times with chloroform. This extract on evaporation gave 1 g. of a syrup which crystallised spontaneously after 2 weeks; m. p. 71—73° (after crystallisation from light petroleum). It was recognised as 2 : 3 : 4 : 6-tetramethyl galactose by direct comparison and mixed melting-point determination with the specimen prepared from lactose by Haworth and Long (this vol., p. 544), $[\alpha]_D$ + 149·4° ⟶ 116·9°.

The anilide also was prepared; m. p. 192—193°, unchanged in admixture with an authentic specimen of tetramethyl galactose

anilide. The portion of the hydrolysed product which was not extracted by the chloroform was recovered on evaporation of the aqueous solution under diminished pressure. This was a liquid (0·65 g.) representing the trimethyl hexose fragment of the hydrolysed product. A small quantity of this material was also present in the chloroform extract already mentioned, containing principally the tetramethyl galactose fragment, so that approximately equal weights of the latter and of the trimethyl hexose comprised the total products of hydrolysis (weighing 1·65 g.).

The syrupy trimethyl hexose was dissolved in dry methyl alcohol containing 0·5% of hydrogen chloride and heated at 100—110° for 10 hours. Neutralisation of the solution with freshly precipitated silver carbonate and removal of the solvent led to the isolation of a glucosidic substance, having no action on Fehling's solution and distilling under 0·01 mm. almost completely from a bath heated to 110—130°. The colourless distillate crystallised spontaneously in the receiver, but the crystals were contaminated with liquid, which was drained on porous tile. Evidently both a liquid α-form and a crystalline β-form of the glucoside were present. The crystalline product was purified by means of light petroleum and obtained as a mat of interlaced needles, m. p. 92°, and this m. p. was not depressed by admixture with 2 : 3 : 4-trimethyl β-methylglucoside which had previously been isolated from (*a*) methylated gentiobiose (Haworth and Wylam, J., 1923, **123**, 3120), (*b*) methylated amygdalin (Haworth and Leitch, J., 1922, **121**, 1921), (*c*) methylated raffinose (Haworth, Hirst, and Ruell, *loc. cit.*), (*d*) a specimen obtained from 6-triphenylmethyl glucose (compare Helferich, Moog, and Jünger, *loc. cit.*) which had been methylated with methyl iodide and silver oxide and hydrolysed to remove the triphenylmethyl residue.

Hydrolysis of Hendecamethyl Raffinose.—A specimen of this derivative of raffinose remained over from the previous research and it was considered desirable to obtain confirmation of the identity of the trimethyl glucose fragment occurring in the mixture of hydrolytic products obtained by digesting hendecamethyl raffinose with dilute mineral acid. Accordingly, 3·7 g. were hydrolysed at 85° with 150 c.c. of 5% hydrochloric acid. The subsequent treatment of the products followed the usual procedure, but instead of separating the mixture of partly methylated hexoses by distillation, the neutralised aqueous solution of these was extracted several times with chloroform. This treatment completely removed the fructose and galactose fragments, and the aqueous solution was now evaporated under diminished pressure, giving rise to the trimethyl hexose, which appeared as a syrup. Digestion of this syrup with methyl-alcoholic hydrogen chloride (containing 0·53% HCl) during

10 hours at 110° gave, on neutralisation followed by evaporation of the solvent, a glucoside which distilled completely, and the distillate afterwards crystallised, giving long, colourless needles, m. p. 92·5°. This was identified as 2 : 3 : 4-trimethyl β-methylglucoside by admixture with the authentic specimens previously referred to (Found : C, 50·7; H, 8·5. Calc. : C, 50·8; H, 8·5%).

Isolation of Heptamethyl Methylmelibioside from the Products of the Methylation of Raffinose [with D. A. RUELL].—On fractional distillation of crude hendecamethyl raffinose prepared by repeated methylation of raffinose (Haworth, Hirst, and Ruell, J., 1923, **123**, 3125), a syrupy product (b. p. 185—190°/0·03 mm.; n_D 1·4660) was obtained. This solidified after some days and purification by means of light petroleum yielded crystals, m. p. 78°, which after further recrystallisation melted at 101—103° and had $[\alpha]_D$ + 113·8° in water (c = 1·22). Analytical data indicated that this crystalline substance was a completely methylated disaccharide (Found : C, 53·3; H, 8·4; OMe, 51·8. Calc. : C, 52·9; H, 8·4; OMe, 54·6%). On admixture of this compound with an authentic specimen of heptamethyl methylmelibioside, m. p. 101°, the melting point showed no depression.

Hydrolysis and Identification of Cleavage Products.—Heptamethyl methylmelibioside was hydrolysed under conditions identical with those applied in the case of methylated raffinose (Haworth, Hirst, and Ruell, *loc. cit.*) and the process was complete after 24 hours :

Time in hours	0	6	13	18	24	30
$[\alpha]_D$	+106°	93·9°	88·3°	82·3°	73·6°	74·0°

A syrupy, amber-coloured product was obtained which was soluble in dry ether. The syrup was digested in ethyl-alcoholic solution with excess of aniline for 3 hours, and on removal of the solvent and of free aniline, a semi-solid mass remained. Drainage on porous tile gave crystals which, purified by means of ethyl alcohol, appeared as silky needles, m. p. 192—193°, identical in all respects with a specimen of tetramethyl galactose anilide previously prepared from methylated raffinose or lactose, in admixture with which the m. p. was not depressed.

The syrup separating after removal of the crystals of tetramethyl galactose anilide was dissolved in alcohol, and the solution clarified with charcoal; on concentration a further small quantity of crystals separated, which were identical with the anilide mentioned above. Complete evaporation of the solution gave a viscid syrup, which was dissolved in a little aqueous alcohol and rendered faintly acid to Congo-paper with hydrochloric acid. The solution was steam-distilled in order to remove traces of aniline, and the aqueous residue

was again clarified and evaporated to dryness in a vacuum. The product obtained from this treatment was dissolved in methyl alcohol containing 0·5% of hydrogen chloride, and heated in sealed tubes at 110° for 10 hours. Thereafter the solution was neutralised with silver carbonate, and the filtrate evaporated. Extraction of this residue with dry ether yielded a viscid liquid, which distilled at 0·01 mm. from an oil-bath heated at about 140°. The distillate was a colourless liquid which partly crystallised on nucleation with 2 : 3 : 4-trimethyl β-methylglucoside. The crystals were collected and washed in light petroleum; they then melted at 90—91°. Recrystallisation from light petroleum gave m. p. 93—94°. On admixture with a specimen of 2 : 3 : 4-trimethyl β-methylglucoside obtained from a previous research on the constitution of gentiobiose, no depression of melting point was observed.

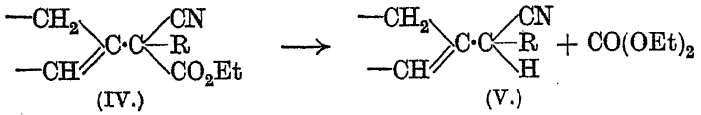
CCIII.—*The Chemistry of the Three-carbon System. Part XII. The Effect of Positive Substituents in the α-Position on the Tautomerism.*

By GEORGE ARMAND ROBERT KON and BINDIGAWAVALE TIRUMALACHAR NARAYANAN.

IN studying the influence of substituents on three-carbon tautomerism, we examined first the effect produced by a group in the α-position, that is, attached to the carbon atom bearing the negative activating group. The effect of introducing a negative or activating group in this position has been discussed (Kon and Speight, J., 1926, 2727); the effect of a positive group on the mobility and point of equilibrium of three-carbon systems is described below.

Theoretically, the effect of a positive substituent in the α-position should be a general diminution of the mobility of the system—a phenomenon frequently observed in keto-enol systems, glutaconic esters, etc. The effect on the position of equilibrium is less easy to forecast, because it is probably made up of more than one factor, both polar and steric in nature. It must be assumed that the polar effect diminishes that due to the activating group; and as this favours the αβ-phase, it is to be expected that the βγ-phase will be favoured by the presence of an α-alkyl group. A phenyl group should behave in the same way from the electronic point of view, but the strong tendency to conjugation exhibited by this group (Linstead and Williams, J., 1926, 2735; Johnson and Kon, *ibid.*,

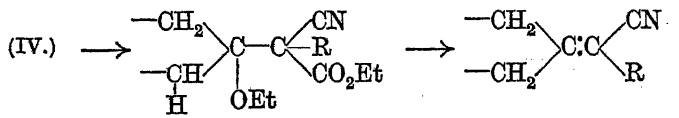
p. 2748) would probably neutralise this tendency, and it would be expected that the αβ-phase in α-phenylated systems would possess considerable stability. We were not able to study this case owing to difficulty in preparing suitable material for investigation; we have, however, examined a number of systems bearing an ethyl group on the α-carbon atom and belonging to several representative types, namely, acids, ketones, and nitriles of the general types (I), (II), and (III).



(I.) (II.) (III.)

X = CO_2H, COMe, or CN.

The properties of the first two groups of compounds are in full agreement with theoretical considerations. The mobility of the systems appears to be less than that of the parent substances; indeed, Birch, Kon, and Norris (J., 1923, **123**, 1361) had failed to condense α-ethyl-Δ^1-*cyclo*hexenylacetone with ethyl sodiomalonate and concluded that this ketone did not react in the αβ-phase. That statement requires revision, for the condensation does proceed, although it requires a considerable time for completion. The mobility of the system in ketones of this series is, however, still considerable, because only one substance, having in every case the βγ-structure, is obtained under the conditions of the Blaise–Maire synthesis from either the αβ- or the βγ-acid; the conversion of αβ-acids into their βγ-isomerides on treatment with alkali is actually unexpectedly rapid. These facts indicate that the βγ-forms of the compounds in question are even more favoured than those of the parent (unsubstituted) compounds and that the mobility of the system is not very greatly affected.



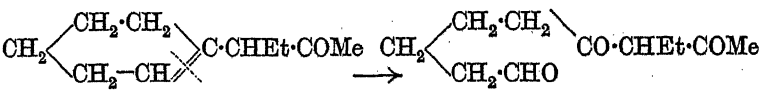
It is, therefore, all the more surprising to find that the α-substituted nitriles, of which several have been prepared by Birch and Kon (J., 1923, **123**, 2440), constitute a sharp contrast to the acids and ketones just mentioned. They are invariably obtained in the αβ-form, and no direct evidence had until lately been obtained of the existence of a βγ-phase, although it is abundantly proved that unsubstituted nitriles, such as *cyclo*hexenylacetonitrile, exist in the βγ-form, but can also react in the αβ-form (compare Birch and Kon, *loc. cit.*). Whilst this difference appears at first to be in contradiction with theoretical considerations, it is capable of a ready explanation. The reaction by which α-substituted nitriles are produced involves the elimination of ethyl carbonate from the corresponding cyano-esters under the influence of alcoholic sodium ethoxide and it has been shown by Ingold and Thorpe (J., 1919,

115, 143) to proceed in many cases in the presence of very small amounts of the reagent. The cyano-esters from which they are produced have necessarily a $\beta\gamma$-unsaturated structure (IV) and it has been assumed hitherto that the $\beta\gamma$-form (V) of the nitrile would be produced at first :

(IV.) (V.)

This view of the mechanism is, however, incorrect; the only way in which the system can reacquire its mobile hydrogen atom, and one which at the same time explains the ready occurrence of such reactions, consists in the addition of the elements of alcohol to the double bond, the hydrogen becoming attached to the γ-carbon atom; the system then loses ethyl carbonate with the formation of an $\alpha\beta$-double bond :

This possibility was overlooked in the original paper (Birch and Kon, *loc. cit.*), but it would appear that the scheme now suggested is of general application and that $\alpha\beta$-unsaturated compounds are always produced by the elimination of ethyl carbonate from fully substituted but potentially tautomeric systems (compare Thole and Thorpe, J., 1911, **99**, 2191; Thorpe, J., 1912, **101**, 871; Feist, *Annalen*, 1922, **428**, 25).



The $\alpha\beta$-compounds so produced can, of course, pass into the $\beta\gamma$-forms if they are sufficiently mobile under the conditions of the experiment; this is, apparently, not the case for the nitriles under discussion. The probable reason for this lack of mobility was suggested by Prof. R. Robinson (private communication), who pointed out that the retarding effect of the α-alkyl group on the mobility of the system was likely to be greater the weaker the activating group on which mobility ultimately depends; it would be greatest in a system activated by a weak group such as CN (compare Bradley and Robinson, J., 1926, 2356). For this reason, α-substituted nitriles are probably static or nearly so and are therefore isolated in the $\alpha\beta$-form, although this may not be the most stable. Experiments have been undertaken to confirm this view : the $\beta\gamma$-isomeride of *cyclo*hexylidenebutyronitrile has already been prepared and found to differ from the $\alpha\beta$-compound; its properties are now under investigation.

The α-substituted nitriles can be hydrolysed by means of alcoholic sulphuric acid to the corresponding αβ-unsaturated esters (or ester containing a high proportion of the αβ-compound), but these cannot be further hydrolysed to the acids without undergoing conversion into the βγ-form.

Some experiments were carried out to ascertain the positions of equilibrium between the αβ- and βγ-acids in the presence of alkali of various concentrations, but an exact estimate was impossible owing to the insufficient analytical methods available at the time. Conversion of the acids into their amides shows, however, that the equilibrium is so much on the side of the βγ-compound that the presence of the αβ-isomeride cannot be recognised with certainty. The acids are mostly liquids and extremely difficult to purify, and therefore do not lend themselves well to investigation by the analytical methods recently developed by Linstead (this vol., p. 355).

The semicarbazones of the α-substituted ketones are isolated in only one form in the ordinary way; a small amount of a second form can, however, be obtained in all cases by previously treating the ketone with cold sodium ethoxide for 40 hours.

The oxidation of ketones of this group is always difficult. Ozonisation, however, gives definite evidence of the βγ-form of these substances; in every case an oil, giving a deep colour with ferric chloride, is formed, evidently according to the scheme

We have, moreover, succeeded in oxidising one of the ketones to the corresponding acid by means of hypobromite, the βγ-acid being the sole product obtained.

EXPERIMENTAL.

1-*Hydroxy*-α-*ethyl*cyclo*hexaneacetic Acid*.—The ester was obtained by the Reformatski reaction as described by Wallach (*Annalen*, 1908, **360**, 44); the yield (55%) was slightly improved by adding the magnesium in several portions. The hydrolysis of the ester was difficult and considerable fission into ketone and butyric acid always occurred. The best method was as follows: 100 G. of the ester were added to a hot solution of 100 g. of potassium hydroxide in 100 c.c. of water; 100 c.c. of methyl alcohol were then added gradually and the mixture was refluxed for 2—3 hours. The solution was freed from alcohol under reduced pressure, diluted, extracted with ether, and acidified with ice-cold 30% sulphuric acid. The *acid* thus

liberated was extracted with ether, dried, and distilled under reduced pressure, some 24 g. boiling at 167—170°/16 mm. This fraction was a viscous oil with a strong odour of butyric acid; $d_4^{18\cdot8°}$ 1·0010, $n_D^{18\cdot8°}$ 1·46798 (Found: C, 64·7; H, 10·05. $C_{10}H_{18}O_3$ requires C, 64·5; H, 9·7%. Found for the *silver* salt: Ag, 36·9. $C_{10}H_{17}O_3Ag$ requires Ag, 36·9%).

α-Ethyl-Δ^1*-cyclohexenylacetic Acid.*—The hydroxy-ester on dehydration with phosphorus oxychloride or potassium hydrogen sulphate yielded ethyl α-ethyl*cyclo*hexenylacetate (Wallach, *loc. cit.*), b. p. 112—116°/15—18 mm., $d_4^{18\cdot2°}$ 0·862624, n_D 1·45593; $[R_L]_D$ 57·09 (Calc., 56·72) (Found: C, 63·8; H, 9·9. Calc.: C, 63·5; H, 10·2%). The acid obtained from it on alkaline hydrolysis had b. p. 154—156°/20 mm., $d_4^{20\cdot6°}$ 1·01528, $n_D^{20\cdot6°}$ 1·47014 (Found: Ag in silver salt, 39·2. Calc.: Ag, 39·3%). Wallach's hydrobromide, m. p. 106—107°, was readily obtained. The *amide*, prepared by leading dry ammonia into a benzene solution of the acid chloride, was recrystallised from dilute methyl alcohol and had m. p. 115—116° (Found: C, 71·3; H, 10·4. $C_{10}H_{17}ON$ requires C, 71·8; H, 10·2%). The p-*toluidide* was similarly obtained and had m. p. 115° after crystallisation from alcohol (Found: N, 5·6. $C_{17}H_{23}ON$ requires N, 5·4%).

A small quantity of the acid was ozonised in dry chloroform solution, and the ozonide shaken with cold water for 20 minutes. The aqueous solution gave a deep violet colour with ferric chloride; 20% sulphuric acid was then added and the product steam-distilled. Adipic acid was identified in the residue in the flask.

*α-Ethyl*cyclo*hexylideneacetic Acid.*—This acid was prepared by treating the hydroxy-acid with acetic anhydride in the usual manner and isolated from the steam distillate by means of ether. On distillation, some hydrocarbon, a fraction, b. p. up to 160°/20 mm., and one, b. p. 164—166°/20 mm., were obtained, the last being the almost pure αβ-acid. This had $d_4^{19\cdot0°}$ 1·01831 and n_D 1·47977 (Found in the silver salt: Ag, 39·3. Calc.: Ag, 39·3%). The yield was poor (20%).

An attempt was also made to prepare the acid from the ester obtained by hydrolysis of α-*cyclo*hexylidenebutyronitrile, b. p. 129°/20 mm.* (Farrow and Kon, J., 1926, 2128), as described by Harding, Haworth, and Perkin (J., 1908, **93**, 1949); the crude ester had b. p. 120—124°/20—23 mm., $d_4^{18\cdot8°}$ 0·936298, $n_D^{18\cdot8°}$ 1·46827, $[R_L]_D$ 58·22 (Calc., 56·72). The ester on careful alkaline hydrolysis gave a mixture of acids in which the βγ-acid predominated.

The *chloride*, prepared by the action of thionyl chloride, boiled

* The b. p. of this substance was omitted in the original description (*loc. cit.*).

at 110—112°/20 mm. and gave an *amide*, m. p. 104—105° after crystallisation from dilute alcohol, in which it is more soluble than the βγ-amide; a mixture of the two amides melted at 94—98° (Found: C, 71·3; H, 10·6%). The p-*toluidide* melted at 104°.

The acid did not give well-defined oxidation products with permanganate; on treatment with ozone in chloroform solution, traces of *cyclo*hexanone and some adipic acid were obtained. The product obtained by treating the ozonide with cold water did not give a colour with ferric chloride.

Equilibration Experiments.—3·36 G. of α-ethyl*cyclo*hexylideneacetic acid (the αβ-acid) were boiled with a large excess of 20% sodium hydroxide solution for ½ hour. The product was isolated in the usual way and separated into a neutral and an acid portion by means of sodium hydrogen carbonate. The neutral compound (0·5—0·7 g.) was evidently a lactone; it was converted into the silver salt of the corresponding hydroxy-acid (Found: Ag, 37·0. Calc. for $C_{10}H_{17}O_3Ag$: Ag, 36·9%). The acid recovered from the bicarbonate solution was converted into the amide, which melted at 106—108° (mixed m. p. with the βγ-amide, 106—110°) in the crude state and at 114° after two crystallisations.

The experiment was repeated with 50% alkali. A larger quantity (1—1·2 g.) of the lactone was obtained, the amide of the acid melted at a lower temperature, and by repeated crystallisation some 10% of the αβ-amide could be isolated from it, in addition to the βγ-amide, m. p. 114°.

α-Ethyl-Δ^1-*cyclo*hexenylacetic acid (the βγ-acid) also was treated with 20% potassium hydroxide solution. About 0·5 g. of the lactone was isolated; the amide obtained melted at 113—114° after two crystallisations; the αβ-amide was present only in traces.

α-*Ethyl*cyclo*hexenylacetone.*—This ketone was obtained in 50—55% yield by the action of zinc methyl iodide on the chloride of *either* the αβ- or the βγ-acid; the latter reaction has already been carried out by Birch, Kon, and Norris (*loc. cit.*). It is most conveniently prepared by the ethylation of *cyclo*hexenylacetone in the presence of sodium (Kon, J., 1926, 1792) or sodium ethoxide. The semicarbazone has m. p. 177—182° (crude) and 185° after crystallisation (Found: C, 64·1; H, 9·3; N, 19·0. Calc.: C, 64·6; H, 9·4; N, 18·8%). The ketone regenerated from it had $d_4^{18·6°}$ 0·92011 and n_D 1·46798 and gave the same semicarbazone on treatment with semicarbazide.

The ketone (3·32 g.) was kept for 40 hours in a solution of 0·46 g. of sodium in 10 c.c. of alcohol. The ketone was recovered (2·6 g.) and converted into the semicarbazone (1·2 g.), which melted at 167—180°. On recrystallisation from alcohol, this gave 0·9 g.

m. p. 185°; the mother-liquor on dilution gave a crop, m. p. 172—176°. After two more crystallisations, 0·1 g. was obtained, m. p. 175—176° (mixed m. p. with compound of m. p. 185°, 167—172°).

A solution of the ketone (2·24g.) in acetic acid at −4° was saturated with hydrogen bromide and poured into water after 15 minutes. The brown oil obtained was isolated by means of ether, the ether removed, and the bromo-ketone warmed on the steam-bath with aqueous sodium carbonate for 15 minutes. The regenerated ketone was converted into the semicarbazone, which melted at 185° after one crystallisation; no other semicarbazone appeared to be formed.

Attempts were made to alkylate the ketone in the presence of "molecular" sodium or sodium ethoxide, but no trace of alkylation product was obtained.

The ketone (5·4 g.) was heated over-night with ethyl malonate (5·2 g.) and sodium (0·82 g.) in 20 c.c. of alcohol. The product was cooled and poured into water, neutral impurities were removed with ether, and the aqueous layer was strongly acidified and again thoroughly extracted with ether. On removing the ether, a solid (6·5 g.) was obtained which gave a blood-red colour with ferric chloride, and melted at 76—77° after crystallisation from benzene and petroleum; it was hydrolysed by boiling it for 3 hours with 20% potassium hydroxide solution. The product was acidified, warmed for another hour, and shaken with ether. The dried extract gave on evaporation a solid, which was recrystallised from acidified water and again from dilute alcohol; lustrous needles, m. p. 159—160°, of cyclo*hexane*spiro-2-*ethyl*cyclo*hexane*-3 : 5-*dione* were thus obtained (Found: C, 74·8; H, 9·9. $C_{13}H_{20}O_2$ requires C, 75·0; H, 9·6%).

Oxidation of α-*Ethyl*cyclo*hexenylacetone*.—The ketone (2·5 g.) was suspended in a solution of 1·2 g. of potassium hydroxide in 10 c.c. of water and kept at 0° while 0·8 c.c. of bromine was gradually added with shaking; the mixture was kept at 0° over-night. A part of the ketone remained unchanged; from the alkaline liquid an acid was obtained (1 g.) which was converted into the amide (m. p. 108—112°; 113—114° after crystallisation); this was identified as the βγ-amide (α-ethyl-Δ^1-*cyclo*hexenylacetamide) by direct comparison.

No definite products were obtained on oxidation of the ketone with potassium permanganate; with ozone, an ozonide was formed which decomposed when shaken with cold water. The product, which gave a deep violet colour with ferric chloride, was mixed with 20% sulphuric acid and distilled in steam, but no definite products except adipic acid could be identified.

Ethyl 1-*Hydroxy*-α-*ethyl*cyclo*pentaneacetate*.—This ester was prepared from *cyclo*pentanone as was its higher homologue from *cyclo*-

hexanone, some 40 g., b. p. 127—137°/20—25 mm., being obtained from 1 g.-mol., in addition to 20 g. each of high and low fractions (Found: C, 66·5; H, 9·8. $C_{11}H_{20}O_3$ requires C, 66·0; H, 10·0%). The *acid* was obtained in 42% yield, b. p. 157—160°/23 mm., $d_4^{20·5°}$ 1·01232, $n_D^{20·5°}$ 1·43869, $[R_L]_D$ 44·55 (Calc., 44·65) (Found: C, 62·6; H, 9·5. $C_9H_{16}O_3$ requires C, 62·8; H, 9·3%. Found in silver salt: Ag, 38·8. $C_9H_{15}O_3Ag$ requires Ag, 38·7%).

α-Ethyl-Δ^1*-cyclopentenylacetic Acid.*—This βγ-acid could not be prepared by the usual method involving the dehydration of ethyl 1-hydroxy-α-ethyl*cyclo*pentaneacetate and hydrolysis, because the hydroxy-ester remained practically unchanged after treatment with potassium hydrogen sulphate and with anhydrous oxalic acid, whilst phosphorus oxychloride gave a very small yield of an impure ester accompanied by tarry by-products. Thionyl chloride also was unsatisfactory. The hydroxy-acid (44 g.) was boiled with 250 c.c. of 20% sulphuric acid for 2 hours, the product distilled in steam, and the distillate extracted with ether and divided into neutral (8 g.) and acid (15 g.) constituents. The latter consisted of an oil, b. p. 138—142°/15 mm., in addition to about 1 g. of a solid acid, m. p. 80—81° (the αβ-acid). The oily βγ-acid has a strong odour of butyric acid, $d_4^{17·4°}$ 1·01909, $n_D^{17·4°}$ 1·47525, $[R_L]_D$ 42·65 (Calc., 42·75) (Found: C, 70·5; H, 8·7. $C_9H_{14}O_2$ requires C, 70·1; H, 9·1%. Found in the silver salt: Ag, 41·4. $C_9H_{13}O_2Ag$ requires Ag, 41·3%). The *chloride*, prepared by means of thionyl chloride, has b. p. 96—98°/20 mm.; the *amide* obtained from it was appreciably soluble in water and formed lustrous needles, m. p. 102—103°, from dilute alcohol (Found: C, 70·2; H, 10·1. $C_9H_{15}ON$ requires C, 70·6; H, 9·8%).

The acid readily adds on bromine in ether or acetic acid, but the *bromide* is unstable; the *hydrobromide* also was prepared in acetic acid solution, but could not be obtained solid.

*α-Ethyl*cyclo*pentylideneacetic Acid.*—This αβ-acid was prepared from the hydroxy-acid (70 g.) by the method described on p. 1540. The first runnings were liquid; thereafter 14 g. of a solid, m. p. 80—81° after crystallisation from ether–petroleum, were obtained (Found: C, 70·4; H, 9·2. $C_9H_{14}O_2$ requires C, 70·1; H, 9·1%). The liquid by-product gave three fractions on distillation; 4 g. boiled below 100°/16 mm., 6 g. up to 158°, and 8 g. at 158—162°. The *chloride* had b. p. 102—106°/16—18 mm.; the *amide* formed pearly plates, m. p. 97° (mixed m. p. with the βγ-amide, 78—82°), from aqueous alcohol, and was less soluble than the βγ-isomeride (Found: C, 70·7; H, 10·1. $C_9H_{15}ON$ requires C, 70·6; H, 9·8%). The *bromide* was unstable; the *hydrobromide* could not be obtained solid.

The *nitrile* was obtained in the same way as the higher homologue (Farrow and Kon, *loc. cit.*), the yield being 65%. It had b. p. 116—118°/20 mm., $d_4^{21\cdot7°}$ 0·923586, $n_D^{21\cdot7°}$ 1·47555, $[R_L]_D$ 41·22 (Calc., 40·90). The nitrile was hydrolysed to the *ethyl* ester, which had b. p. 116—118°/25 mm., $d_4^{19\cdot5°}$ 0·936298, $n_D^{19\cdot5°}$ 1·47417, $[R_L]_D$ 54·65 (Calc., 52·10). Both ester and nitrile gave *cyclo*pentanone on oxidation with ozone. Hydrolysis of the ester led to a mixture of acids in which the βγ-acid predominated.

α-*Ethyl*-Δ^1-cyclo*pentenylacetone*.—This βγ-ketone was obtained in about 60% yield by the action of zinc methyl iodide on α-ethyl-*cyclo*pentenylacetyl chloride; the yield from the αβ-chloride was much lower (40%). The semicarbazone formed plates, m. p. 166—167°, from dilute alcohol, and was identical with that prepared from the ethylated parent ketone (Kon and Linstead, J., 1925, **127**, 821). The ketone regenerated from it had b. p. 94°/15 mm., $d_4^{19\cdot5°}$ 0·917685, $n_D^{19\cdot5°}$ 1·45942, $[R_L]_D$ 45·32 (Calc., 45·72).

The ketone was treated with sodium ethoxide exactly as described on p. 1541; the semicarbazone obtained from the product contained about 10% of a more soluble form, m. p. 143—145°.

Addition and removal of hydrogen bromide produced no change, and attempts to introduce another alkyl group failed.

The ketone condensed readily with ethyl sodiomalonate, the reaction being complete in 3 hours, but neither the dihydroresorcinol ester nor its hydrolysis product could be obtained solid; the liquid products showed the usual reactions of their class with ferric chloride, etc. A small amount of the diketone was oxidised with hypobromite and the resulting dibasic acid (α-*ethyl*cyclo*pentane*-1 : 1-*diacetic acid*) was analysed in the form of its *silver* salt (Found: Ag, 50·8. $C_{11}H_{16}O_4Ag_2$ requires Ag, 50·5%).

The ketone formed an ozonide, which was decomposed by cold water to an oil giving an intense colour with ferric chloride but from which no definite compounds could be obtained on hydrolysis. Oxidation with permanganate also was inconclusive.

β-*Hydroxy*-β-*methyl*-α-*ethylpentanoic Acid*.—The ester was prepared from methyl ethyl ketone as before; the reaction started very slowly, but the yield was good, being 127 g., b. p. 106—108°/18 mm., together with 20 g. of a lower fraction which can be used for preparing the βγ-ester (Found: C, 63·4; H, 10·9. $C_{10}H_{20}O_3$ requires C, 63·8; H, 10·8%). On hydrolysis, a 50% yield of the *acid* was obtained as an oil, b. p. 132—136°/20 mm. (Found for the *silver* salt: Ag, 40·6. $C_8H_{15}O_3Ag$ requires Ag, 40·5%).

β-*Methyl*-α-*ethyl*-Δ^β-*pentenoic Acid*.—The preceding hydroxy-ester gave a 70% yield of ethyl β-methyl-α-ethyl-Δ^β-pentenoate, b. p. 84—88°/20 mm., $d_4^{19\cdot2°}$ 0·93160, $n_D^{19\cdot2°}$ 1·43618, $[R_L]_D$ 48·67 (Calc.,

49·34) on dehydration with phosphorus oxychloride, and about a 50% yield with potassium hydrogen sulphate. The *acid*, obtained on hydrolysis in 66% yield, was a liquid with a penetrating smell, b. p. 122—126°/20 mm., $d_4^{20\cdot4°}$ 0·95884, $n_D^{20\cdot4°}$ 1·45113, $[R_L]_D$ 39·90 (Calc., 40·23) (Found for the *silver* salt: Ag, 43·3. $C_8H_{13}O_2Ag$ requires Ag, 43·4%). The *chloride* had b. p. 76—78°/18—20 mm.; the p-*toluidide* formed needles, m. p. 102—104°, from methyl alcohol.

The acid in dry chloroform was treated with ozone, and the ozonide decomposed with water; acetaldehyde was formed in quantity and was identified by means of β-naphthol as usual (compare Kon and Linstead, J., 1925, **127**, 616).

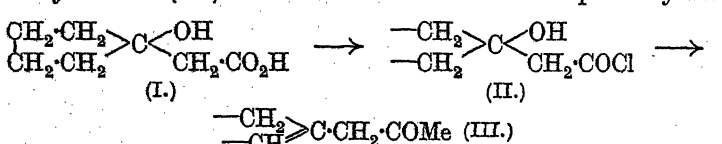
β-*Methyl*-αβ-*diethyl*-Δ^{α}-*pentenoic Acid.*—This acid, prepared in poor yield from β-hydroxy-β-methyl-αβ-diethylpentanoic acid by means of acetic anhydride, had b. p. 126—130°/15—18 mm., $d_4^{20\cdot4°}$ 0·95930, $n_D^{20\cdot4°}$ 1·45193, $[R_L]_D$ 39·94, and was probably still contaminated with some of the hydroxy-acid, although the silver salt gave correct figures on analysis (Found: Ag, 43·3. Calc.: Ag, 43·4%). The *chloride* had b. p. 86—90°/20 mm.; a small lower fraction (b. p. 72—76°) also was obtained. The p-*toluidide* crystallised from methyl alcohol, in which it is more soluble than the βγ-toluidide, in plates, m. p. 112—113° (mixed m. p. 87—89°). The *hydrobromide* was unstable.

δ-*Methyl*-γ-*ethyl*-Δ^{δ}-*hexen*-β-*one.*—This ketone was obtained in good yield from β-methyl-α-ethyl-Δ^{β}-pentenoyl chloride. The *semicarbazone* formed lustrous needles or plates, m. p. 163—164°, from methyl or ethyl alcohol (Found: C, 61·3; H, 9·3. $C_{10}H_{19}ON_3$ requires C, 60·9; H, 9·6%). The *ketone* regenerated from it had b. p. 72—74°/16 mm., $d_4^{19\cdot7°}$ 0·85068, $n_D^{19\cdot7°}$ 1·43908, $[R_L]_D$ 43·30 (Calc., 43·38). The *same* ketone was also obtained, although in poorer yield, from the αβ-chloride. The ketone was oxidised in dry chloroform solution with ozone; the ozonide on decomposition gave acetaldehyde, which was identified as before.

The ketone was treated with cold sodium ethoxide for 48 hours (p. 1541). The semicarbazones prepared from the product consisted for the most part of δ-methyl-γ-ethyl-Δ^{δ}-hexen-β-one semicarbazone, m. p. 163—164°, but contained also about 7% of a semicarbazone which melted, after repeated crystallisation, at 151—152°. A mixture of the two semicarbazones melted at 138—149°. After treatment with hydrogen bromide, the original ketone also gave a very small amount of a semicarbazone, m. p. 148—149°.

Attempts to alkylate the ketone were unsuccessful. The ketone condensed readily with ethyl sodiomalonate to a liquid ester which gave an intense colour with ferric chloride; the dihydroresorcinol

obtained on hydrolysis of the ester did not solidify and was not further examined.



The authors' thanks are due to the Chemical Society for a grant which has partly defrayed the cost of the investigation.

CCIV.—*The Preparation of Unsaturated Ketones from the Chlorides of Hydroxy-acids.*

By GEORGE ARMAND ROBERT KON and BINDIGAWAVALE TIRUMALACHAR NARAYANAN.

IN seeking to extend the methods by which ketones of the type of *cyclo*hexenylacetone are obtained, we were led to examine the action of zinc methyl iodide and of zinc ethyl iodide on the chlorides produced directly from hydroxy-acids, without previously converting these into unsaturated acids. This object had already been partly achieved by Blaise and Maire (*Ann. Chim. Phys.*, 1908, **15**, 556), who acetylated the hydroxy-acids before converting them into their chlorides; they found, however, that this method failed when applied to β-disubstituted acids, as these, instead of being acetylated, were dehydrated to a mixture of unsaturated acids. The work of Darzens (*Compt. rend.*, 1911, **152**, 1314, 1601) also made it appear probable that the action of thionyl chloride or phosphorus pentachloride on hydroxy-acids would lead to dehydration. Actually, it was found that cyclic β-hydroxy-acids gave each a mixture containing, in addition to varying quantities of the chlorides of the two possible unsaturated acids, a considerable proportion of its own chloride, from which it could be regenerated. These chlorides, on treatment with zinc methyl iodide, gave ketones identical with those obtainable from the chlorides of the unsaturated acids. Thus, *cyclo*pentanolacetic acid (I) gave a chloride (II) from which, on treatment with zinc methyl iodide, a fair yield of *cyclo*pentenylacetone (III) was obtained. This ketone is probably best

prepared by the process now described. The corresponding ethyl ketones were obtained only in very poor yield, owing to the simul-

taneous formation of the ethyl ester of the $\beta\gamma$-unsaturated acid. The production of this ester is at present unexplained. Experiments carried out with a few α-hydroxy-acids sufficed to show that the chlorides were highly unstable and had no practical value for the synthesis of ketones; a small quantity of tetrahydroacetophenone was, however, prepared from *cyclo*hexanolcarboxylic acid.

EXPERIMENTAL.

1-Hydroxy*cyclo*pentane-1-carboxylic acid (43 g.) was treated with excess of thionyl chloride in the cold. When the frothing had subsided, the mixture was warmed for 20 minutes, and the excess of reagent removed in a vacuum. The chloride decomposed during distillation even under 3·5 mm.

In another experiment the acid (43 g.) was gradually added to 69 g. of phosphorus pentachloride and the mixture was warmed for 30 minutes, but no attempt was made to purify the chloride. A portion of it gave, on treatment with formic acid, the original acid, m. p. 103°. The crude chloride was then treated with zinc methyl iodide, but only a very small amount of a disagreeable-smelling, non-ketonic liquid was obtained.

1-Hydroxy*cyclo*hexane-1-carboxylic acid behaved exactly like the lower homologue both with phosphorus pentachloride and with thionyl chloride. The action of zinc methyl iodide on the crude chloride gave a very poor yield of a substance which combined with semicarbazide, giving tetrahydroacetophenone semicarbazone (m. p. and mixed m. p. 216—217°). The action of zinc ethyl iodide gave no ketonic product, but a small amount of an oil, b. p. 110—114°/20 mm., which appeared to be ethyl tetrahydrobenzoate.

A chloride could not be obtained from hexahydromandelic acid.

1-Hydroxy*cyclo*pentane-1-acetic acid (48 g.), after treatment with excess of thionyl chloride, gave on distillation 5 g. of a chloride, b. p. 85—87°/17 mm., and 16 g. (30%) of another chloride, b. p. 98—110°/17 mm. The former gave, when poured into formic acid, *cyclo*pentenylacetic acid, m. p. 51—52°, and when treated with aniline, cyclo*pentenylacetanilide*, which crystallised from methyl alcohol in silky needles, m. p. 98° (Found: C, 77·3; H, 7·9. $C_{13}H_{15}ON$ requires C, 77·6; H, 7·5%). The higher-boiling chloride gave a mixture of anilides from which cyclo*pentylideneacetanilide* could be isolated in nodules, m. p. 152—153°, after several crystallisations (Found: C, 77·2; H, 7·6. $C_{13}H_{15}ON$ requires C, 77·6; H, 7·5%). On pouring the chloride into formic acid, a gummy acid was obtained from which the original acid, m. p. 77°, was isolated after repeated treatment with benzene–petroleum.

The action of zinc methyl iodide (1/3 mol.) on the higher-boiling

chloride prepared from 48 g. of the hydroxy-acid gave 8 g. of a ketone. The semicarbazone prepared from this was separated by crystallisation into three forms, m. p. 138°, 189°, and 121—122°, respectively, the last being apparently a constant-melting mixture of the other two. These were the two semicarbazones of *cyclo*pentenylacetone (Kon, J., 1921, **119**, 823); the one of m. p. 138° was formed in greater quantity.

The action of zinc ethyl iodide on the same chloride gave an ester, probably ethyl *cyclo*pentenylacetate; no ketone appeared to be formed.

The action of thionyl chloride on 1-hydroxy*cyclo*hexane-1-acetic acid (53 g.) gave 35 g. of a product, b. p. 95—98°/15—17 mm., consisting mainly of the chloride of the hydroxy-acid, as it gave the original acid on being poured into formic acid. The action of aniline on it gave a mixture from which the *anilides* of *cyclo*hexenylacetic acid, needles, m. p. 117° (Found: C, 77·9; H, 8·2%) and of *cyclo*hexylideneacetic acid, m. p. 138—139° (Found: C, 78·4; H, 7·8. $C_{14}H_{17}ON$ requires C, 78·1; H, 7·9%), were obtained. The anilide of the hydroxy-acid appears to be indefinite.

The acid chloride from 53 g. of the acid was treated with zinc methyl iodide; 17 g. of *cyclo*hexenylacetone, b. p. 102—104°/20 mm., identified by means of the semicarbazone, were obtained.

The reaction was repeated with zinc ethyl iodide, but the yield of ketone was very much less, partly owing to the formation of ethyl *cyclo*hexenylacetate in some quantity. The ketone gave two semicarbazones, m. p. 153° and 184—185° respectively. The former is identical with the semicarbazone of Δ^1-*cyclo*hexenylmethyl ethyl ketone (Kon, J., 1926, 1797), whilst the latter is isomeric with it and is probably the semicarbazone of the $\alpha\beta$-form [Found: (for the form of low m. p.) C, 63·2; H, 9·2; (for the form of high m. p.) C, 62·9; H, 9·5. $C_{10}H_{17}ON_3$ requires C, 63·2; H, 9·0%].

1-Hydroxy-α-ethyl*cyclo*pentane-1-acetic acid (see preceding paper) (29 g.) gave 17 g. of a chloride, b. p. 99—102°/25 mm. The chloride gave with ammonia a mixture of the $\alpha\beta$- and the $\beta\gamma$-unsaturated amide, in the proportion of 1 : 2; a third amide, melting indefinitely at about 70°, was also obtained but could not be purified. The action of zinc methyl iodide (1/6 mol.) on 15 g. of the acid chloride gave 8·5 g. of a liquid, b. p. 103—105°/25—27 mm., from which the semicarbazone of α-ethyl-Δ^1-*cyclo*pentenylacetone, m. p. 166—167° after crystallisation, was readily obtained.

1-Hydroxy-α-ethyl*cyclo*hexane-1-acetic acid (see preceding paper) (30 g.) gave 22 g. of a chloride, b. p. 122—127°/20 mm. This, on treatment with ammonia, gave an amide, m. p. 108—110°, which, on repeated crystallisation, melted at 113—114° and proved identical

with the βγ-unsaturated amide; a trace of another amide, m. p. 108—109°, distinct from both the αβ- and the βγ-amide, was also obtained. By the action of zinc methyl iodide (1/6 mol.) on the acid chloride (20 g.), 9 grams of a liquid, b. p. 122—124°/20 mm., were obtained. This contained a considerable amount of unsaturated ester in addition to α-ethyl*cyclo*hexenylacetone, which was isolated in the form of its semicarbazone, m. p. 185°.

β-Hydroxy-β-methyl-α-ethylpentanoic acid gave a 70% yield of chloride, b. p. 75—90°/20—25 mm., on treatment with thionyl chloride. It consisted mainly of the chlorides of the two unsaturated acids, as evidenced by the *p*-toluidides obtained from it, but a third, indefinite, product was also formed, probably derived from the hydroxy-acid. The yield of ketone, b. p. 78—82°/25 mm., from the acid chloride was poor; it readily gave the characteristic semicarbazone, m. p. 163—164°, identical with that previously obtained from the unsaturated acids.

The authors' thanks are due to the Chemical Society for a grant which has defrayed the cost of this investigation.

CCV.—*The Chemistry of the Three-carbon System. Part XIII. The Effect of Bulky Substituents and of the* cyclo*Heptane Group on the Tautomerism.*

By GEORGE ARMAND ROBERT KON and CECIL JOHN MAY.

THE effect of a positive substituent in the α-position on the tautomerism of a three-carbon system has been discussed (this vol., p. 1536); that of bulky substituents in the β-position is now described.

To obtain a strictly comparable series it would be necessary to work with β-substituted pentenoic acids, because it has already been shown that the βγ-phase does not become stable until the γ-carbon atom carries at least a methyl group, as in the acid $CHMe{:}CMe{\cdot}CH_2{\cdot}CO_2H$ (Kon and Linstead, J., 1925, **127**, 616). The next member of the series is diethylacrylic acid; this and its βγ-isomeride were studied by Kon and Linstead. Other β-substituted pentenoic acids are, however, difficult to prepare owing to lack of accessible initial materials, and a further difficulty is that there are in every case two possible βγ-acids, according as the double bond is in the shorter or the longer chain. We have therefore

limited the present experiments to two compounds, namely, ββ-dipropyl- and ββ-di*iso*butyl-acrylic acids (I; R = Et and Pr^{β}, respectively) and their βγ-isomerides (II), to which these objections do not apply.

(I.) $\begin{matrix}CH_2R\\CH_2R\end{matrix}\!\!>\!C{:}CH\cdot CO_2H$ $\qquad$ $\begin{matrix}CH_2R\\CHR\end{matrix}\!\!>\!C\cdot CH_2\cdot CO_2H$ (II.)

The γ-substituent in these acids may be expected to have some effect on the stabilities of the αβ- and βγ-forms. From considerations based on the electronic theory (compare Allan, Oxford, Robinson, and Smith, J., 1926, 401; Ingold, Shoppee, and Thorpe, *ibid.*, p. 1477), it is deduced that the presence of a positive substituent in the γ-position would favour the βγ-phase, whilst in the β-position this substituent would have little effect. These effects will be comparatively insignificant if it is merely a question of substituting a larger for a smaller group. Should, however, steric factors have any considerable influence on the equilibrium, then it might be expected that such a substitution would produce a very definite effect; and this will be shown to be the case. The tendency of a double bond to migrate from the αβ- to the βγ-position appears to be connected with the alteration of the normal tetrahedral angle about the β-carbon atom (J., 1926, 2727); the case may be compared with the formation of a three-membered ring by ring-chain tautomerism (Bains and Thorpe, J., 1923, **123**, 1206; Deshapande and Thorpe, J., 1922, **121**, 1430).

(A) $\begin{matrix}R\\R'\end{matrix}\!\!>\!C\!<\!\begin{matrix}CO\cdot CO_2H\\CH_2\cdot CO_2H\end{matrix}$ $\longrightarrow$ $\begin{matrix}R\\R'\end{matrix}\!\!>\!C\!<\!\begin{matrix}C(OH)\cdot CO_2H\\CH\cdot CO_2H\end{matrix}$

(B) $\begin{matrix}R\\R'\end{matrix}\!\!>\!C\!<\!\begin{matrix}CH\cdot CO_2H\\\cdots\end{matrix}$ $\longrightarrow$ $\begin{matrix}R\\R'\end{matrix}\!\!>\!C{=}CH\cdot CO_2H$

The formation of an αβ-double bond in (B) will be analogous to the formation of a three-membered ring from (A), an increase in bulk of the groups R and R′ in each case facilitating the formation of the "ring" system. In (B) there are three possible positions for the double bond; the four valencies of the central carbon atom must be regarded as asymmetrically directed, the angle between any two of them being determined by the resultant of two opposing steric factors. The double bond should therefore be most readily produced in the direction of the smallest group (this does not apply to the methyl group owing to the comparative instability of a terminal methylene group, unless specially stabilised as in itaconic acid). In straight-chain acids where R = H (*e.g.*, the pentenoic acids), the steric effect is negligible and the αβ-phase is the more stable; as the bulk of R increases, the βγ-form is stabilised. When, however, both R and R′ increase to such an extent that the group

$-CH{\cdot}CO_2H$ becomes relatively small, the equilibrium again tends towards the αβ-form. It is doubtless for this reason that Johnson and Kon (J., 1926, 2748) found the equilibrium in the β-ethylcinnamic acids to be on the side of the βγ-form (76 : 24), whilst in the next higher acids the equilibrium was already of the order 50 : 50. Again, in the *gem*-diethyl series, the equilibrium is strongly on the side of the βγ-form (95 : 5, according to Linstead; this vol., p. 355). The two pairs of acids now studied fall well into line, for the equilibrium in the dipropyl series is 67 : 33 in favour of the βγ-form, whilst in the di*iso*butyl series it is already 51 : 49, thus illustrating the effect of bulky groups.

In the behaviour of the cyclic acids, other factors come into play. The tendency of a ring to acquire a double bond—which is a measure of the stability of the βγ-phase—is difficult to correlate with the distortion of the normal tetrahedral angle in these rings; *e.g.*, the stability of the βγ-phase increases but slightly from the *cyclo*pentane (85 : 15; Linstead, private communication) to the *cyclo*hexane series (88 : 12; Linstead, *loc. cit.*), although the difference in the distortion of the normal tetrahedral angle is considerable; it decreases appreciably in the *cyclo*heptane series, the equilibrium being about 75 : 25 in favour of the βγ-phase. In other words, the *cyclo*heptane ring shows less tendency to acquire a double bond than either of the smaller rings.

ββ-Dipropylacrylic acid (I; R = Et) has been described by Albitzki (*J. pr. Chem.*, 1884, **30**, 209) as a solid, m. p. 80—82°; this was analysed only in the form of variously hydrated salts. Reformatski (*J. Russ. Phys. Chem. Soc.*, 1890, **22**, 44) obtained the acid only as a liquid; the dibromide he prepared from it differed from Albitzki's dibromide. We have prepared the acid, which melts at 9°, by dehydrating ββ-dipropylhydracrylic acid with acetic anhydride and have characterised it by the formation of an amide, m. p. 72°; its structure was confirmed by oxidation. Albitzki's method of dehydrating the hydroxy-acid could lead only to the βγ-acid, and did so in our hands. The βγ-acid obtained thus and in other ways was always contaminated with αβ-acid; all the preparations were liquid (all the βγ-acids studied up to the present melt at lower temperatures than the αβ-acids; the converse holds for the amides), and the acid itself has not yet been obtained pure, although a pure ester and an amide (m. p. 120—121°) have been prepared. The di*iso*butyl compound proved even more discouraging in this respect, as inseparable mixtures of the two acids were obtained by all the available methods.

cyclo*Heptylideneacetic acid*, on the other hand, was readily obtained as a solid, m. p. 54°, giving a dibromide, m. p. 125°.

Baker and Ingold isolated a small quantity of a liquid which they described as the αβ-acid and characterised by the formation of a dibromide, m. p. 125°; this must have been the αβ-dibromide. This is surprising, because, under the experimental conditions used by Baker and Ingold, the αβ-acid is rapidly isomerised to the extent of 75% into the liquid βγ-isomeride, previously described by Wallach as the αβ-form (*Annalen*, 1902, **314**, 157) and yielding a dibromide, m. p. 103—104°. It must be assumed that Baker and Ingold's hydrolysis was carried out so rapidly that complete equilibration of the αβ-acid first produced could not take place and the mixture contained enough αβ-acid to give its dibromide.

Experimental.

ββ-Dipropylacrylic Acid (I; R = Et).—The reaction between dipropyl ketone and ethyl bromoacetate with magnesium proceeded well in benzene solution, the yield of ethyl ββ-dipropylhydracrylate, b. p. 139°/15 mm., being 50%. The acid was obtained from the ester, on hydrolysis in the usual manner, as a thick oil which could not be distilled even at 2 mm.

On dehydration with acetic anhydride (Wallach, *Annalen*, 1907, **353**, 288), it yielded ββ-dipropylacrylic acid (I), which is a colourless, practically odourless oil, b. p. 144°/17 mm.; this set, on freezing, to a mass of crystals which melted at 9°. It had $d_4^{20\cdot0°}$ 0·93624, $n_D^{20\cdot0°}$ 1·46350, $[R_L]_D$ 45·97 (calc. 44·84) (Found: C, 68·9; H, 10·4. Calc. for $C_9H_{14}O_2$: C, 69·1; H, 10·3%. Found in the silver salt: Ag, 41·1. Calc.: Ag, 41·1%). The *chloride* had b. p. 128°/25 mm. and gave with ammonia in ethereal solution the *amide*, which separated from light petroleum in long, flattened needles, m. p. 72°. The p-*toluidide* crystallised from dilute methyl alcohol in needles, m. p. 82·5°. The *ethyl* ester, prepared through the acid chloride, had b. p. 108—109°/14 mm., $d_4^{18\cdot0°}$ 0·89284, $n_D^{18\cdot4°}$ 1·44923, $[R_L]_D$ 55·35 (calc., 54·19). Both the ester on treatment with ozone and the acid on oxidation with permanganate gave good yields of dipropyl ketone, which was identified by means of its semicarbazone, m. p. 133°.

β-Propyl-Δ^β-hexenoic Acid (II; R = Et).—The ethyl ester was readily obtained pure by heating ethyl ββ-dipropylhydracrylate with a 20% excess of phosphorus pentoxide under reduced pressure; it gradually distilled and was purified by redistillation (yield 75%); b. p. 116—118°/25 mm., $d_4^{25\cdot0°}$ 0·89264, $n_D^{25\cdot0°}$ 1·43778, $[R_L]_D$ 54·13. It gave no trace of dipropyl ketone on oxidation. The acid was prepared by the hydrolysis of this ester, also by dehydrating the hydroxy-acid by means of 20% sulphuric acid (compare Farrow and Kon, J., 1926, 2138; Albitzki, *loc. cit.*; Reformatski, *loc. cit.*),

50% sulphuric acid, or phosphorus trichloride. In the last case, the acid (3 mols.) in ether was gradually added to rather more than 2 mols. of the chloride with cooling, and the mixture was kept for 24 hours and finally warmed on the steam-bath until no more hydrogen chloride was evolved. The acid obtained by these processes had b. p. 138—140°/22 mm. and 126—128°/11 mm., and the following properties:

(1; 20% H_2SO_4) $d_4^{22°}$ 0·93400, n_D 1·45593, $[R_L]_D$ 45·43.
(2; 50% H_2SO_4) $d_4^{16°}$ 0·93813, n_D 1·45833, $[R_L]_D$ 45·42.
(3; PCl_3) $d_4^{19°}$ 0·93692, n_D 1·45753, $[R_L]_D$ 45·42.

All the samples thus showed a slight exaltation, and gave on oxidation small quantities of dipropyl ketone. Many methods of purification were tried without success. The *chloride* boiled at 107°/30 mm. and gave a mixture of amides on treatment with ammonia. This was resolved into its constituents by repeatedly washing it with petroleum, in which only the αβ-amide was freely soluble. The residue, after several crystallisations from benzene–petroleum, consisted of the pure *βγ-amide*, m. p. 120—121°; it could be sublimed (Found: C, 69·5; H, 11·2. $C_9H_{15}ON$ requires C, 69·6; H, 11·1%).

Equilibration of the Acids.—The αβ- and the βγ-acid (in the latter case, the purest sample available) were each refluxed with ten times the calculated quantity of potassium hydroxide (20 or 60% solution) for 24 hours; the acid mixture was then isolated by Linstead's method (*loc. cit.*). The percentage of αβ-acid in the mixture was determined by Bougault's method (*Ann. Chim. Phys.*, 1908, **14**, 145) with the following results:

Equilibrium mixture from the αβ-acid: (a) 35·7%, (b) 33·0%.
„ „ βγ-acid: (a) 31·4%,

from which the mean figure is 33%. A discussion of the details of procedure is reserved for a future communication.

Attempts to Prepare the Acids by Other Methods.—An attempt to prepare the αβ-acid by elimination of hydrogen bromide from α-bromo-β-propylhexoic acid was abandoned because the bromo-acid could not be obtained free from unbrominated material. The preparation was carried out as follows: Dipropylcarbinol (100 g.), prepared in 50% yield by the method followed by Grignard (*Compt. rend.*, 1901, **132**, 336) for preparing di*iso*butylcarbinol and in 75% yield by reducing dipropyl ketone with sodium wire in wet ether (Kurtz, *Annalen*, 1876, **181**, 205), was refluxed for 4—5 hours with 600 g. of hydrobromic acid (*d* 1·5) free from sulphuric acid. The bromide, b. p. 161—165°/749 mm. (slight decomp.), 88°/64 mm.,

thus obtained in 50% yield, was condensed with ethyl sodiomalonate in alcohol in the usual manner, a good yield of *ethyl hydrogen iso*heptylmalonate, b. p. 168°/35 mm., being obtained in the place of the diethyl ester (Found: C, 62·9; H, 9·4. $C_{12}H_{22}O_4$ requires C, 62·6; H, 9·6%). The acid was readily obtained on alkaline hydrolysis; it refused to solidify and therefore was distilled, a good yield of β-*propylhexoic acid* being collected as a colourless liquid with a not unpleasant odour, b. p. 144°/30 mm. (Found: C, 68·2; H, 11·3. $C_9H_{16}O_2$ requires C, 68·3; H, 11·5%). The acid was converted into its chloride and brominated, crystals of an unstable bromo-acid chloride being obtained; these could not be freed from unbrominated material and rapidly decomposed on distillation or on exposure to the air.

Attempts to obtain the corresponding β-bromo-acid (hydrobromide of dipropylacrylic acid) were also unsuccessful.

ββ-*Diisobutylacrylic Acid.*—Di*iso*butyl ketone (*iso*valerone) was condensed with ethyl bromoacetate; the yield of ethyl β-hydroxy-ββ-di*iso*butylpropionate was always poor, the best (35%) being obtained by carrying out the condensation in ether and warming the reaction product over-night; 30% of the ketone was recovered. The ester boiled at 138—140°/20 mm. and yielded a viscous liquid acid on hydrolysis. The hydroxy-acid could not be purified by distillation. It was dehydrated both with acetic anhydride and with dilute sulphuric acid, mixtures of unsaturated acids being obtained in every case; b. p. 144—149°/20 mm. (Found: C, 71·5; H, 10·6. $C_{11}H_{18}O_2$ requires C, 71·7; H, 10·9%). The properties of different preparations were as follows ($[R_L]_D$ calc., 54·06):

Source of acid.	*t.*	*d.*	n_D.	$[R_L]_D$ obs.
(1) Dehydr. by Ac_2O	21°	0·92530	1·46091	54·60
(2) ,, ,, ,, ...	21	0·92488	1·46111	54·65
(3) ,, ,, ,, ...	26	0·91885	1·46982	54·88
(4) ,, ,, dil. H_2SO_4	19	0·92141	1·46723	54·46
(5) KOH on (1)	18·5	0·92609	1·46131	54·56
(6) ,, (4)	20	0·91660	1·46603	54·51
(7) Regen. from acid chloride...	17·5	0·92782	1·46144	54·54

Equilibration. This was carried out as described on p. 1553, and the percentage of αβ-acid in the mixture determined as before; the mean value was 49% of αβ-acid.

cyclo*Heptylideneacetic Acid.*—Suberone, obtained in 40% yield from thorium suberate by Ruzicka's method (*Helv. Chim. Acta*, 1926, **9**, 515), was converted into ethyl *cyclo*heptanolacetate (Wallach, *loc. cit.*) as before, 30 g. being obtained from 56 g. of suberone, 16 g. of which were recovered. This quantity of ester gave 20 g. of hydroxy-acid which did not solidify.

The acid (20 g.) was boiled with 35 c.c. of acetic anhydride for

3—4 hours, and the unsaturated acid isolated by distillation in steam, 5 g. of solid being obtained in addition to a small amount extracted from the head and tail fractions; it formed colourless needles, m. p. 54° (Found: C, 69·6; H, 9·2. $C_9H_{14}O_2$ requires C, 70·1; H, 9·2%).

A small quantity of the acid was treated with dry ozone in chloroform solution; the ozonide on decomposition gave an 80% yield of suberone (weighed as semicarbazone).

αβ-*Dibromo*cyclo*heptylacetic Acid.*—The αβ-acid (0·5 g.) was dissolved in 2 c.c. of acetic acid, 0·5 g. of bromine in acetic acid added, and the mixture left in an exhausted desiccator; crystals of the dibromide slowly separated. On recrystallisation from chloroform–petroleum colourless crystals, m. p. 125°, were obtained.

Δ^1-cyclo*Heptenylacetic Acid.*—The hydroxy-acid (15 g.) was refluxed for 3 hours with an excess of 10% sulphuric acid, and the unsaturated acid was distilled in steam and isolated by means of ether, the yield being 2·5 g. Its properties corresponded closely with those of Wallach's acid: b. p. 158—160°/18 mm., $d_4^{22°}$ 1·0382, $n_D^{22°}$ 1·49232, $[R_L]_D$ 43·09. When examined by Bougault's method, this acid was proved to contain 24% of αβ-acid.

βγ-*Dibromo*cyclo*heptylacetic Acid.*—The crude βγ-acid was converted into a dibromide under the same conditions as the αβ-acid; it crystallised only partly, the solid being the new dibromo-acid, which on crystallisation formed hard, colourless prisms, m. p. 103—104°. A mixture of this with the αβ-dibromide melted at about 79°. On standing, the βγ-dibromide gradually darkened and appeared to be converted into a bromo-lactone.

Equilibration. Experiments were carried out starting both with the αβ- and with the βγ-acid; the mean of several determinations gave the percentage of the αβ-acid in the mixture as 25·6.

The authors' thanks are due to the Royal Society and to the Chemical Society for grants which have defrayed the cost of this investigation.

CCVI.—*Low Temperature Oxidation of Hydrocarbons.*

By JOHN STANLEY LEWIS.

IN his researches on the combustion of methane and ethane, Bone proved conclusively that reaction with oxygen takes place at temperatures well below the ignition point, the products being aldehydes,

water, etc. As a result of this work he put forward his hydroxyl theory (J., 1902, **81**, 535; 1903, **83**, 1074; 1904, **85**, 693, 1637; *Proc. Chem. Soc.*, 1905, **21**, 220). More recent work has shown that paraffin oils and waxes undergo oxidation at low temperatures, and the latter have been converted into fatty acids, but attention has been given also to the unsaturated hydrocarbons, especially diolefins, which are prevalent in "cracked" spirit. A review of the work on "Gasolines" is given by Brooks (*Ind. Eng. Chem.*, 1926, **18**, 1198). An advance has been made by Callendar (*Engineering*, February, 1927), who has proposed the theory that the initial step in the oxidation of paraffins at low temperatures is the formation of peroxides which decompose eventually into aldehydes, acids, water, etc.

The present paper contains an account of (*a*) a simple arrangement for determining the temperatures of initial oxidation of paraffin hydrocarbons at constant volume; (*b*) the influence of certain factors upon these temperatures; (*c*) a proposed mechanism of the reaction, which may be called the "primary dehydrogenation theory"; and (*d*) an attempt to apply this theory to account for the instability of paraffin hydrocarbons as measured by their ignition and detonation characteristics.

Experimental.

Molecular Weights at High Temperatures.—The determination of molecular weights by the Victor Meyer method at temperatures above 200° gives anomalous results for paraffins, the molecular weights decreasing as the temperature increases (Ormandy and Craven, *J. Inst. Petroleum Tech.*, Nov., 1925), as shown in Table I.

Table I.

Molecular-weight determinations (Ormandy and Craven).

Temp.	Heptane.	Shell.	Pratt's.	Benzene.
200°	102	100	97	77
220	73	96	96	76
250	79	98	95	78
265	74	80	78	75
275	70			
275 (plus piece of porous pot)	78			

The suggested explanation of this decrease is that chemical action of some kind has taken place causing an increase in the number of molecules, and the above workers attributed this partly to the cracking of the paraffins, and to partial combustion whilst the spirit remained in the liquid phase, vapours being affirmed to be more stable. Experiments conducted with coal-gas gave more normal results. The foregoing results have been disputed by some

workers, but they have been confirmed in this laboratory, and some of the results obtained for hydrocarbons other than paraffins are shown in Table II.

TABLE II.

Molecular-weight determinations of typical hydrocarbons.

Benzene.		Toluene.		*cyclo*Hexane.		Amylene.	
Temp.	*M.*	Temp.	*M.*	Temp.	*M.*	Temp.	*M.*
198°	78·6	187°	92	230°	85	200°	72
240	78·4	360	92	260	83	254	73
285	79·8	400	93	342	68	297	60
350	78·4	310 (in oxygen)	93	362	61	295 (in nitrogen)	72
360 (in oxygen)	78·8	385 (in oxygen)	93	400	73	303 (in nitrogen)	70
				400 (in oxygen)	Exploded.	310	65
				400 (in nitrogen)	85	355 (in oxygen)	Exploded.

The aromatic substances are apparently stable up to 400° in these experiments, whereas the olefin and the naphthene are affected by oxygen, but not by nitrogen, and their molecular weights are normal. This seems to discount the view that cracking takes place to any appreciable extent, and experiments are in progress on the lines described later to ascertain the exact temperatures at which the various hydrocarbons crack, and thus to obtain comparative values for their stability in the absence of oxygen. Increase in the expected volume of gas, *i.e.*, decrease in the measured molecular weight, is to be attributed to oxidation, but this oxidation can and does take place in the vapour phase, as will be shown later. It was observed also that the tubes used for weighing the liquid always contained films of gums or tarry deposits at the end of the experiments; these were light brown for low temperatures, and deepened to black tars as the temperature of experiment was increased. These gums are probably formed during cooling and are the condensation products of aldehydes.

The results of the earlier molecular-weight determinations were erratic and variable owing to the fact that the weights of liquid in each experiment differed, thus altering the ratios of hydrocarbon to oxygen and to the surface area of the Victor Meyer bulb. By using the same weighing tube throughout, with approximately equimolecular proportions of liquid for each temperature, and a large bulb, more concordant results were obtained, the observed molecular weights of hexane and octane decreasing gradually with rise of temperature above a certain limit. A fairly smooth curve was thus recorded for temperature–molecular weight (Fig. 1). The figures are in Table III.

TABLE III.

* Ormandy and Craven (*loc. cit.*).

These curves meet the horizontal line of constant molecular weight at a point corresponding approximately to the temperature of initial oxidation. At the other extreme the curves presumably intersect the horizontal lines corresponding to the molecular weights that would be attained if oxidation to water and carbon dioxide was complete; but before this temperature could be reached spontaneous ignition would take place, as indicated diagrammatically by the vertical lines. The above method is obviously unsatisfactory for determining the exact temperature at which oxidation is initiated, and the following simple method was used.

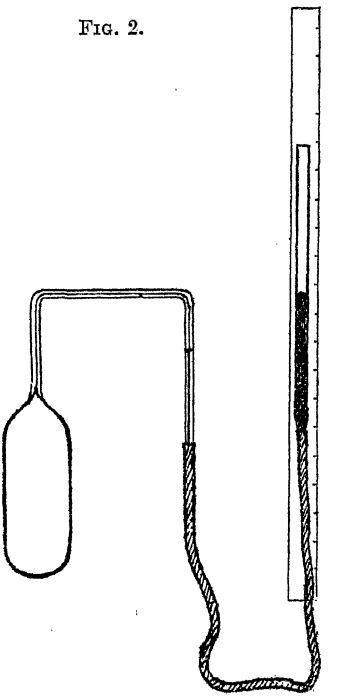

FIG. 1.

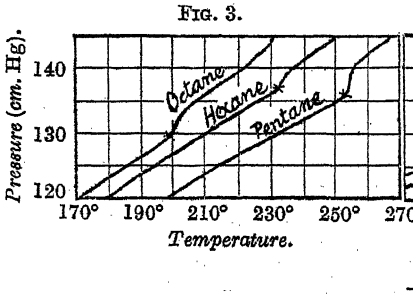
Constant-volume Method.—A known quantity of the liquid was enclosed in a large cylindrical bulb to which was attached a stout capillary tube connecting with a mercury manometer, as in the usual form of an air thermometer (Fig. 2). During the slow heating of the bulb, the manometer was raised constantly so that the mercury in the capillary tube was kept at a constant mark, the height of the mercury in the manometer plus the barometric pressure being the pressure of the mixture inside the bulb. Readings were taken at small intervals of temperature, and a pressure–temperature diagram was drawn. If no chemical action takes place the curve should follow approximately that of the gas laws, but in the case of the

paraffins there occurs a sudden rise or inflexion indicating chemical action. The temperature at which this rise occurs will be known as the " critical inflexion temperature " or the *C.I.T.* Typical curves are given in Fig. 3. Most of the hydrocarbons used in these experiments were either Kahlbaum preparations or of a purity complying with the recognised physical data. The following results were obtained: Pentane, 253°; hexane, 232°; octane, 198°. (It is possible to read the *C.I.T.*'s to within 1° or 2°.)

FIG. 2.

The initial part of the curve follows the air-thermometer curve approximately until the *C.I.T.* is reached, and once this is passed there is no rapid rise of pressure corresponding to a reaction with increased number of molecules. In fact, for some distance the curve does not differ much from the air curve, having a tendency to fall below rather than to rise above it, as though molecules were combining and becoming fewer in number. At much higher temperatures the curves revealed a progressive, but slow, decomposition. The form of the curve is unexpected, because the sudden rise at the *C.I.T.* denotes a reaction which is completed at this temperature, accompanied by an increase in the number of molecules. Hydroxyl or peroxide formation would cause a decrease in the number of molecules, and hence a depression in the curve, unless these oxygen derivatives were produced and decomposed at the same

FIG. 3.



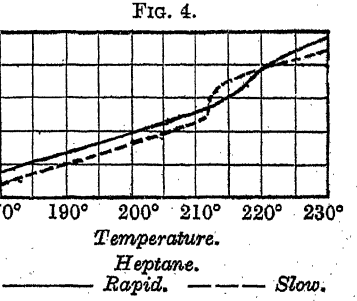


FIG. 4.

temperature. That the whole of this reaction takes place at the *C.I.T.* was proved by maintaining the temperature constant for some time, whereupon the pressure increased to a maximum and remained stationary.

It appears that for paraffin hydrocarbon–air mixtures there is a critical temperature at which rapid chemical action takes place with an increase in the number of molecules.

The critical temperature is dependent upon molecular weight, as seen in the results for pentane, hexane, and octane; but other factors influence it and the following experiments were instituted with a view to determine them.

Rate of Heating.—Two experiments were carried out with heptane, the rise of temperature in one case being extremely slow, and in the other about 1° per minute, the same bulb and equal quantities of liquid being used. The initial parts of the curves are parallel up to the *C.I.T.*, indicating that if chemical action has taken place the extent is the same for the two rates of heating. At the *C.I.T.* the rise for slow heating is more abrupt and is completed within 1° or 2°. That the reaction occurs with measurable velocity is shown by the curve for rapid heating (Fig. 4). In the case of pentane, which has a higher *C.I.T.*, the velocity of the reaction is greater, and with a rate of heating comparable with that denoted as "rapid" above, reaction is completed in a small range of temperature. It may be justifiably concluded that when one of these paraffin hydrocarbon–air mixtures is suddenly raised to a temperature well above the *C.I.T.* but below that of spontaneous ignition, as, *e.g.*, during sudden compression, the chemical change involved at the *C.I.T.* will take place almost instantaneously, giving rise to a pressure higher than the calculated, and also causing evolution of heat.

Concentration of the Vapour.—At first it was thought that concentration played no part, because the differences obtained were very small. To test this point, one bulb was used for a set of experiments in which gradually increasing weights of octane, and also hexane, were employed. The results for octane, depicted in Fig. 5, show that concentration affects the *C.I.T.* to a small but appreciable extent.

It is possible that chemical reaction begins below the *C.I.T.*, but if so, it must be very slight, because on heating some of the mixtures to temperatures below the *C.I.T.*, cooling, and reheating, the curves obtained were almost identical, but on occasions the contents of the bulb reduced a very weak solution of potassium permanganate. No "gumming" or coloration of the finally cooled liquid occurred, however, in any instance.

Atmosphere of Oxygen.—The curves for hydrocarbon–oxygen

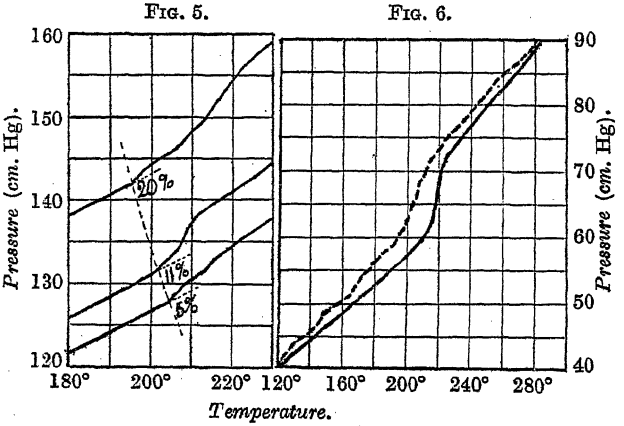
mixtures were of the same nature as for air. The bulbs were filled with oxygen, a measured quantity of hydrocarbon was added, and pressure–temperature curves were determined as before. These curves varied only in the fact that the *C.I.T.* was more abrupt and completed within a smaller range of temperature (1—2°), showing that, whatever chemical change is taking place at the *C.I.T.*, the velocity is much greater in oxygen. The actual temperature, however, differed very little from that in a similar determination with air, and no more than would be expected from the change in the concentration ratio of vapour–oxygen to vapour–air.

A remarkable feature is that once the *C.I.T.* is passed, the contents of the bulb are apparently stable at least up to 450°, and have been heated to this point without explosion or spontaneous ignition occurring. Callendar, in his tube experiments, heated a paraffin–air mixture to 666° before ignition was reached, but slight explosions occurred at 516° with flashes of flame when the same mixture carried liquid drops of the hydrocarbon. It appears, therefore, that the liquid phase is more unstable than the vapour state, and the *C.I.T.* has some bearing upon this phenomenon. Spontaneous-ignition temperatures for liquid particles must give results which are far below those for complete vapour–air or oxygen mixtures.

Atmosphere of Nitrogen.—Hexane was heated in the apparatus, which had been filled with nitrogen, and up to 365° the pressure–temperature curve was normal and showed no inflexion. No gum was formed and the liquid remained colourless on cooling. On reheating, the pressure–temperature curve was practically identical with the first, thus confirming the work on molecular-weight determinations in nitrogen and the conclusion that no decomposition or "cracking" takes place. The sudden rise in pressure at the *C.I.T.* can only be attributed to oxidation of the paraffin–hydrocarbon molecules, accompanied by an increase in the final number of molecules.

Comparison of Isomerides.—Spontaneous-ignition tests are untrustworthy for making a comparison of the stability of the hydrocarbons in the presence of oxygen, and the recorded results are very variable. The method adopted in these experiments is suitable for comparing two isomerides if the *C.I.T.* is taken as the initial oxidation temperature. Thus in the case of *n*- and *iso*-pentane, when equal weights were heated separately in the same bulb, the *C.I.T.*'s were: Pentane, 253°; *iso*pentane, 260°.

In this experiment the *n*-pentane is less stable than its isomeride, and if there is a relationship between this temperature and spontaneous ignition and detonation, then pentane should detonate more readily in the engine. It has been shown that an *iso*octane possesses



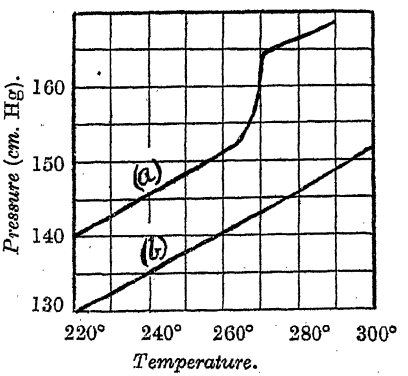
much feebler detonating properties than *n*-octane (Graham Edgar, *Ind. Eng. Chem.*, 1927, **19**, 145).

Surface Area.—The bulbs used were of good soda glass; the effect of surface area is shown by the *C.I.T.* in the following results :

Hydrocarbon.	Large bulb.	Small bulb.
*iso*Pentane	259—260°	263—264°
Heptane	210—212	214—215

Catalysts.—Two typical catalysts were used : (*a*) platinum, an oxidising catalyst, and (*b*) lead tetraethyl, a poison or negative catalyst.

Fig. 5. Fig. 6.



——— *Heptane alone.*

— — — *Heptane with platinum as catalyst.*

(*a*) *Platinum.* This was used both in the form of a coating on the bulb and as platinised asbestos. The effects were very marked : chemical reaction proceeded slowly even at low temperatures, and the pressure–temperature curves showed much irregularity. A typical example of the curves is found in Fig. 6, for heptane, both with and without the catalyst. When the catalyst is present there is a steady rise in pressure above the normal curve, commencing at about 130—140°. Chemical action must be proceeding at or below this temperature. Heating was continued up to 275°; here an unexpected change took place, which must be regarded as a kind of rapid combustion, not an explosion or detonation. The mercury was pushed down the capillary tube with considerable speed, and when it was brought back to zero by raising the manometer, a big increase of pressure was registered. Thereafter, the curve proceeded normally. At the end of the experiment, the bulb was coated with a carbon deposit, and the remaining gases contained carbon monoxide and dioxide. There was none of the usual peculiar smell after heating in the bulbs nor any gummy residue.

(*b*) *Lead tetraethyl.* The remarkable inhibiting properties of this substance were very evident: in every case examined, it either completely obliterated the inflexion in the pressure–temperature curve, or, if a rise did occur when smaller quantities were used, this took place at higher temperatures but was exceedingly small, denoting only slight chemical change with increase in number of molecules. The effect of lead tetraethyl, therefore, is to prevent or reduce that particular chemical change which occurs at the *C.I.T.* A typical example illustrating this fact is given in Fig. 7 for *iso*-pentane, which normally gives a well-defined and easily observed rise of pressure at the *C.I.T.*, but in the presence of 1% of lead tetraethyl there is no sign of a break in the curve up to the highest temperature studied, *viz.*, 298°. On cooling the tube, no gum formation was obtained and the characteristic odour of the oxidation products was absent. In some cases, the bulb was cooled and reheated, and the second curve was then generally in close agreement with the first.

FIG. 7.

(a) iso*Pentane without lead tetraethyl.*
(b) „ *with* „ „

The inhibiting action of lead tetraethyl in oxidation appears to be more general, as the following examples show. The gumming of cracked spirit is attributed chiefly to the formation of peroxides by the "dienes" present. More than a year ago, two samples of cracked spirit were enclosed in glass cylinders, only one of them containing 1% of lead tetraethyl, and at the present time this remains clear and colourless, whilst a thick gum has collected at the bottom of the untreated sample, which is now yellow. These results seem to support Callendar's statement that the action of the lead tetraethyl is to prevent the formation of peroxides. The conditions are, however, entirely different in the two experiments: in the one just described, the temperature is that of the room, and therefore the lead tetraethyl remains as such; at high temperatures it is decomposed, and any negative action must be exerted by the lead itself.

A second experiment was carried out with equal volumes of a light lubricating oil contained in four separate flasks. No. 1 flask was heated to 250° with constant stirring, and then cooled. It had darkened rapidly and become almost opaque. No. 2 contained

lead tetraethyl and during the same treatment underwent little change except in colour (from light yellow to a light reddish tint), but was otherwise quite transparent. The oils in Nos. 3 and 4 flasks, of which only the former contained lead tetraethyl, were exposed to sunlight for some weeks. The latter darkened gradually, and the final appearances of these samples were identical with those of Nos. 1 and 2, which had been heated. In all cases a solid was deposited after several months' standing.

Further evidence of the negative catalytic action of lead tetraethyl is given by dynamic oxidation tests. Air (free from carbon dioxide) was passed through the oil heated to a known constant temperature, then through a series of U-tubes, two empty for collecting light oily products and part of the water, two filled with calcium chloride, and one with soda lime for carbon dioxide estimation. Experiments were carried out (i) heating the oil alone without air bubbling through, (ii) passing air through the heated pure oil, (iii) passing air through the heated oil containing 1% of lead tetraethyl. The weights of carbon dioxide and water produced were determined, and the oil after treatment was examined quantitatively for hard asphalt, coking test (R.A.F.), and acidity. The first experiment was carried out at 200° for 12 hours, and the rate of air flow was 15 litres per hour. The untreated oil darkened very rapidly, becoming almost black, whereas the sample containing lead tetraethyl remained pale yellow for more than 3 hours, after which it darkened slowly, showing that the catalyst was gradually losing its effectiveness. The coking tests, etc., indicated that the treatment was too severe for this oil; the experiments were therefore repeated at 180° with an air-flow of 10 litres per hour, and were stopped at intervals of 2 hours for analysis of the oil and for the weighing of the water and carbon dioxide. These results are in Table IV, and two points are brought out clearly, *viz.*, the inhibiting action of lead tetraethyl (which, however, decreases slowly), and, secondly, the fact that water is produced during oxidation, but is partially suppressed by the lead tetraethyl. This second point seems to favour the theory of primary dehydrogenation, to be discussed later.

Moisture.—When hydrocarbon–air mixtures were heated with appreciable quantities of water, the pressure–temperature curves were peculiar in that they were exceedingly irregular, even for temperatures just above the boiling point of water, and appreciably higher than the normal curve. Apparently water exerted some chemical or catalytic action, and it was decided to try the effect of eliminating moisture. Accordingly, the bulb was dried as far as possible by heating it in a current of dry air; it was then filled with

TABLE IV.

* Determined at 70° F. in a No. 1 Redwood viscometer.

dry oxygen, and hexane was introduced. To the neck of the bulb was attached a tube containing phosphorus pentoxide, and the apparatus was fitted up and allowed to remain for 2 weeks, after which the pentoxide tube was sealed off and a reading taken. It was found that up to 275° there was only a very small rise of pressure above the normal curve, equal to about 10% of that usually occurring.

Contents of Bulb after Heating.—Qualitative tests only have been carried out, and in view of the work recently published by Callendar (*loc. cit.*), the project of quantitative work was abandoned. After being cooled, the contents of the bulbs possessed a peculiar penetrating smell, somewhat resembling that of a terpene. Water (even at temperatures just above the *C.I.T.*), aldehydes, acids, and oxides of carbon were detected, but no peroxides. In the case of all paraffins, however, a certain amount of gum was formed, light yellow for moderate temperatures, black for high temperatures. It was necessary to ascertain if these gums were produced during the process of heating, or if they were formed on cooling. Two test-tubes containing small quantities of octane were heated in a glycerol-bath to 250°, one tube being completely immersed, and the other partially. A brownish gum was observed on the exposed, and hence, cooler, part of the latter tube, whilst the other tube was clear when removed from the bath, but on subsequent cooling the condensed liquid was of a pale yellow colour. It is assumed that

the gums are condensation products of the aldehydes which have been produced at the higher temperatures. Further, when any bulb containing paraffin hydrocarbon is heated above the *C.I.T.* and cooled, there is a fall of pressure, and after reheating, the derived pressure–temperature curve is lower than the first.

Comparative Results for Paraffin Hydrocarbons.—Since the temperature at which initial oxidation occurs is dependent on various factors, a series of experiments was arranged so that conditions were more comparable, and the following details were taken into consideration: (1) The bulbs were of the same material and volume; (2) the rates of heating were identical as far as possible; and (3) the hydrocarbon vapours were in equimolecular proportion.

In Table V are the *C.I.T.*'s of several hydrocarbons of the paraffin series determined under these constant conditions, and also other data appertaining to them. An unsuccessful attempt has been made to discover some physicochemical significance of this initial oxidation temperature, but graphical methods show no linear relationship between these temperatures and boiling point, spontaneous-ignition temperature, heat of formation, or flash-point. The following conclusions, however, are drawn from these figures:

(i) The *C.I.T.* is lowered by increase of molecular weight.

(ii) The temperature for normal hydrocarbons may be below that of the isomerides.

(iii) There is a general parallelism between the *C.I.T.*'s and spontaneous-ignition temperature, both decreasing with rise of molecular weight.

(iv) The flash-point is lowered, whilst the *C.I.T.* is raised, when the molecular weight decreases.

TABLE V.

The Mechanism of the Reaction and its Bearing on Detonation.

Two theories have been advanced to explain the primary action of oxidation of paraffin hydrocarbons: the older hydroxyl theory of Bone, and the recently advocated "peroxide" theory of Callendar (*vide supra*). The latter theory possesses no advantage over the former, and differs from it merely in postulating the interposition of two oxygen atoms in place of one between a C–H or C–C linkage. It is true that peroxides have been detected by passing vapour–air

mixture through heated tubes and suddenly cooling the products, the effective yield being increased when the experiment was carried out with droplets, but the experiments of Callendar are inconclusive in that they do not show definitely that the peroxides are alkyl or dialkyl peroxides and not hydrogen peroxide. Even if the former are present they may be the result of secondary oxidation of unsaturated hydrocarbons previously produced, for these substances have been proved to yield peroxides readily. Moreover, there is the difficulty that the volume (or number of molecules) increases at the temperature of initial oxidation to the extent of 15—20% of the number of hydrocarbon molecules present. Peroxide formation can only occur with decrease in the number of molecules, and a simple peroxide decomposition cannot increase the final number of molecules. The pressure–temperature curves given on p. 1559 indicate a sharp rise in the number of molecules at the *C.I.T.*, followed by a small decrease in pressure below the normal curve, indicating chemical change occurring with decrease in the number of molecules.

Stability of Paraffin Hydrocarbons.—This depends on the molecular weight and configuration of the molecule. In accordance with the researches of Berthelot, the effect of heat may be summarised in the reversible reactions

(i) $C_nH_{2n+2} \rightleftarrows C_nH_{2n} + H_2$ (lower temperatures).
(ii) $C_nH_{2n+2} \rightleftarrows C_{n/2}H_n + C_{n/2}H_{n+2}$ (higher temperatures).

Many objections have been raised against this theory of a state of equilibrium, and in actual practice several side reactions may be concurrent, especially at higher temperatures. At 300—400°, however, there is an undoubted production of hydrogen, but this is always accompanied by molecular changes.

A priori reasoning might lead one to conclude that with increasing hydrogen–carbon ratio the former element would split off more easily. Such, however, is not the case, and methane, with its higher proportion of hydrogen, is more stable than any member of the series. For hydrocarbons of this series, the heat of formation may be taken as a measure of the mean stability of the carbon atoms in the molecule. The molecular heat of formation increases with the number of carbon atoms present, but the heat of formation per carbon atom diminishes as shown by Thomsen's results :

Hydrocarbon.	Heat of formation (constant volume).	Mean heat of formation per carbon atom.
Methane (CH_4)	+16·5 Cals.	16·5 Cals.
Ethane (C_2H_6)	22·1	11·05
Propane (C_3H_8)	25·4	8·46
Butane (C_4H_{10})	29·1	7·27
Pentane (C_5H_{12})	1·5	6·30

The same investigator has shown that the average thermal values of the C–C and C–H linkages are approximately the same, so that Mean heat of formation/Valency of carbon may be taken as a relative measure of each valency attraction. There is no experimental justification for assuming that in a given molecule the forces of attraction of the C–C and C–H linkages are equal, and evidence is in favour of the view that there are some hydrogen atoms which are more easily split off than others. Besides the position of the hydrogen atoms and molecular weight, isomerism will be a contributing factor to the ease or otherwise of splitting off the hydrogen atoms.

A comparison of hydrocarbons of the different series presents more difficulty in that the naphthenes and aromatics contain ring compounds, but for those members containing the same number of carbon atoms, *viz.*, hexane, *cyclo*hexane, and benzene, the proportion of hydrogen and heat of formation decrease in the order given, whilst it seems probable, from the scanty data available, that the ease with which hydrogen is split off is greatest for that molecule containing the highest ratio of hydrogen atoms to carbon atoms, the latter being constant in each series.

Primary Dehydrogenation Theory.—The view held, as the result of the experimental work, is that primary oxidation consists in the direct combination of oxygen with those atoms of hydrogen which are most easily split off from the hydrocarbon molecule, the initial products being unsaturated hydrocarbons, containing one or more double bonds, and water. This will account for (*a*) the increase in the number of molecules at the *C.I.T.*, *e.g.*, $2C_2H_6 + O_2 \longrightarrow 2C_2H_4 + 2H_2O$; (*b*) the high percentage of water in the products formed above the *C.I.T.*, this percentage being only slightly increased at considerably higher temperatures; and (*c*) the appreciable proportion of unsaturated hydrocarbons formed near the *C.I.T.*

Secondary reactions ensue, the oxygen combining with the unsaturated hydrocarbons to produce aldehydes, peroxides, etc. This reaction reveals itself in the slight fall in the pressure–temperature curves just above the *C.I.T.* Striking confirmation of this was obtained by heating amylene–air as in the above experiments : an actual depression in the curve occurred, commencing at 232° and continuing up to 254°, after which a gradual rise above the theoretical curve followed. No water was detected in the finally cooled products; but considerable gum formation had taken place.

From the foregoing statements on stability it would appear that methane is the most stable of the hydrocarbons towards oxygen. This is actually the case and it must be observed that the difficulty of oxidation is increased by the probability that two hydrogen

atoms must be removed from one carbon atom to form water, leaving CH_2 residues, which react eventually in various ways. Ethane is far less stable and one hydrogen atom may be removed from each of two adjacent carbon atoms to yield a double bond. Similarly, the higher hydrocarbons can give rise to conjugated double bonds which will enter vigorously into secondary oxidations. In the two cases which have been studied, the normal hydrocarbons appear to be more active than the isomerides. If this statement is of general validity, it may be that the isomeride with the fewest carbon atoms in the main chain is most stable, or that side chains retard removal of hydrogen atoms, or that two or more hydrogen atoms attached to adjacent carbon atoms are more readily oxidised.

Thermal Value of the Dehydrogenation.—The removal of hydrogen with formation of water will be exothermic, and the elimination of only two hydrogen atoms from heptane will produce considerable heat :

$$C_7H_{16} + O = C_7H_{14} + H_2O + 38 \text{ Cals.}$$

These two factors, *viz.*, (*a*) increase in number of molecules, and (*b*) production of heat, must play a considerable part in the detonation of hydrocarbons in petrol engines. The former increases the maximum pressure attained slightly above that calculated from the compression ratio, whilst the second factor may under suitable conditions raise the temperature above that of spontaneous ignition, thus giving rise to pre-ignition. During the slow heating of these hydrocarbon–air or oxygen mixtures, the heat of the initial reactions is dissipated by conduction and radiation, and it has been shown (Callendar) that under such conditions the mixture can be heated to temperatures above 650° without explosion. This is not the case, however, for sudden heating by compression, and, on the assumption that this takes place adiabatically, the theoretical rise in temperature above that resulting from compression alone may be calculated. For a 10% heptane–air mixture, if only two hydrogen atoms are removed from the molecule to produce water, and if the high value of 0·5 cal. is taken as the specific heat of heptane (liquid), the rise in temperature due to primary dehydrogenation alone is calculated to be more than 400°. A final temperature of about 370° is obtained by a compression ratio of 3 : 1, so a theoretical maximum of at least 770° is possible. The high value for the specific heat of heptane is used because it has been shown that condensation of these vapours can occur during compression.

This factor must be considered in the question of detonation. In internal combustion engines, to the heat of compression must be added the heat liberated by primary dehydrogenation, which must

considerably raise both the pressure and the temperature of the mass of vapours. The increase in the number of molecules above the *C.I.T.* will also contribute to a rise in pressure. Primary dehydrogenation must then be the main cause of pre-ignition and detonation, and the ease of detonation increases with the hydrogen ratio. It is significant that the unsaturated hydrocarbons are more unstable and possess lower ignition temperatures than the paraffins, yet the latter detonate more easily. The reason is that the temperatures attained by equal compressions are far from comparable. Any factors, therefore, which will reduce the amount of heat liberated by primary dehydrogenation will diminish the tendency to detonation and allow of higher compressions. They may include reduction of paraffins, especially those of high molecular weight, dilution, negative catalysts, or a preliminary slow heating to a temperature above the *C.I.T.* Moreover, at higher speeds of the engine, the time may be too small to allow of completion of the chemical reactions involved at the *C.I.T.*

Action of Metallic Catalysts.—These are divided into two groups : (*a*) promoters of detonation; (*b*) " antiknocks." They have been classified also as positive and negative catalysts, and there is some apparent connexion between the ease of oxidation and oxide stability, and their catalytic action. The antiknock metals promote the combination of hydrogen and unsaturated hydrocarbons at low temperatures, and it is now suggested that their action as antiknocks depends upon the complete or partial prevention of dehydrogenation with its attendant water and heat formation, thus reducing the final temperature at the end of the compression stroke. From what has been said, it may be concluded that positive catalysts, *e.g.*, platinum, promote the reaction $H_2 + O \longrightarrow H_2O$, and that lead tetraethyl inhibits this change or even poisons the direct action of oxygen on the hydrocarbon, but there is no doubt that the amount of water formed is either nil or almost negligible.

The Action of Unsaturated Hydrocarbons and Aromatics.—These hydrocarbons have an appreciable effect in lowering the detonating qualities of a petrol, but large percentages must be present. It is well known, for example, that " cracked spirit " can be subjected to higher compression ratios than straight spirit, and this raises an objection to the peroxide theory of Callendar. Cracked spirit contains unsaturated hydrocarbons of the olefin type and also dienes even after refining; these are essentially peroxide-forming, and should increase rather than decrease detonation. It is suggested, therefore, that these hydrocarbons are effective as antiknocks in that they (*a*) have a smaller hydrogen content and are less likely to be dehydrogenated, *i.e.*, they act partially as diluents; and (*b*) they

may enter into combination with the hydrogen evolved from the paraffins, by increasing the active mass of unsaturated hydrocarbons. Thus in the reaction $C_nH_{2n+2} \rightleftarrows C_nH_{2n} + H_2$, the olefins produced are reinforced by the unsaturated hydrocarbons of the petrol, and even of the aromatics, and so tend to reverse the reaction with a decrease in the active mass of hydrogen. These unsaturated hydrocarbons are reducing agents. Benzene itself has a tendency to combine with hydrogen at low temperatures. In view of the nature of unsaturated hydrocarbons, their instability, and their tendency to form peroxides, their behaviour in an engine is contrary to expectation; the above may be the real explanation of the facts, and perhaps secondary oxidation products, such as aldehydes, peroxides, etc., are practically negligible on account of the time factor.

The Action of Aromatic Amines.—Any substance that combines with hydrogen under conditions prevailing in the engine, *i.e.*, that competes with oxygen for the hydrogen split off from the hydrocarbons, will tend to decrease detonation. The action of substances such as aromatic amines may be due in small part to dilution, but chiefly to the fact that they undergo decomposition, leaving residues which can unite with hydrogen. In the simplest case, aniline, the possible changes are

$$\text{(i)}\ C_6H_5{\cdot}NH_2 = C_6H_5{\cdot} + {\cdot}NH_2,$$
$$\text{(ii)}\ C_6H_5{\cdot} + {\cdot}NH_2 + 2H = C_6H_6 + NH_3.$$

The effectiveness of such reagents will therefore depend on (*a*) their concentration, (*b*) the ease (or temperature) of decomposition, and (*c*) the thermal action with hydrogen, which should be as small as possible and preferably endothermic.

The action of iodine is capable of some similar explanation, and it is noteworthy that, unlike iodine, bromine and chlorine are slight "knock" inducers; moreover, it is suggestive that their compounds with hydrogen are exothermic, whereas hydrogen iodide is endothermic. Finally, there is the suggestion contained in the above that the ethyl groups from the decomposition of lead tetraethyl increase its efficiency by reducing the effective mass of hydrogen.

Ignition of the Liquid Phase.—The published results of ignition temperatures are far from concordant even when determined by similar methods, and the two factors already discussed, *viz.*, increase of volume at the *C.I.T.* and the exothermic nature of this change, must be considered in methods based upon compression. Moore's method (*J. Soc. Chem. Ind.*, 1917, **36**, 109) consists in allowing drops of the liquid to fall on a hot platinum dish containing oxygen. The liquid phase, however, is less stable than the vapour (see above),

and the results are lower than those obtained by the compression method. Doubtless, too, the size of the droplet and the catalytic effect of the surface play an important part, and this subject is reserved for a future paper. It might be argued that the ignition point of the liquid phase is lower on account of the adsorption of peroxides by the liquid, according to the views of Callendar, but it is known that peroxides do not affect the ignition temperature to any appreciable extent. This constitutes a serious objection to the peroxide theory. According to the views elaborated in this paper, the greater instability of paraffin droplets is due to the great concentration of molecules in the neighbourhood of the drop, with the attendant increase of chemical activity near the surface, and to the fact that the liquid phase absorbs far more heat than the vapour. Thus some of the heat of primary dehydrogenation may be used in suddenly heating the hydrocarbon above its ignition temperature.

CCVII.—*Striated Photographic Records of Explosion-Waves.*

By COLIN CAMPBELL and DONALD WHITLEY WOODHEAD.

IN a previous paper (J., 1926, 3010) attention was directed to the notable appearance of a moving-film record of the explosion-wave passing through the mixture $2CO + O_2$. Fig. 11 in that paper is remarkable in that closely striated illumination is recorded behind the trace of the wave-front, and not the uniform illumination which occurs in the great majority of previously published photographic records of explosion-waves. Close examination of some of Dixon's records (*Phil. Trans.*, 1903, *A*, **200**, 315; notably Fig. 11, $2CO + O_2$, and Fig. 21, $CS_2 + 2O_2$) discloses striations similar to those now described, but they are ill-defined and do not appear to have been noticed hitherto. The present paper deals with experiments made with a view to define some of the conditions required for the production of such striated records.

The explosive mixture under observation (moist $2CO + O_2$, unless otherwise stated) was contained in a horizontal glass tube 2—3 m. long, usually 15 mm. in internal diameter and 2·5—3·0 mm. in thickness of wall, open at the far end. The flame in this mixture was initiated by the explosion of a hydrogen–oxygen mixture contained in a similar tube in a co-axial position, complete separation of the two mixtures until a very short time before firing being

effected by a metal shutter. The flame was photographed by means of a drum-camera having a peripheral speed of about 45 m./sec. Details of the experimental arrangements are given in our former paper (*loc. cit.*).

The first striated record we obtained was given by the flame in the mixture $2CO + O_2$ to which about 2% of hydrogen had been added (Fig. 1). The mixture was fired by the flame produced by detonating the mixture $2H_2 + O_2$. The flame edge in this record presents a regular undulatory appearance, but the mean rate of progress of the wave is uniform and characteristic of the explosion-wave in this mixture (about 1770 m./sec.). The *apparent* propagation is *per saltum*, each spurt taking place at approximately equal intervals of 45 mm. in the tube, the frequency of the undulations in this record being thus of the order of 39,000 per second. The major portion of the luminosity behind the wave-front is segregated into bands, each of which appears to have its origin in one of the undulations of the wave-front. The bands appear to be equally spaced; they are straight in this record, but definitely curved in others. They are inclined at a small angle to the horizontal in a direction opposite to that of the movement of the explosion-wave, suggesting a reverse motion at some tens of thousands of metres per second. The very high value of this rate is not favourable to the simple interpretation of the bands as a series of waves sent back from the front of the explosion-wave through the burning gases. Moreover, in some records the bands are horizontal, and in two they actually slope forward.

Mode of Ignition.—The production of striated records from $2CO + O_2$ was independent of the means taken to establish the explosion-wave, for they were obtained in equal intensity and with a similar period when the method of ignition was by the explosion-waves from (i) mixtures of hydrogen and oxygen other than $2H_2 + O_2$; (ii) from $C_2N_2 + O_2$; (iii) from $2H_2 + O_2$, which had itself been ignited by a uni-directional spark; or by (iv) direct sparking of $2CO + O_2$ containing about 2% of hydrogen. (Without the presence of a little hydrogen, we failed to obtain the explosion-wave in moist $2CO + O_2$ by direct sparking in a tube 12·5 mm. in diameter and 8 m. long.) In each of these experiments, the photographic record was taken after the explosion-wave had been established. We were unable to detect any differences in records made in similar experiments on Kodak orthochromatic film and on Lumière paper. Figs. 2, 3, 6, and 8 are copies of the negatives obtained with Lumière paper; the remainder are prints made from Kodak films.

Composition of Gases.—When increasing quantities of carbon

monoxide in the mixture $2CO + O_2$ were replaced by hydrogen, the striations remained distinct until the mixture contained about 3% of hydrogen; as the hydrogen content was increased up to about 6%, they became rapidly less distinct; and they were no longer visible when between 6 and 20% was present. Figs. 2, 3, and 4 show this gradation of appearance with 2·2, 3·6, and 10%, respectively, of hydrogen. The compositions of the mixtures are recorded in Table I.

TABLE I.

Mixtures saturated with water vapour at 15°.

Fig.	CO.	O_2.	H_2.	Appearance of record.
	100	50	0	Striated.
1	98	50	2·	,,
2	96·7	50	3·3	Faintly striated.
3	94·6	50	5·4	,, ,,
	91	50	9	Not striated.
4	85	50	15	,, ,,

The distance between successive undulations in the wave-front may be dependent to some extent on the amount of added hydrogen, but this cannot yet be stated with certainty since, as will be shown later, the distance is dependent on the internal diameter of the experimental tube, and differences in the measured distances may be due to slight indeterminate variations in the bores of the glass tubes used.

The presence of hydrogen in a carbon monoxide–oxygen mixture is not essential for the production of a striated record, for such records were obtained of the wave in the mixture $2CO + O_2$, not only when it was saturated with water vapour at room temperature, but also when fairly well dried with sulphuric acid.

The addition of diluent gases (carbon monoxide, nitrogen, and oxygen) to $2CO + O_2$ did not produce any change in the appearance of the records, striations being obtained in each experiment with the mixtures $3CO + O_2$, $4CO + O_2$, $CO + O_2$, and $2CO + O_2 + N_2$. The distance between successive undulations in the wave-fronts did not vary substantially from 45 mm. when the tube was of 15 mm. internal diameter.

Some experiments were made with $2H_2 + O_2$ in which small amounts of the hydrogen had been replaced by carbon monoxide, but no striated records were obtained. Mixtures of hydrogen and oxygen varying in composition from $6H_2 + O_2$ to $2H_2 + 3O_2$ also failed to give striated records. In order to increase the actinic value of the flame in the more dilute mixtures of these gases, the experimental tube was dusted with thorium oxide, and under these conditions very faint striations were obtained only with mixtures containing a large excess of oxygen.

The explosion-wave in certain mixtures of oxygen with methane, ethane, ethylene, carbon disulphide, and cyanogen also gave striated records similar to that reproduced in Fig. 1.

Initial Pressure.—A number of experiments were made with $2CO + O_2$ at initial pressures greater than atmospheric, the experimental conditions being the same as before, save that the far end of the tube was closed. The compression apparatus described by Ellis (J., 1923, **123**, 1435) was used. Striated records were given in all experiments, and the distances between successive undulations were not materially different from those obtained at atmospheric pressure, being 46 and 45 mm. when the initial pressures were 2 and 3 atm., respectively. Fig. 5 is the record obtained at 2 atm. The narrowness of the exposed strip of film is due to the very rapid shattering of the explosion tube after the passage of the wave.

Diameter of Tube.—When explosion tubes of internal diameters less than 15 mm. were used, the records bore striations similar to those obtained with the 15 mm. tubes, but the undulations in the traces of the wave-fronts were nearer together. The striations were thus more closely packed and less easily resolvable. Tubes having internal diameters of 12·5 and 10 mm. were used. The lengths of the undulations, constant in each record, are given in Table II.

TABLE II.

$2CO + O_2$ *saturated with water vapour at* 15°.

Bore of tube, D (mm.).	Distance between undulations, L (mm.).	Ratio L/D.
15	45	3·0
12·5	36	2·9
10	29	2·9

It appears that, within the limits examined, the distance between the undulations is closely related to the bore of the experimental tube. Since the velocity of an explosion-wave is normally unaffected by the diameter of the tube through which it passes, the frequency of the undulations is also related to the bore.

Fig. 6 is a record of the explosion-wave in $2CO + O_2$ contained in an 8 mm. tube; it shows undulations in the wave-front 25 mm. apart ($L/D = 3·0$), with striations lying closely together in the burning gases behind. An additional variant made in this experiment was in the thickness of the walls of the tube. The tube was composite, consisting of two portions cemented together in a metal sleeve (represented on the record by the broad vertical band). The internal diameter was constant throughout, but the thickness of wall changed at the junction from 4 mm. to 1·5 mm. No difference in the characteristic undulations of the trace of the wave-front

in the two portions can be detected. In the diagrammatic representation of the tube given in Fig. 6 (and in succeeding figures) the unshaded area indicates the position of the window in the paper covering of the tube, the solid areas representing the thickness of the tube wall; the diameters are not to scale.

Fig. 7 shows the explosion-wave passing from a 15 mm. into a 9 mm. tube. The two portions of this experimental tube were fused together, and the change in diameter at the junction was made as abrupt as possible. The velocity of the explosion-wave is unaltered by the change in diameter of the tube (see Campbell, J., 1922, **121**, 2483), but the spacing of the undulations is decreased immediately on the entry of the wave into the narrower tube. In the latter, $L = 28$ mm., whence $L/D = 3{\cdot}1$. The tube was intact after the experiment. The striations in the narrow portion of the tube do not appear to exist entirely independently of those in the wider portion, for near the junction the former are apparently retarded, and more markedly so in the gas some distance behind the wave-front. We have here an explosion-wave displaying undulations of two distinct frequencies simultaneously in different portions of the same tube.

A further interesting observation has been made in records showing both detonation-waves and slow flames accelerating rapidly towards detonation. Whereas the explosion-wave is striated, the earlier flame is comparatively uniform, and the striations are usually sharply confined to that portion of the gas which has detonated. In other words, the burning gases in one portion of a tube may show striations, whilst in another portion of the same tube the illumination is normal.

A few of the slow pre-detonation flames which we have photographed show traces of striations of a period similar to those in the later explosion-wave. Because of their narrow and regular spacing these undulations must be regarded as distinct from those of the "vibratory movement" or of the "uniform movement" that precedes it. The undulations of the latter are well-known features of slow flames and result from the establishment of resonance, the flame-front acquiring an undulatory motion leading to vibrations which vary in amplitude according to the extent of the resonance, and in period according to the length of the tube (Mason and Wheeler, J., 1920, **117**, 36).

Photographic Definition.—In order to avoid fogging of the photographic film by extraneous reflexions, the experimental tube was usually enclosed in a sheath of light-proof paper, the light from the explosion reaching the camera through a horizontal slit cut in this covering. Usually the width of this window was equal to the

internal diameter of the tube. The records already described (with the exception of Fig. 6) were obtained through such a window. Although reduction in the width of the window decreased the intensity of the exposure, the striations did not become more clearly defined. However, enhanced photographic definition was secured when a 4 mm. window was cut near the upper (instead of at the middle) portion of the tube. Fig. 8 was obtained with such an arrangement, the position of the window (viewed horizontally from the camera) being shown diagrammatically in the figure. This record is of further interest in showing how the striations persist in the burning gases for some time after the wave-front has reached the open end of the explosion-tube.

An experiment was arranged in which a central window 2 mm. and an upper window 4 mm. wide were cut in the paper sheath over different lengths of the same tube. The record (Fig. 9) shows the clearly defined striations from the upper window, whilst the exposure from the central window produced a greater number of less well-defined striations. In a further experiment, a lower window 4 mm. wide was made in the second portion of the same tube. The record (Fig. 10) shows that there was in the illumination from each of these windows an independent series of undulations out of phase with one another, their alternate appearances occurring at approximately equal time intervals (about 1/80,000 sec.). Undulations visible through narrow central windows have periods considerably shorter than those recorded when the window is of the same width as the diameter of the tube. A similar, but temporary, effect has been observed through wide windows during the first 20 cm. of travel of the flame in $2CO + O_2$ after its ignition by the flame of $2H_2 + O_2$ (*e.g.*, in Fig. 1), before the flame-speed had completed its fall to that normal for the detonation-wave in $2CO + O_2$.

Summary.

Some of the conditions required for the production of an apparently undulatory form of the explosion-wave have been examined. This form appears to be characteristic of the wave in the mixture $2CO + O_2$ and in some of the more dilute mixtures of carbon monoxide and certain other gases with oxygen or oxygen and nitrogen. The presence of about 6% of hydrogen in $2CO + O_2$, saturated with water vapour at the ordinary temperature, eliminated visible undulations.

Increase in the initial pressure of the gaseous mixtures to 3 atm. did not effect any definite change in the distance between the undulations, but this was found to depend directly on the internal diameter of the explosion-tube. The most sharply defined records

were obtained when only the layers of gas near the walls of the tube were visible to the camera. The undulations visible through a window in the extreme upper portion of a tube occurred alternately with those visible through the extreme lower portion.

The experimental evidence is not yet sufficient to afford a complete interpretation of the striated records. It does not indicate whether they are due to induced vibrations of the apparatus or to a periodic propagation of the explosion-wave. It can be said, however, that the striations are not due to mechanical chattering of the heavier parts of the camera, since undulations of two different periods can be obtained on one and the same record.

An interpretation based on the assumption that the records disclose what is actually occurring in the flames has been communicated to us by Mr. E. F. Greig, who suggests that the part of the wave-front, the light of which affects the photographic film, traverses a helical path on the walls of the tube. The extension of this interpretation to the illumination from the outer layers of the burning gases *behind* the wave-front would also imply a rotation of the source of light affecting the photographic film. It is clear that a wave being propagated along a helical path could account for the dependence of the length of the undulations on the bore of the tube and for the alternate production of undulations in the records from the upper and lower windows. Further experiments are in progress to test the validity of this and the other possible interpretations mentioned above.

We wish to acknowledge our indebtedness to the Chemical Society and the Brunner–Mond Research Fund Committee for grants towards the cost of photographic materials and apparatus, and to Mr. A. C. Finch, B.Sc., for laboratory assistance.

THE UNIVERSITY, MANCHESTER. [*Received, April 14th,* 1927.]

CCVIII.—*The Nature of the Sintering of Active Copper Catalysts.*

By FREDERICK HUBN CONSTABLE.

THE conceptions of Taylor (*Proc. Roy. Soc.*, 1925, *A*, **108**, 106) and of Armstrong and Hilditch (*ibid.*, p. 111) concerning the structure of active metallic surfaces seem to have progressed very far in such a direction as to attribute to the centres of activity a quantity of energy that would approach the heat of vaporisation of the metallic atoms (see Constable, *ibid.*, p. 355). Armstrong and

Hilditch have assumed that the nickel atom responsible for hydrogenation reactions is actually gaseous at the instant of the chemical change. Pease (*J. Amer. Chem. Soc.*, 1923, **45**, 1196, 2238, 2297) and Constable (*Proc. Roy. Soc.*, 1926, *A*, **110**, 283), while fully convinced of the existence of centres of activity, do not attribute to them such great energy, the facts being much more in accord with the assumption that they consist of groups of atoms frozen in such a manner that they can still possess intense fields of external force, while being far removed from the condition of vapour.

Taylor (*loc. cit.*) laid considerable stress on the sensitiveness of the surface to heat treatment: "A granule of the catalyst must therefore possess, in part, the ordered arrangement of the atoms found in crystals of the metal. The sensitivity of the product to even moderate heat treatment, whereby marked sintering occurs, suggests that this completely ordered arrangement of the atoms has not been attained, and that here and there, on the surface of a mainly crystalline granule, there are groups of atoms in which the processes of crystallisation are not yet complete." In reality the process of sintering is more complicated than this,* for the boundaries of individual grains are in contact, and therefore the granular structure is itself capable of such a growth as to reduce the area of the exposed surface in a marked degree. Thus, evidence that heat treatment reduces catalytic activity is valueless by itself as a criterion that some of the active centres on the surface have collapsed owing to the increased thermal agitation, for the total active surface has also been reduced in a marked manner. It is therefore essential for the solution of the problem to measure both the surface area of the catalyst and its catalytic activity.

The investigations of Dunn (*ibid.*, 1926, *A*, **111**, 210) provide a means of elucidating this problem. If the course of oxidation of a metal be followed, both by measurements of the electrical conductivity of the metal–oxide mixture, and by estimation of the thickness of the surface film of oxide by means of its colour in normally reflected light, a direct measure of the surface area of the catalyst can at once be obtained. Unfortunately, it is only possible to estimate the equivalent air thickness of the oxide film, *i.e.*, the thickness of a film of air that would produce the same colour effects, and thus the absolute measurement of the area of the surface is not possible by this method, without introducing very distinct assumptions as to the refractive index and nature of the oxide. It is, however, possible to measure the fractional decrease in the

* There are at least two variables: the number of centres of activity per unit area of the surface, and the relative rate of reaction on each individual centre of activity.

surface area when the catalyst is exposed to a high temperature. Let S be the surface area of the catalyst, C the conductivity of the film of metal supported on a China-clay rod, a the thickness of the oxide film, t the time the metal has been exposed to oxidation, and ρ the density of the oxide of mass W. Then, assuming that the electrical conductivity of the film is a measure of its metallic content (compare Palmer, *Proc. Roy. Soc.*, 1921, *A*, **103**, 444),

$$\rho S(da/dt)/W = -(dC/dt)/C \quad . \quad . \quad . \quad . \quad (1)$$

As the oxidation proceeds, the value of S must become smaller, and as its *initial* value only is important, it is necessary to measure da/dt and dC/dt at the commencement of the reaction. According to Dunn (*loc. cit.*; his conclusions are confirmed by the present work), the process is controlled by the rate of diffusion of oxygen through the protecting layer, and if W is the weight of the oxide formed in time t, then

$$W^2 = Kt \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where K is a constant. It was found that both the fall in the conductivity and the equivalent air thickness follow the law quoted above for the weight of oxide formed in time t, when the catalysts are rendered inactive by sintering. But for the most active catalysts the value of K obtained fell considerably with increasing time. Dunn showed this to be due to the influence of time on the oxide film: some hardening process apparently takes place which causes the film to become less permeable to oxygen. Therefore, in the case of active catalysts it is necessary to find the *initial* value of K in equation (2).

If c be the fall in conductivity, *i.e.*, $c = C_0 - C_t$, then $c^2 = K_c t$. Hence $dc/dt = \frac{1}{2}\sqrt{K_c/t}$; similarly $da/dt = \frac{1}{2}\sqrt{K_a/t}$. Thus equation (1) becomes

$$\rho S\sqrt{K_a}/W = \sqrt{K_c}/C \quad . \quad . \quad . \quad . \quad (3)$$

Let the symbols with suffix 1 relate to the active catalysts, and those with suffix 2 to the sintered catalyst; then dividing the two equations of type (3) for the active and sintered catalysts, respectively, after the same small time interval t from the commencement of the oxidation of each at the same temperature, we obtain

$$S_2\sqrt{K_{a_2}}/S_1\sqrt{K_{a_1}} = \sqrt{K_{c_2}/K_{c_1}} \quad . \quad . \quad . \quad . \quad (4)$$

The ratio of the area of the catalyst in its two states (*i.e.*, S_2/S_1) can thus be measured and compared with the fall in catalytic activity, without assuming any particular value for the refractive index of the copper oxide.

Experimental.

The films used were prepared as described previously (*Proc. Roy. Soc.*, 1924, *A*, **106**, 251). They were rendered active by alternate oxidation and reduction at 210°, and the nature of the departure from the parabolic law was studied, together with the effect of arrested oxidation. The fractional conductivities of the film of copper and the constants of the parabolic law are shown in Table I.

Table I.

t (mins.).	Fraction of original metal remaining.	c (ohm^{-1}).	$c^2/t = K_c$.
0	1·000	0·000	—
1	0·747	0·149	0·0222
2	0·671	0·193	0·0183
3	0·600	0·236	0·0159
4	0·558	0·261	0·0170
5	0·525	0·281	0·0157
6	0·494	0·299	0·0149
10	0·422	0·342	0·0117
15	0·349	0·385	0·0099

The fall in the initial conductivity noticed by Dunn was confirmed, some 18% being lost in five alternate oxidations and reductions. The fractions of the initial conductivities were plotted against time, so that each curve should be strictly comparable. If the arrested oxidation follows the same law, then the value of the constant so obtained would be of importance as a characteristic of the hardened oxide film produced in the second experiment. A difficulty arises in calculating the value of K_c for all curves after the first, because the origin of the later curves is not the point $t = 0$, $c = 1{\cdot}00$; this can be removed by considering later curves as part of a parabolic curve of the form $c^2 = K_c(t + \tau)$, and deriving K_c from the relation $2c.dc/dt = K_c$. The results so obtained are recorded in Table II.

The value of K_c is thus the same whether the oxidation has been arrested for 20 or 70 minutes; hence the sintering and hardening of the oxide is moderately rapid. The oxide formed during continuous oxidation has, however, a higher permeability to oxygen, since it does not have time completely to attain the final state, owing to the constant formation of a fresh layer. The result nevertheless confirms that the fall in the constant for the most active catalysts can be accounted for by the hardening of the newly formed oxide layer; thus it is necessary for the solution of equation (4) to compare the values of K in the initial stages of the oxidation.*

* It is fortunate that the values of K, both for the equivalent air thickness curves and for the fall in conductivity compared with time, fall in the same manner for the most active catalysts. Hence the average values may be used for comparison, and for solution of equation (4).

20	0·339				

The same film of metallic copper was studied by simultaneously measuring its conductivity and comparing its colour with a standard. An activated film, prepared at 210°, was sintered at 440° for 10, 50, 100, and 200 minutes, and its rate of oxidation studied immediately after each sintering. (After each experiment the film was reduced at 210° by carbon monoxide, and sintered for the requisite time for the next experiment.) It was more convenient to use an old rod coated with copper which had been oxidised and reduced a large number of times; there was thus less volatilisation of copper during the series of experiments than would have been found with a freshly prepared rod.

The results obtained with the old rod are recorded in Table III, which shows the validity of the parabolic law; α represents the equivalent air-thickness of the oxide film (in cm. $\times 10^{-5}$), and K_a is the corresponding constant ($K_a = \alpha^2/t$).

The mean values of K_c and K_a are used, since it is evident from Tables III A and B that the fall in the constants for the fully activated catalysts occurs in the results of both methods and to a strictly comparable extent (see footnote, p. 1581). The surface area is reduced to about one-third while the catalytic activity is reduced to about one-seventh; thus the reduction in the surface is somewhat more effective in reducing the catalytic activity than is the collapse in the actual centres existing on the surface.

It has therefore been shown that the active centres collapse when exposed to temperatures considerably in excess of those at which the surface was formed, and hence that these centres of activity are in a state of strain. But the coarse structure seems to collapse even more easily, suggesting that the energy present in the centres

of activity is not very greatly in excess of that possessed by the regular arrangement of the surface atoms. Thus the theory in the form advanced by Taylor, and by Armstrong and Hilditch, seems to be too drastic, and the more moderate views of Pease and Constable accord better with the experimental facts.

LABORATORY OF PHYSICAL CHEMISTRY,
CAMBRIDGE. [*Received, May 23rd*, 1927.]

CCIX.—*The Electroendosmosis of Aqueous Solutions through a Diaphragm of Sintered Glass Powder.*

By FRED FAIRBROTHER and HAROLD VARLEY.

GLASS capillaries and diaphragms of powdered glass have been used for many quantitative investigations on electrokinetic phenomena. A review of the earlier work (to the end of 1913) is given by Smoluchowski (Graetz, "Handb. d. Elektrizität u. des Magnetismus," Vol. 2, p. 366). Powis (*Z. physikal. Chem.*, 1915, **89**, 91), Kruyt (*Kolloid Z.*, 1918, **22**, 81), Freundlich and Rona (*Sitzungsber. Preuss. Akad. Wiss. Berlin*, 1920, **20**, 397), and Hepburn (*Proc. Physical Soc.*, 1926, **38**, 363; 1927, **39**, 99) have also used a glass–water interface for electrokinetic experiments.

The results of Lachs and Kronman (*Bull. International Acad. Polonaise*, 1925, **10**, *A*, 289), however, appear to throw some doubt on the quantitative value of previous work, for they found that the stream potentials through glass and quartz capillaries could be reproduced with an accuracy of only 14% under seemingly identical conditions, and they state that "the streaming potential has no constant value and is varying in time." Hence they argue that all results obtained for flow potentials of aqueous solutions in glass or quartz capillaries must be considered to be merely qualitative (*Rocz. Chem.*, 1926, **6**, 641). Such a conclusion necessarily involves also electroendosmosis of aqueous solutions through glass powder or capillary tubes.

The results now recorded, which were carried out before the work of Lachs and Kronman came to our notice, were the outcome of preliminary experiments with diaphragms of sintered Jena-glass powder, carried out with aqueous solutions prior to the use of such a diaphragm for electroendosmotic investigations in non-aqueous systems.

A diaphragm of sintered glass powder possesses the advantages of rigidity and simplicity, *i.e.*, no foreign material (glass wool, etc.) is required to keep the diaphragm in place, and the apparatus can

be made of the same kind of glass holding the diaphragm fused in position.

EXPERIMENTAL.

The apparatus employed was essentially that described by Fairbrother and Mastin (J., 1924, **125**, 2319), the central compartment A (*loc. cit.*) being replaced by a tube carrying the sintered diaphragm fused into its centre, and the capillary tubes, EE, extended to the sides of the diaphragm. The particular glass disc used, of sintered Jena "Geräte" glass, was of the closest grain manufactured (designated as G3/<7), and was approximately 2 cm. in diameter and 3 mm. thick. It was supplied fused in position by the makers, Messrs. Schott u. Gen. of Jena.

The diaphragm was cleaned first in alcohol or acetone to remove grease, and then in concentrated sulphuric acid. Air was removed from the pores by placing the tube carrying the diaphragm in a larger tube, and evacuating by a water pump; a small quantity of air-free water was then admitted to the containing vessel and allowed to boil under reduced pressure for some time, after which air-free water was allowed to fill the vessel. Before each series of estimations, the apparatus was well rinsed with the solution employed, several hundred c.c. being allowed to pass through the diaphragm over-night.

The value of l/q (the ratio of the effective length of the diaphragm to its effective cross section) was measured with several solutions in the manner described by Fairbrother and Mastin (*loc. cit.*). Each estimation was repeated many times with various voltages across the diaphragm. The individual readings showed good agreement. In Table I are the average values of l/q for each solution; they show a small increase with concentration, even in such comparatively well-conducting solutions.

TABLE I.

Solution.	l/q.	Solution.	l/q.
N/100-KCl	1·723	N/100-HCl	1·758
N/10-KCl	1·736	N/10-HCl	1·782
N/5-KCl	1·751	N/5-HCl	1·783
N/1-KCl	1·755		

In Table II are the results of electroendosmosis experiments with water and dilute hydrochloric acid. ET (in volt-seconds) is the product of the potential gradient across the diaphragm and the time for the transport of 1 c.c. of solution. ζ, the potential of the double layer as calculated from the Helmholtz–Smoluchowski formula, is also given for comparison; in making this calculation, a value for l/q of 1·77 has been assumed.

For some time no great difficulty was experienced in obtaining concordant and reproducible results, which are given as Series I.

TABLE II.

	Series I.		Series II.	
Solution.	*ET*.	ζ (volt).	*ET*.	ζ (volt).
Water	4,520	−0·0557	14,880	−0·0169
N/5000-HCl	4,880	−0·0516	26,700	−0·0094
N/1250-HCl	5,668	−0·0444	43,500	−0·0058
N/400-HCl	6,546	−0·0394	?	0·00
N/100-HCl	10,200	−0·0247	17,970	+0·0140

At this time, the glass was still negatively charged in *N*/40-hydrochloric acid. During experiments with this solution, however, effects similar to those found by Lachs and Kronman were first observed, *i.e.*, ζ became less negative with time. Repetition of the estimations in the solutions previously used gave the results of Series II, the diaphragm having in the meantime been carefully cleaned. The results obtained in this series were also quite concordant among themselves, but ζ was throughout less negative than in the same solution in Series I. The glass surface appears to have undergone some change which has the effect of rendering it more positive. Experiments with dilute solutions of lanthanum nitrate gave further indications that ζ was decreasing with increase of time; and at the conclusion of these experiments, ζ in distilled water was found to have undergone a further decrease.

Some time previous to the foregoing experiments, the permeability of this particular diaphragm had been measured for the purpose of proving that Poiseuille's law held good, and that the resistance of the bubble and connecting tubes to the flow of water was negligible compared with that of the diaphragm—necessary conditions for accurate work by our method. It was found that the diaphragm had a "specific permeability" at 20° of $2{\cdot}10 \times 10^{-4}$: by this term is meant the number of c.c. of water passing through per second under a head of 1 cm. of water. After the foregoing experiments, the permeability was redetermined, and was found to have fallen to $2{\cdot}43 \times 10^{-5}$, or about one-ninth of its former value.

The permeability estimations were carried out by allowing boiled distilled water, under a head of about 80 cm. (measured by a cathetometer), to flow through the diaphragm and escape by a small tube into a tared weighing bottle. The estimations were performed in a room the temperature of which remained practically constant during an estimation. The temperature of the water was further observed in the proximity of the diaphragm, and the permeability corrected for changes in viscosity and density to 20°. Great care was taken to ensure the absence of grease or suspended impurities in the water.

Continued passage of water through the diaphragm brought about a still further decrease of permeability. After the diaphragm had been soaked over-night in pure concentrated nitric acid, the permeability rose to $2{\cdot}038 \times 10^{-4}$, which is approximately the same as that found originally. Subsequent passage of water again effected a decrease in the permeability, rapidly at first, and then more slowly.

It was observed that the permeability decreased at a greater rate if the water were passed through than if it were allowed merely to remain in the diaphragm. A determination of the electroendosmosis in distilled water, immediately after the diaphragm had been treated with nitric acid, gave $\zeta = -0{\cdot}0557$ volt, which is the same as that initially found. This, however, was only a temporary value, and subsequent estimations in dilute hydrochloric acid agreed more nearly with Series II.

The decrease in permeability on passage of water was confirmed with other diaphragms. In one case, where the porous plug was of the same kind as that used above, but 5 mm. instead of 3 mm. thick, even consecutive estimations showed a decrease, and in 4—5 hours the permeability fell from $1{\cdot}746 \times 10^{-5}$ to $0{\cdot}574 \times 10^{-5}$. Another plug of the same porosity, 3 cm. diam. and 3 mm. thick, was attached directly to the receiver of a conductivity-water still: passage of about 3 litres of water, over a period of a week, reduced the permeability to half its initial value.

In these latter cases the change appears to have taken place much more quickly than with the apparently similar filter disc used in the first set of experiments. This may be partly accounted for by the fact that the first disc had been heated and annealed more than the others, during the process of forming ground joints on the tube which contained it. In the case of this diaphragm also, it would almost appear that there was an initial period during which no appreciable change took place.

Discussion.

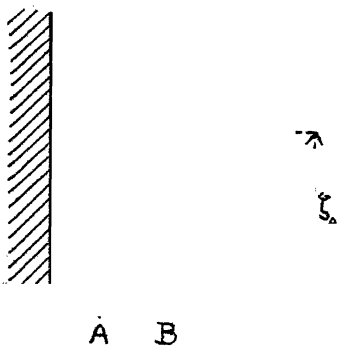
The foregoing results suggest strongly that the glass surface has undergone a swelling process. Haber and Klemensiewicz (*Z. physikal. Chem.*, 1909, 67, 385) postulate the existence of a swollen layer on the surface of the glass in explaining their observations with the glass electrode, and Lachs and Kronman (*loc. cit.*) suggest that their results are probably due to a swelling process which advances with time.

A simple decrease in the effective size of the pores of the diaphragm, although explaining a decrease in the amount of electroendosmosis, and hence in the (negative) value of the interfacial potential (when this is calculated on the assumption of a too small

value of l/q), would not in itself bring about a reversal in the direction of electroendosmosis. We must therefore conclude, either that the swelling of the surface layer is accompanied by a change which has the effect of imparting a positive charge to the diaphragm, or that the distribution of potential within the swollen layer is such as to cause a reversal of sign in certain solutions, *e.g.*, $N/100$-hydrochloric acid. Lachs and Kronman attribute the decrease of ζ, due to the thickening of the wall layer by swelling, to a shifting of the line along which displacement occurs (Fig. 1, A and B).

If, however, the course of the potential should be as in Fig. 2, as suggested by Freundlich ("Kapillarchemie," 1922, p. 342) in order to explain the difference in sign between thermodynamic and electrokinetic potentials, then we might obtain a reversal of direction of electroendosmosis by a thickening of the wall layer.

FIG. 1.



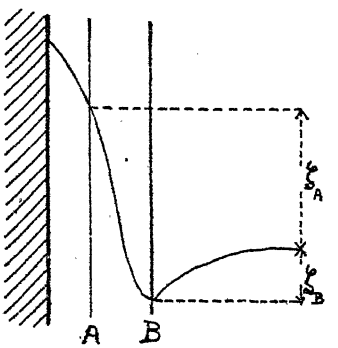


FIG. 2.

The present work therefore supports the conclusion of Lachs and Kronman, that the interfacial equilibrium between glass and aqueous solutions is not a true one, but one which changes with time. Since, however, the change in the surface may, with suitable material, take place relatively slowly, this change does not necessarily invalidate experiments carried out on the effects of ions of different kinds on the interfacial potential. It is to be expected, for example, that the change will occur more slowly with the Jena "Geräte" glass used in the present work than with the ordinary Thuringian glass used by Lachs and Kronman.

We also passed considerable quantities of alcohol and of benzene through the dried diaphragm, without observing any change in the permeability to these liquids. Such a diaphragm, therefore, can probably be used successfully for quantitative experiments in non-aqueous liquids.

Summary.

(1) Electroendosmosis experiments have been carried out with a diaphragm of sintered Jena " Geräte " glass powder in water and in dilute hydrochloric acid.

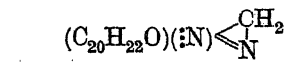
(2) The amount of electroendosmosis decreased after a time, and in $N/100$-hydrochloric acid it became reversed in direction.

(3) Experiments were also carried out on the permeability of the diaphragm to water. This also decreased with the time during which water was passed through the diaphragm.

(4) It is suggested that these results indicate that the glass surface undergoes a swelling process, and, further, that the distribution of potential within the swollen layer may account for the reversal of direction.

In conclusion, we should like to thank Mr. C. E. Marshall, who carried out a number of preliminary measurements, and to acknowledge our indebtedness to the Chemical Society Research Fund and the Brunner-Mond Research Grant to this Department, which have partly defrayed the cost of this work. One of us (H. V.) also desires to thank the Department of Scientific and Industrial Research for a maintenance grant during its prosecution.

THE UNIVERSITY, MANCHESTER. [*Received, May 5th*, 1927.]



CCX.—*Strychnine and Brucine. Part IV.*

By GEORGE ROGER CLEMO, WILLIAM HENRY PERKIN, junr., and ROBERT ROBINSON.

THE present communication contains the description of part of a general investigation into the reduction products of strychnine, $C_{21}H_{22}O_2N_2$, and is mainly concerned with the examination of strychnidine, $C_{21}H_{24}ON_2$. It also includes a short account of experiments which we have carried out on the decomposition of methylstrychnine under various conditions.

Our knowledge of the reduction products of strychnine is due almost entirely to Tafel, who in 1892 (*Annalen*, **268**, 235, 245) published the results of an important investigation on the reduction of this substance with hydriodic acid in the presence of phosphorus. He showed that strychnine, under these conditions, is converted into deoxystrychnine, $C_{21}H_{26}ON_2$, by the addition of six atoms of hydrogen and elimination of water. This important substance yields, on hydrolysis, deoxystrychnic acid, $C_{21}H_{28}O_2N_2$, which, on treatment with acids, is again converted into deoxystrychnine.

It is clear, therefore, that it still contains the group —CO·N=, so characteristic of strychnine, and that it is the second oxygen atom in the molecule which has taken part in the reduction. In a subsequent paper (*Annalen*, 1898, **301**, 285), Tafel describes the reduction of deoxystrychnine (i) to strychnoline, $C_{21}H_{26}N_2$, by treatment with sodium and *iso*amyl alcohol and (ii) to dihydrostrychnoline, $C_{21}H_{28}N_2$, by electrolytic reduction. Tafel also examined the products of the electrolytic reduction of strychnine itself, and showed that this substance is converted, under the conditions he employed, into a mixture of strychnidine, $C_{21}H_{24}ON_2$, and tetrahydrostrychnine, $C_{21}H_{26}O_2N_2$. Since the latter is converted into the former by dehydrating agents, he suggested that the relationship between these substances is probably that represented by the scheme:

Strychnidine.

Tetrahydrostrychnine.

In the course of an inquiry into the properties of strychnidine, we have much simplified the preparation of this substance and its separation from tetrahydrostrychnine (p. 1600), and we have thus been able to prepare, in a comparatively simple manner, both of these substances in considerable quantities. The results of an investigation into the properties and decompositions of tetrahydrostrychnine, which are of considerable interest, will form the subject of a later communication. The starting point in the experiments described in the present communication has been strychnidine methosulphate, $C_{21}H_{24}ON_2,Me_2SO_4$, which has been obtained (i) by the direct union of strychnidine with methyl sulphate and (ii) from strychnine methosulphate by electrolytic reduction, and from which a number of simple derivatives such as the methobromide, methochloride, and methiodide have been conveniently prepared.

From the fact that these two methods give rise to identical substances, it is evident that the nitrogen atom which is methylated in the course of the formation of strychnidine methosulphate is not that which occurs in the amide group of strychnine. Strychnidine methosulphate is therefore  . When strychnidine methosulphate is digested with methyl-alcoholic potash it is converted into *methoxymethyldihydrostrychnidine*, $C_{23}H_{30}O_2N_2$, m. p. 126°, which crystallises splendidly in prisms, the interesting peculiarities of which have been examined by Dr. T. V. Barker (see p. 1602). This substance, produced from strychnidine by the introduction of a methyl group and addition of methyl

alcohol, is a mono-acid base yielding a *hydriodide*, $C_{23}H_{30}O_2N_2$,HI, and a *methiodide*, $C_{23}H_{30}O_2N_2$,MeI, and the latter is converted by silver hydroxide into the *methohydroxide*, $C_{23}H_{30}O_2N_2$,MeOH, m. p. 117°. Like strychnidine, but unlike strychnine, these substances give each an intense crimson coloration when a drop of dichromate is added to its solution in dilute sulphuric acid, and this and other reactions (see below) suggest that the further methylation of methoxymethyldihydrostrychnidine again occurs at that nitrogen atom which is responsible for the basic properties of strychnine. The conclusion appears inevitable that methoxymethyldihydrostrychnidine and its methiodide should be represented by the expressions

$$C_{20}H_{22}O(OMe)(:NMe)\begin{cases}CH_2\\ \\ N\end{cases} \quad \text{and} \quad C_{20}H_{22}O(OMe)(:NMe_2)\begin{cases}CH_2\\ \\ N\end{cases}\Big\}I$$

respectively.

The simplest conceivable formulation of the decomposition of strychnidine methosulphate by means of methyl-alcoholic potassium hydroxide is in accordance with the scheme:

$$\begin{matrix}>C-NMe\\ \\ >C-N\end{matrix}\Big\}SO_4Me \text{ and } MeO\}K \longrightarrow \begin{matrix}>C(OMe),\\ \\ >C=N\end{matrix}\Big\}Me \text{ and } SO_4Me\}K.$$

It is, however, by no means certain that the groups $C_{20}H_{22}O$ of strychnidine and of methoxymethyldihydrostrychnidine are identical. Indeed the reconstitution of the quaternary salts with loss of methyl alcohol leads, as shown below, not to methylstrychnidinium salts, but to an isomeric series.

A curious property of methoxymethyldihydrostrychnidine is the fact that, while the direct action of methyl iodide yields the methiodide just mentioned, an entirely different result is obtained when methyl iodide acts on the methyl-alcoholic solution of the base. In these circumstances, two *oxymethoxymethyldihydrostrychnidines*, $C_{23}H_{30}O_3N_2$, namely (A), m. p. 235°, and (B), m. p. 270°, are produced; the former is convertible into the latter in a variety of ways, for example, by merely boiling with xylene. The investigation into the constitutions of these substances and the significance of these curious changes has not yet been completed.

Although methoxymethyldihydrostrychnidine combines with methyl sulphate with difficulty and is only gradually converted into the monomethosulphate under ordinary conditions, it is remarkable that it yields a substance, $C_{23}H_{30}O_2N_2,2Me_2SO_4$, evidently a mixture of two *dimethosulphates* (A) and (B), when its solution in dry benzene is boiled with methyl sulphate for several hours; of these, only the one (A) and its derivatives have so far been obtained in a pure condition. When sodium iodide is added to the aqueous solution of

the mixed dimethosulphates, the *dimethiodide* (A), $C_{23}H_{30}O_2N_2,2MeI$, m. p. 297° (decomp.), is precipitated and readily obtained pure. The *dimethochloride* (A), $C_{23}H_{30}O_2N_2,2MeCl,3H_2O$, obtained from the dimethiodide by the action of silver chloride, crystallises from water in glistening prisms and is decomposed by boiling with methyl-alcoholic potash with loss of two molecules of methyl chloride and regeneration of methoxymethyldihydrostrychnidine. It is evident that the dimethochloride must have the formula

$$C_{20}H_{22}O(OMe)(:NMe_2)\left\langle \begin{matrix} CH_2 \\ NMe \end{matrix} \right\rangle Cl_2,$$

and since, on decomposition as just described, each nitrogen atom loses a methyl group in the form of methyl alcohol and no rings are broken, it is apparent that the heterocyclic ring system of methoxymethyldihydrostrychnidine is one possessing quite unusual stability. When, however, the dry dimethochloride (A) is heated, it loses two molecules of methyl chloride and methyl alcohol and yields *methyl-ψ-strychnidine* (see below). Methoxymethyldihydrostrychnidine, dissolved in dilute methyl-alcoholic potash, is readily oxidised by hydrogen peroxide with the formation of *methoxymethylstrychnidonic acid*, $C_{21}H_{28}O_5N_2$, a gum which is evidently an amino-acid, because, on slow evaporation of its aqueous solution, it is converted into *anhydromethoxymethylstrychnidonic acid*, $C_{21}H_{26}O_4N_2$, which crystallises well from alcohol and melts at 222°.

The further investigation of this interesting substance is in progress.

Ethoxymethyldihydrostrychnidine.—In order to determine whether a process similar to the formation of methoxymethyldihydrostrychnidine would occur if ethyl alcohol were substituted for the methyl alcohol used in the preparation of this substance, strychnidine methosulphate was digested with ethyl-alcoholic potash; a substance was then obtained which melted at about 98° and proved to be ethoxymethyldihydrostrychnidine, $C_{24}H_{32}O_2N_2$. This substance differs from the corresponding methoxy-derivative in the absence of the facility for crystallisation so remarkable in the latter and also in its greater instability on exposure to the air, whereby it rapidly becomes dark purple; it was therefore not further investigated.

Methyl-ψ-strychnidine, $C_{22}H_{26}ON_2$.—This interesting base is obtained when methoxymethyldihydrostrychnidine dimethochloride (see above) is heated and also by heating methyl*neo*strychnidinium chloride (A) or (B) (see p. 1593). It melts at 203—204° and forms well-defined salts, of which the *hydriodide*, $C_{22}H_{26}ON_2,HI$, is characteristic.

The *methiodide*, $C_{22}H_{26}ON_2,MeI$, produced by the direct com-

bination of the base with methyl iodide, also crystallises well, and is converted by silver chloride into the corresponding *methochloride*, which decomposes on heating into methyl chloride and the base. Methyl-ψ-strychnidine is not changed by electrolytic reduction, but is readily and almost quantitatively oxidised by permanganate to *strychnidone*, $C_{21}H_{24}O_3N_2$, an atom of carbon being lost during the process. This substance crystallises well, melts at 152°, and yields a *monoxime*, $C_{21}H_{25}O_3N_3$, and a *disemicarbazone*, $C_{23}H_{30}O_3N_8$; it is characterised by being remarkably resistant to further oxidation by permanganate. When it is boiled with methyl-alcoholic potash, it is converted into an isomeride, allo-*strychnidone*, m. p. 260—265°, which is no longer capable of combining either with hydroxylamine or with semicarbazide.

*The Methyl*neo*strychnidinium Salts* (A) *and* (B).—When methoxymethyldihydrostrychnidine is boiled with dilute sulphuric acid, methyl alcohol is eliminated and a solution is obtained which evidently contains the quaternary *methyl*neo*strychnidinium sulphates* (A) and (B), and this solution does not give any precipitate on the addition of ammonia or caustic potash. On adding excess of sodium iodide, *methyl*neo*strychnidinium iodide* (A) is precipitated, the isomeride (B) remaining in solution. The iodide (A) crystallises well from water, melts at about 300° (decomp.), and is converted by silver chloride into *methyl*neo*strychnidinium chloride* (A), $C_{22}H_{27}ON_2Cl,3H_2O$, which separates from water in splendid, glistening, prismatic needles, for the description and measurement of which (p. 1612) we are indebted to Dr. T. V. Barker. When this chloride is digested with methyl-alcoholic potash, it adds on methyl alcohol with the formation of methoxymethyldihydrostrychnidine (m. p. 126°), but if the dry chloride is heated it loses hydrogen chloride, and methyl-ψ-strychnidine (m. p. 203°) remains in an almost pure condition. *Methyl*neo*strychnidinium iodide* (B), $C_{22}H_{27}ON_2I$, is obtained when the mother-liquor from the separation of the isomeride (A, see above) containing sodium iodide is mixed with much 50% aqueous potassium hydroxide. This substance separates from acetone as a sandy, crystalline precipitate, m. p. 277° (decomp.), and is converted by silver chloride into *methyl*neo*strychnidinium chloride* (B), $C_{22}H_{27}ON_2Cl,H_2O$, m. p. 255° (decomp.), which, unlike the isomeride (A), exhibits little facility for crystallising. When it is digested with methyl-alcoholic potash, it is converted into methoxymethyldihydrostrychnidine and, on heating in a test-tube, it yields methyl-ψ-strychnidine. This reaction shows that the latter base may be represented by the formula $C_{20}H_{21}O(:NMe)<\begin{matrix}CH_2\\N\end{matrix}$, but the elimination of methyl alcohol may not be a simple process

involving the formation of a double bond. The difficulty is that methyl-ψ-strychnidine is unchanged by electrolytic reduction, whereas methoxymethyldihydrostrychnidine yields a dihydro-derivative under similar conditions.

Methoxymethyltetrahydrostrychnidine, $C_{23}H_{32}O_2N_2$.—This substance is obtained when methoxymethyldihydrostrychnidine is reduced electrolytically; it melts at 220° and is characterised by the facility with which it crystallises, separating, for example, from xylene in brilliant prisms. Considered as a strong base, it is mono-acid and yields a *hydriodide*, $C_{23}H_{32}O_2N_2$,HI, and a *methiodide* (*a*), $C_{23}H_{32}O_2N_2$,MeI, m. p. 227°, both of which crystallise well. The *methochloride* (*a*), prepared from the methiodide (*a*) with silver chloride, is a readily soluble, waxy, crystalline substance which is decomposed by boiling methyl-alcoholic potash with elimination of methyl chloride and separation of methoxymethyltetrahydrostrychnidine. When this base is boiled with dry benzene and excess of methyl sulphate for 20 hours, it yields a horny mass, which is a mixture of the two dimethosulphates (A) and (B), and the benzene solution gradually deposits crystals of the dimethosulphate (A). The horny mass, dissolved in water, yields on the addition of sodium iodide the *dimethiodide* (A), m. p. 315° (efferv.), the isomeride (B) remaining in solution. From the dimethiodide (A) the *dimethochloride* (A) was prepared with the aid of silver chloride as an indefinite crystalline mass which, when heated, loses two molecules of methyl chloride and methyl alcohol and yields *methyl-ψ-dihydrostrychnidine*, $C_{22}H_{28}ON_2$, m. p. 212° (compare p. 1596).

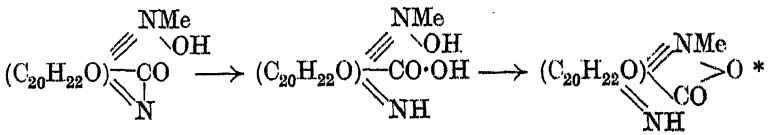
Methoxymethyltetrahydrostrychnidine dimethiodide (B) is precipitated from the mother-liquors of (A), containing sodium iodide, by the addition of a large excess of caustic potash (50%) and separates from alcohol in prisms. This dimethiodide (B) melts at 165°, and at about 230° loses both molecules of methyl iodide with regeneration of methoxymethyltetrahydrostrychnidine. If, however, the dimethiodide (B) is boiled with mesitylene, only one molecule of methyl iodide escapes, and a *methiodide* (*b*) of methoxymethyltetrahydrostrychnidine separates which has m. p. 325° (decomp.) and is isomeric with the methiodide (*a*) produced by the direct combination of the base with methyl iodide (see above). The methiodide (*b*), on heating at 250°, loses methyl iodide with formation of methoxymethyltetrahydrostrychnidine. The *dimethochloride* (B) obtained from the dimethiodide (B, m. p. 165°) by the action of silver chloride is a horny mass which, when heated in a test-tube, behaves differently from the dimethochloride (A) (see above), since it decomposes simply into methyl chloride and methoxymethyltetrahydrostrychni-

The most probable explanation of the isomerism of the dimethosalts of the series (A) and (B) is that they are stereoisomerides corresponding to the formula $C_{20}H_{24}O(OMe)(:NMe_2)\left\langle \begin{matrix} CH_2 \\ NMe \end{matrix} \right\rangle I_2$, since it is clear that the formation of the di-quaternary salts involves the appearance of a new asymmetric nitrogen atom. The reactions of the methiodides (*a*) and (*b*) show, however, that they are structurally different, and it will be convenient at this stage to mention briefly the methods and arguments which we employ in this and similar cases; some aspects of the matter are also discussed in the following communication (see p. 1633). The presence of an aromatic nucleus bearing the –N·CO– group is the cause of important reactions, many of which were first observed by Tafel. The dichromate reaction (bluish-violet to reddish-violet) in moderately concentrated sulphuric acid solution is characteristic of strychnine; it is not given by strychnidine or its derivatives. On the other hand, these give a crimson coloration when a little potassium dichromate is added to their solutions in dilute sulphuric acid. Closely allied to this is the crimson colour developed in dilute hydrochloric acid solutions of strychnidine derivatives on the addition of ferric chloride. With strychnine, this reaction is completely negative. Finally, strychnidine derivatives, but not strychnine, couple with diazonium salts to give characteristic azo-compounds. In this connexion, we have usually employed diazobenzenesulphonic acid as the reagent, and the alkaline or neutral solutions are then yellow or orange, becoming bluish-red on the addition of a mineral acid. Incidentally it may be mentioned that Tafel's view of the nature of methylstrychnine receives support from the circumstance that this substance couples readily with diazobenzenesulphonic acid. The behaviour of strychnidine derivatives in these reactions is very much influenced by the concentration of acid in the solution, and this again harmonises with the view that we are observing the reactions of a tertiary aromatic amine. Thus in strong hydrochloric acid solution strychnidine does not form azo-compounds and is not affected by ferric chloride. In the latter case, the red colour appears on dilution of the solution, and many strychnidine and brucidine derivatives show a similar behaviour. Tetrahydrostrychnine fails to exhibit these colour reactions at a smaller acid concentration than is necessary to inhibit the strychnidine reactions, whilst, in connexion with other work not described in this communication, strychnidine derivatives have been obtained which only exhibit the ferric chloride reaction in very dilute hydrochloric acid solution and will not couple with diazo-salts in acid solution unless an excess of sodium acetate is introduced. Analogies with the already ascertained

behaviour of aromatic amines suggest that when, for example, strychnidine is dissolved in hydrochloric acid of such a strength that the ferric chloride reaction fails, the explanation is that the base is present in the solution as the dihydrochloride. We already know (see above) that the nitrogen atom not joined to the aromatic nucleus is the more basic of the two which are present in the molecule. Important confirmation of this view is derived from the fact that without exception the dimetho-salts of strychnidine derivatives do not couple with diazonium salts and do not give the ferric chloride reaction. Reverting to the question of the constitutions of the methiodides (*a*) and (*b*) of methoxymethyltetrahydrostrychnidine, it is clear that we might expect one of these, that which contains a quaternary ammonium group attached to the benzene ring, to give negative results in the colour tests. Actually, after conversion into methochloride, the methiodide (A) couples easily with diazobenzenesulphonic acid and exhibits a good ferric chloride reaction. The behaviour of the salt is closely similar to that of the parent base. On the other hand, the methochloride from the methiodide (*b*) did not give entirely negative results in the tests, but the colours were developed much more slowly and did not reach the intensity observed in the case of the (*a*) salt. We conclude that the methiodide (*a*) is $C_{20}H_{24}O(OMe)(:NMe_2)\left\langle \begin{matrix} CH_2 \\ | \\ N \end{matrix} \right\rangle I$, whilst the methiodide (*b*), which may not be entirely homogeneous, is

$$C_{20}H_{24}O(OMe)(:NMe)\left\langle \begin{matrix} CH_2 \\ | \\ NMe \end{matrix} \right\rangle I.$$

It is shown in the following communication that the corresponding brucidine derivatives behave differently.

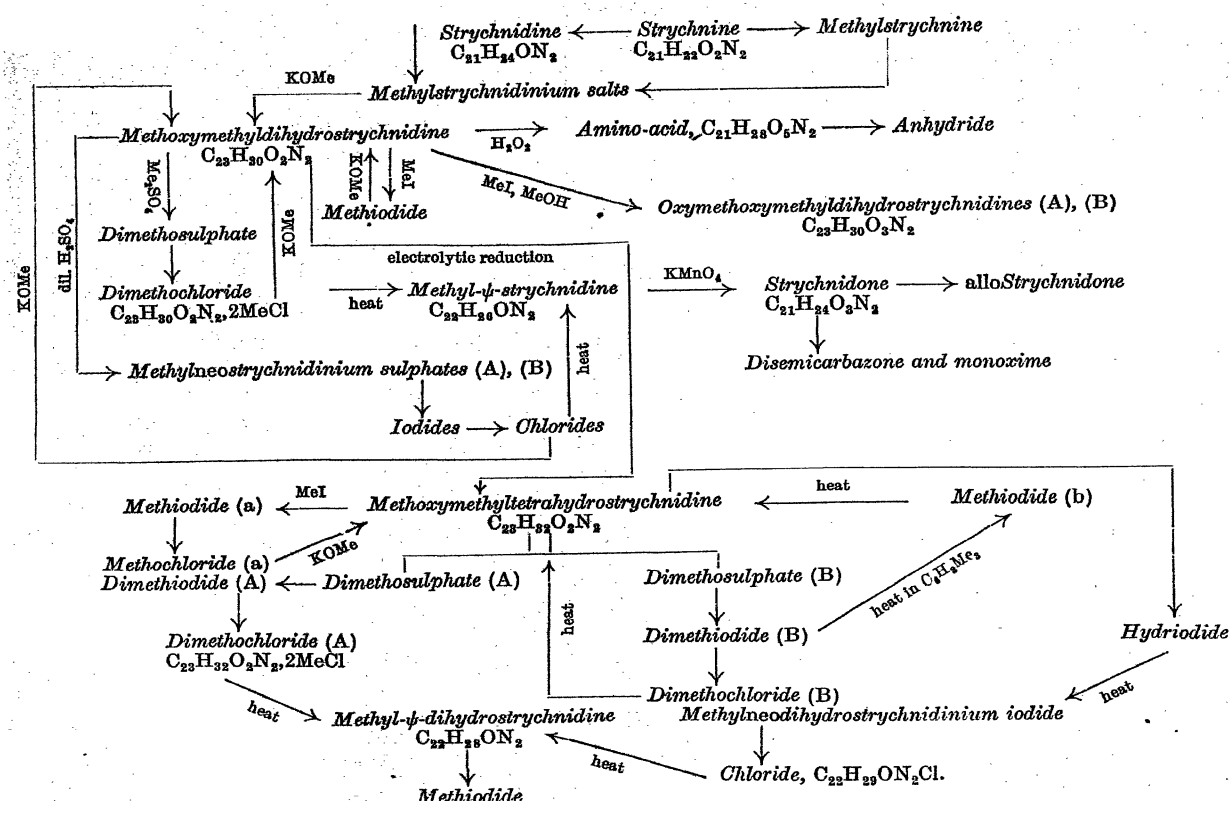


Methyl-ψ-dihydrostrychnidine, obtained either from methoxymethyltetrahydrostrychnidine dimethochloride (A) or from methyl-*neo*dihydrostrychnidinium chloride (see below) by heating, melts at 212° and yields a *methiodide*, $C_{22}H_{28}ON_2,MeI$, m. p. 335° (decomp.); the corresponding *methochloride* decomposed on heating, yielding a black syrup from which nothing definite could be isolated. Methyl-ψ-dihydrostrychnidine is clearly $C_{20}H_{23}O(:NMe)\left\langle \begin{matrix} CH_2 \\ | \\ N \end{matrix} \right\rangle$, but it is not yet certain that it is the dihydro-derivative of methyl-ψ-strychnidine. Further evidence on this point is at present being sought.

*The Methyl*neo*dihydrostrychnidinium Salts.*—As explained in the experimental section, these salts could not be directly obtained from methoxymethyltetrahydrostrychnidine, because this substance, in contrast to the methoxydihydro-base, is not decomposed by boiling with dilute sulphuric acid. The hydriodide of the methoxytetrahydro-base decomposes, however, on heating, yielding methyl

alcohol and *methyl*neo*dihydrostrychnidinium iodide*, m. p. 350° (efferv.), the hot aqueous solution of which gives no precipitate with aqueous potassium hydroxide.

On treatment with silver chloride, this yields *methyl*neo*dihydrostrychnidinium chloride*, which, on heating, is decomposed into hydrogen chloride and methyl-ψ-dihydrostrychnidine (m. p. 212°).



Methylstrychnine, $C_{22}H_{26}O_3N_2,4H_2O$.—This substance was first prepared by Tafel (*Ber.*, 1890, **23**, 2732), who obtained it from strychnine methiodide by decomposition with silver sulphate, followed by removal of the sulphuric acid by baryta and concentration of the filtrate; as the result of an extended examination (*Annalen*, 1891, **264**, 62), Tafel concluded that the formation of this substance from strychnine was best represented by the scheme :

Methylstrychninium hydroxide. *Methylstrychnine.*

We have found that methylstrychnine may be obtained directly by simply mixing a solution of strychnine methosulphate with caustic potash, and it has therefore become an easily accessible substance. During an examination of methylstrychnine we observed that it decomposed, on heating under reduced pressure, with elimination of methyl alcohol and formation of a substance, $C_{21}H_{22}O_2N_2$, isomeric with strychnine, for which we suggest the name *normethylstrychnine*. This base has not yet been obtained in a crystalline condition, but it yields a *methiodide*, $C_{21}H_{22}O_2N_2$,MeI, m. p. 315° (decomp.), and a *methochloride*, both of which are crystalline. When methylstrychnine, mixed with methyl-alcoholic potassium hydroxide, is heated gradually to 250°, a considerable quantity of indole is formed, and after this has been removed by steam distillation, the residue, on heating with soda-lime, yields a further amount of indole and also a small quantity of carbazole. Methylstrychnine is decomposed by heating with soda-lime, with the formation of a base, $C_{10}H_{11}N$, b. p. 93°/25 mm., which yields a picrate, m. p. 168°, and appears to be an ethylindole; carbazole is also produced in small quantity during this decomposition. The electrolytic reduction of a solution of methylstrychnine in dilute sulphuric acid is described on p. 1626. After removal of the sulphuric acid by barium carbonate, the crystalline *methylstrychnidinium*

* In accordance with our present-day conceptions regarding the nature of betaines, methylstrychnine is a dipole and it is no longer necessary to assume propinquity of the groups $\cdot CO_2$ and $\cdot NMe$.

hydrogen carbonate, $C_{22}H_{27}ON_2,HCO_3,H_2O$, is obtained, and this is decomposed by boiling methyl-alcoholic potash, yielding methoxymethyldihydrostrychnidine (m. p. 126°). On treatment with acids the carbonate yields the same strychnidine metho-salts as are obtained from strychnidine methosulphate by decomposition with sodium iodide and other salts.

Whilst it is clearly possible to develop arguments bearing on the structure of strychnine and brucine from the new facts brought to light in this and the following investigation, we prefer to postpone such theoretical deductions until further experimental data are available. The annexed table illustrates the more important relationships described in this memoir.

Experimental.

Strychnine Methosulphate, $C_{21}H_{22}O_2N_2,Me_2SO_4$.—Finely powdered strychnine (50 g.) is mixed with methyl alcohol (250 c.c.), and freshly distilled methyl sulphate (50 g.) added with shaking; the base then dissolves completely and the temperature rises about 17°. The *methosulphate*, which soon begins to separate, is collected after 24 hours, washed twice with a little methyl alcohol, and dried on the steam-bath (yield, 60 g.). The substance discolours at 270—280° and decomposes with effervescence at about 282°. It is very soluble in hot water and separates, on cooling, in quadrilateral plates; it also dissolves readily in hot methyl alcohol and crystallises therefrom in groups of glistening needles. The solution in sulphuric acid (60% by vol.) gives with dichromate an intense purple colour, changing to brown (Found: C, 59·7; H, 6·0; N, 6·3. $C_{21}H_{22}O_2N_2,Me_2SO_4$ requires C, 60·0; H, 6·1; N, 6·1%).

Strychnine Methobromide.—When concentrated aqueous solutions of the methosulphate and sodium bromide are mixed, the *methobromide* separates immediately. It is readily soluble in hot water, from which it crystallises as a voluminous mass of glistening needles; it discolours at 300° and melts at about 320° (efferv.) (Found in material dried at 110°: C, 61·3; H, 5·9. $C_{21}H_{22}O_2N_2,MeBr$ requires C, 61·5; H, 5·8%).

The aqueous solution of the methosulphate gives with sodium iodide an immediate precipitate of strychnine methiodide, which separates from much water in glistening, pearly cubes, darkens at 300°, and effervesces at about 320° (compare Stahlschmidt, *Pogg. Ann.*, 1859, **108**, 513; Tafel, *Ber.*, 1890, **23**, 2733).

Strychnidine and Tetrahydrostrychnine.—The following process for the preparation and separation of these substances is a considerable improvement on that recommended by Tafel (*Annalen*, 1898, **301**, 303, 316).

Strychnine (150 g.), dissolved in sulphuric acid (900 g.) and water (600 c.c.), was placed in the cathode chamber of the electrolytic reduction apparatus described in Part II of this research (J., 1924, **125**, 1798) and reduced for 16 hours at 18° by a current of 5 amps. The product was diluted with ice, filtered, made alkaline with a large excess of concentrated caustic soda solution, and the resulting granular precipitate was collected, washed well with water, and dried on the steam-bath. The mixture was then extracted with boiling alcohol (1 litre) and quickly filtered; on cooling, a crystalline precipitate separated (34 g.); from the concentrated mother-liquor, a further 20 g. was obtained.

This colourless crystalline mass, which, after drying at 100° had m. p. 183—185°, was recrystallised from benzene (700 c.c.); the nearly colourless crystals which separated (36 g.) melted at 202° and proved to be pure tetrahydrostrychnine (Found: C, 74·5; H, 7·7. $C_{21}H_{26}O_2N_2$ requires C, 74·5; H, 7·7%). The benzene mother-liquor was evaporated to dryness, and the residue, on crystallisation from alcohol, yielded a voluminous mass of white needles (17 g.), m. p. 244—245°. The residue from the first alcoholic extract, crystallised from alcohol, in which it was sparingly soluble, gave, after the mother-liquors had been worked up, a further quantity (53 g.) of the same substance, m. p. 243—245°. The two portions were mixed and crystallised from alcohol, pure strychnidine, m. p. 246°, being readily obtained.

Strychnidine Hydriodide.—When strychnidine is shaken with dilute sulphuric acid, a crystalline mass of the sulphate results, and, if this is dissolved in hot water and sodium iodide added, a voluminous mass of needles separates. This is collected, washed, dried, and recrystallised from boiling alcohol, in which the *hydriodide* is sparingly soluble, crystallising in stars of glistening needles (Found: C, 56·6; H, 5·6. $C_{21}H_{24}ON_2,HI$ requires C, 56·3; H, 5·6%). This hydriodide is sparingly soluble in boiling water and the solution gives an immediate precipitate with ammonia. It discolours at 275—280°, is nearly black at 290°, and decomposes at about 305° to a black froth.

Strychnidine Methosulphate.—This substance has been prepared in two ways: (i) by direct union and (ii) by the electrolytic reduction of strychnine methosulphate.

(i). Strychnidine (40 g.) is mixed with methyl alcohol (250 c.c.), freshly distilled methyl sulphate (40 g.) added, and the whole shaken and warmed at 40—50°; all passes into solution and suddenly the *methosulphate* commences to separate. After 12 hours, the precipitate is collected, washed with a little methyl alcohol, and recrystallised from this solvent (Found in material dried at

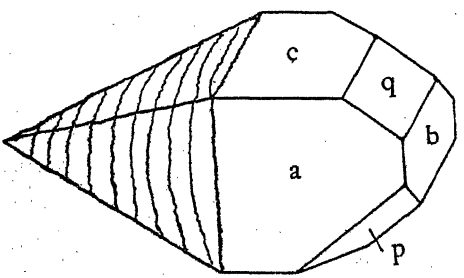
100°: C, 61·2; H, 6·6. $C_{21}H_{24}ON_2,Me_2SO_4$ requires C, 61·8; H, 6·7%).

(ii). Strychnine methosulphate (10 g.), dissolved in sulphuric acid (100 c.c. of 30% by vol.), is reduced in the usual electrolytic cell (p. 1600) by a current of 5 amps. for 16 hours. The clear, almost colourless solution is diluted with water, boiled with excess of barium carbonate, and filtered, and the filtrate and washings are concentrated to a small bulk; the mass of crystals that gradually separates is crystallised from methyl alcohol (Found in material dried at 100°: C, 61·6; H, 6·9; N, 6·4%).

The identity of the methosulphates produced in (i) and (ii) was shown (1) by conversion into identical methobromides and methiodides, and (2) by both yielding methoxymethyldihydrostrychnidine (m. p. 126°) by the action of methyl-alcoholic potash (p. 1602).

The *methobromide* is prepared by mixing a warm, saturated solution of strychnidine methosulphate with sodium bromide; the clear solution slowly deposits a woolly mass of needles, which is washed with water containing a trace of sulphurous acid and dried at 100°. The substance does not melt at 300° (Found: C, 63·9; H, 6·5. $C_{21}H_{24}ON_2,MeBr$ requires C, 63·6; H, 6·5%).

The methiodide separates as a voluminous mass of needles when sodium iodide is added to a hot aqueous solution of the methosulphate; on boiling, a clear solution is obtained from which the methiodide separates as a woolly mass of needles. This substance has already been described by Tafel (*Annalen*, 1898, **301**, 314), who obtained it by direct union of strychnidine with methyl iodide. It decomposes at about 325° to a brown froth.



The Methochloride.—The methiodide just described is readily soluble in boiling water, and on addition of silver chloride and digestion on the steam-bath for an hour decomposition is complete. The filtrate from the silver salts, on evaporation to a small bulk, deposits the very readily soluble *methochloride* in needles. These are collected and dissolved in a very little hot water and the solution is rapidly cooled; it sets to a jelly which gradually changes to colourless needles. The substance, dried at 100°, is a horny mass which begins to darken at 260°, is dark brown at 300°, and decomposes with effervescence at 310° (Found: C, 70·8; H, 7·3. $C_{21}H_{24}ON_2,MeCl$ requires C, 71·1; H, 7·3%). When the dry, powdered methochloride was carefully heated in a test-tube over a free flame, a gas, which burnt with a green-edged flame, was given off and a considerable crystalline sublimate formed. The residual brown syrup crystallised in contact with methyl alcohol, separated from this solvent in needles, melted at 248—250°, and proved to be strychni-

dine (Found: C, 78·2; H, 7·6%), but, owing to considerable decomposition, the yield was a small one.

Methoxymethyldihydrostrychnidine.

Strychnidine methosulphate (20 g.) is mixed with methyl-alcoholic potash (120 c.c. of 25%) and heated in an open flask in a rapidly boiling water-bath; the clear solution gradually clouds and, after 30 minutes, the well-cooled viscid product gives, on dilution with ice and water (600 c.c.), a caseous precipitate, which is washed well and allowed to dry on porous porcelain at the ordinary temperature. The nearly colourless mass, which melts at about 115—119° and is pure enough for many purposes, is rather readily soluble in boiling methyl alcohol, and separates, on slowly cooling, in highly characteristic, large, glistening, pale purple prisms. For reasons explained on p. 1603, it is advisable to dissolve the substance as rapidly as possible in the methyl alcohol and cool the filtered solution quickly by shaking it in a corked flask in contact with ice and water; after being washed with a little methyl alcohol, the crystalline meal is then only slightly coloured (Found: C, 75·4; H, 8·2; N, 7·5; MeO, 8·2. $C_{23}H_{30}O_2N_2$ requires C, 75·4; H, 8·2; N, 7·6; MeO, 8·4%). *Methoxymethyldihydrostrychnidine* melts at 125—126° and the crystals become pale purple when exposed to the air or more rapidly when heated on a watch-glass on the steam-bath. It is readily soluble in boiling alcohol or benzene, sparingly soluble in cold acetone, ether, or ligroin, and separates well in hard crusts of striated, pale lilac-brown prisms when ligroin is added to a boiling solution in benzene.

FIG. 1.

Crystals which had separated slowly from methyl alcohol were kindly examined by Dr. T. V. Barker, who found them to be monoclinic with the highly characteristic habit shown in Fig. 1. The right-hand termination consists of plane faces, whilst the other gradually tapers to a point in a series of curved surfaces. The crystals are all of one kind, the mirror-image form being no doubt proper to the hitherto unsynthesised enantiomeride. The forms developed are $a(100)$, $b(010)$, $c(001)$, $q(011)$ and, not infrequently, $p(111)$. The elements $a : b : c = 0{\cdot}7646 : 1 : 0{\cdot}6864$, $\beta = 109° 6'$

were computed from the following mean results of measurement of four crystals :

	b(010)	a(100)	c(001)	q(011)	p(1̄11)
ϕ	Polar.	0° 0′	*70° 54′	70° 54′	*121° 7′
ρ	Face.	90 0	90 0	*57 2	59 29 (+5)

Optically the axial plane is b(010) with medium axial angle and positive double refraction.

The salts of methoxymethyldihydrostrychnidine are very readily soluble and a solution of a trace of the base in dilute sulphuric acid gives with a drop of dichromate or concentrated nitric acid an intense crimson coloration, the same coloration being also produced when a solution in dilute hydrochloric acid is warmed with ferric chloride. The solution in glacial acetic acid is not precipitated by water and the base separates on the addition of ammonia as a voluminous mass resembling alumina. *The hydriodide.* When the base, dissolved in a slight excess of dilute sulphuric acid, is mixed with sodium iodide, a yellow to brown coloration rapidly develops, due evidently to oxidation. A nearly pure specimen of the hydriodide was obtained by adding a little sulphurous acid to a solution of the base in dilute sulphuric acid and then precipitating the salt with sodium iodide. The precipitate was rapidly collected and recrystallised from water containing sulphurous acid, separating as a colourless, granular powder. This was collected as rapidly as possible, washed with very dilute sulphurous acid, transferred to porous porcelain, and left over sulphuric acid in a desiccator evacuated to 1 mm. Even then, the substance became slightly yellow, but the salt could now be dried at 100° without further discoloration (Found : C, 56·1; H, 6·2. $C_{23}H_{30}O_2N_2,HI$ requires C, 55·9; H, 6·3%). This hydriodide melts at 203° (decomp.).

In the course of a large number of preparations of methoxymethyldihydrostrychnidine, it was always observed that only about 70% of the weight of the crude substance separated during the first crystallisation from methyl alcohol, and still less separated if the boiling with the solvent was prolonged. When the dark purple mother-liquors from several preparations were evaporated to dryness and the residual gum was distilled under reduced pressure, a considerable amount (35 g.) passed over at about 240—260°/2 mm.; from a solution of this in hot methyl alcohol, crystals (5 g.) of methoxymethyldihydrostrychnidine (m. p. 126°) separated. The mother-liquor was again distilled and the fraction 240—250°/1 mm. dissolved in boiling methyl alcohol; on rubbing and keeping for some days, nearly colourless prisms separated (6 g.) which melted at 202—203° after crystallisation and proved to be *methyl-ψ-strychnidine* (Found :

C, 78·8; H, 7·7; N, 8·5. $C_{22}H_{26}ON_2$ requires C, 79·0; H, 7·8; N, 8·4%) (compare p. 1609). On redistilling the mother-liquor of this substance, successive quantities of methoxymethyldihydrostrychnidine (2 g.) and methyl-ψ-strychnidine (2·3 g.) were obtained and also a small quantity of a substance, m. p. 295° (decomp.), which is evidently *oxymethoxymethyldihydrostrychnidine* (Found: C, 72·0; H, 8·0; N, 7·3. $C_{23}H_{30}O_3N_2$ requires C, 72·3; H, 7·8; N, 7·3%) (compare p. 1608). In connexion with the above observations, it was found that methoxymethyldihydrostrychnidine may be distilled without loss of methyl alcohol or other decomposition, and passes over at 235—237°/1 mm. as a colourless syrup, which may set to a resin or become a mass of crystals. The crystals melt, without recrystallisation, at 124—126°, contain C, 75·4; H, 8·2, and show no depression in m. p. after admixture with a specimen crystallised from methyl alcohol.

The distillation of the crude product of the action of methyl-alcoholic potash on strychnidine methosulphate was then investigated, and it was found that this passes over almost without residue at about 240—250°/1 mm. and crystallises at once. This procedure obviates the loss attendant on the crystallisation from methyl alcohol, since the distilled substance is pure enough for most purposes.

Methoxymethyldihydrostrychnidine Methiodide, $C_{23}H_{30}O_2N_2$,MeI.—For reasons explained on p. 1607, this substance must be prepared in the absence of methyl alcohol. The base (10 g.) is heated under reflux with carefully purified methyl iodide (10 c.c.) and the clear solution in about an hour begins to deposit crystals. The mass (12 g.) is collected, washed with methyl iodide, and dried on the steam-bath; m. p. about 275—278° (decomp.) (Found: C, 56·5; H, 6·5; I, 25·4. $C_{23}H_{30}O_2N_2$,MeI requires C, 56·7; H, 6·5; I, 25·0%). This substance does not appear to undergo change when it is crystallised from methyl alcohol, since the large brown prisms which separate melt at 278° (decomp.). It is sparingly soluble in cold, but readily soluble in hot, water and separates on slow cooling in pink, well-developed, arrow-shaped prisms.

In view of the fact that methoxymethyldihydrobrucidine combines with 2 mols. of methyl iodide at 140° (p. 1629), methoxymethyldihydrostrychnidine (5 g.), dissolved in carefully purified methyl iodide (15 c.c.), was heated in a sealed tube at 130° for 7 hours; the purple solution, on cooling, gradually deposited a crust of purple crystals which, after being washed with methyl iodide, had m. p. 265—270° (decomp.) and consisted of the monomethiodide (Found: C, 57·0; H, 6·4%). When this substance was crystallised from water and the mother-liquor allowed to stand exposed to the air, a crust of nodules gradually separated, which melted at 175°

(decomp.), became solid again, and then melted at about 240—250° (decomp.).

This substance appears to be the methiodide crystallising with 1 mol. H_2O which is not lost at 100° (Found: C, 55·0; H, 6·3. $C_{23}H_{30}O_2N_2$,MeI,H_2O requires C, 54·7; H, 6·6%). The methyl iodide mother-liquors from the substance m. p. 265—270° (decomp.) gave, on concentration, a little more of the same substance and then a crystalline crust, m. p. 235°, containing a mere trace of iodine (Found: C, 71·6; H, 7·7%), and this substance is evidently identical with the oxymethoxymethyldihydrostrychnidine described on p. 1608.

Methoxymethyldihydrostrychnidine Methohydroxide, $C_{23}H_{30}O_2N_2$,MeOH.—When the methiodide just described is heated on the steam-bath with water and excess of silver chloride, and the filtrate from the silver salts is evaporated, a syrup remains (which was not analysed) which doubtless contains the methochloride. Boiling methyl-alcoholic potash (25%) decomposes this and, on the addition of water, a resin separates. This is dissolved in boiling methyl alcohol, and the solution, after being concentrated and left in the ice-chest, deposits balls of colourless needles, m. p. 113°; on recrystallisation, the substance melts at 116—117° (Found: C, 72·4; H, 8·7; N, 6·8. $C_{24}H_{34}O_3N_2$ requires C, 72·4; H, 8·8; N, 7·0%). The same substance is formed, but less readily, when the methiodide is digested with methyl-alcoholic potash. The *methohydroxide* is very readily soluble in benzene, rather less readily in boiling petroleum, and sparingly even in boiling water. The solution in sulphuric acid (60% by vol.) gives with dichromate an immediate intense crimson colour; in dilute hydrochloric acid, ferric chloride produces an eosin coloration, becoming intense crimson on warming. The solution in dilute nitric acid (30%) is pink, becoming deeper on standing or warming and intense crimson and then green on boiling, and, on addition of ammonia, a yellow, crystalline base separates. When the methohydroxide is heated, it effervesces between 200° and 215°, yielding a brown syrup which sets to a resin on cooling and has not been examined. The methohydroxide dissolves readily in dilute hydrochloric acid and the solution gives, with sodium iodide, a gum, which soon crystallises and separates from methyl alcohol in glistening prisms of the methiodide, m. p. 278° (decomp.) (Found: C, 56·8; H, 6·6. Calc.: C, 56·7; H, 6·5%).

Methoxymethyldihydrostrychnidine Dimethosulphate, $C_{23}H_{30}O_2N_2$,$2Me_2SO_4$, *the Dimethiodide and the Dimethochloride.*—The methoxydihydro-base does not appear to combine with methyl sulphate when it is mixed with it. Interaction is very slow even when a solution of the

base in benzene is digested with methyl sulphate; combination does, however, take place on long boiling, with formation of the dimethosulphate; in spite of careful search, it has not been found possible to isolate the mono-derivative.

The dry base (10 g.), dissolved in specially dried benzene (200 c.c.), was mixed with methyl sulphate (15 c.c.) which had been distilled immediately before the experiment, and the whole was digested in a reflux apparatus, carefully protected from moisture; the original purple solution gradually became paler and, after about 2 hours, a resinous mass began to separate. The heating was continued for 10 hours, the product allowed to remain over-night, and the benzene layer decanted from the pale lilac resin. The clear benzene solution, left in a corked flask, gradually deposited soft, circular nodules, and these were collected, rapidly washed with dry benzene, and dried over sulphuric acid in a vacuum desiccator. Analysis showed that this substance is the *dimethosulphate* (Found: C, 51·6; H, 6·7. $C_{27}H_{42}O_{10}N_2S_2$ requires C, 52·4; H, 6·8%).

The Dimethiodide (A), $C_{23}H_{30}O_2N_2$,2MeI.—A warm aqueous solution of the crude dimethosulphate gave with excess of boiling aqueous sodium iodide a clear solution, and on standing, warty masses gradually separated. After 2 days, the mass was collected, washed with a little water, drained on porous porcelain, and crystallised from methyl alcohol, from which the *dimethiodide* (A) separated in striated, glistening needles, which became opaque on the steam-bath; m. p. about 297° (decomp.) (Found: C, 46·0; H, 5·5; I, 39·4. $C_{25}H_{36}O_2N_2I_2$ requires C, 46·2; H, 5·5; I, 39·3%). This substance is very readily soluble in boiling water and appreciably soluble in the cold and separates as a sandy powder consisting of round, warty masses. The aqueous solution gives no precipitate with ammonia. The yield of the dimethiodide (A) precipitated from the solution of the dimethosulphate by sodium iodide is only 50% of that required by theory and there can be little doubt that the aqueous mother-liquor contains the dimethiodide (B) corresponding with the dimethiodide (B) of methoxymethyltetrahydrostrychnidine (p. 1620). When solid potash was added to these well-cooled mother-liquors, a caseous precipitate separated in large quantity, and on crystallising this from methyl alcohol a small amount of the dimethiodide (A) was obtained as a crust of small prisms. The bulk of the substance remained in the methyl alcohol, but all attempts to isolate the isomeride (B) in a pure state were unsuccessful. This was due partly to the presence of traces of the dimethiodide (A), but mainly to the ready solubility of the isomeride (B) and the small tendency it exhibited to crystallise in definite form.

The *dimethochloride* (A) is obtained when a hot aqueous solution of the dimethiodide (A) is heated on the steam-bath with excess of silver chloride for an hour; the filtrate from the silver salts gives, on evaporation, a solid mass which separates from a little water in large, well-developed, colourless prisms resembling sugar crystals. The air-dried substance loses 6·6% at 100°, and about the same amount when kept over phosphoric anhydride in a vacuum desiccator, the brilliant crystals becoming chalky (Calc. for $C_{25}H_{36}O_2N_2Cl_2,3H_2O$ losing $2H_2O$: H_2O, 6·9%. Found in the substance dried at 100°: C, 62·0; H, 7·6; Cl, 14·3. $C_{25}H_{36}O_2N_2Cl_2,H_2O$ requires C, 61·9; H, 7·8; Cl, 14·6%). The dry crystals give off steam at about 150° and melt at about 255—257° with evolution of gas and formation of methyl-ψ-strychnidine (p. 1609).

A solution in dilute sulphuric acid gives merely a yellow coloration with dichromate. The dimethochloride is very soluble in water or methyl alcohol, and methyl-alcoholic potash gives an immediate precipitate of potassium chloride; on boiling and addition of water, a viscid, curdy precipitate separates which gives an intense crimson colour with dilute sulphuric acid and dichromate, crystallises from methyl alcohol in prisms, m. p. 125—126°, and proves to be methoxymethyldihydrostrychnidine, the yield being nearly a quantitative one.

Oxymethoxymethyldihydrostrychnidines (A) *and* (B).—The isomeride (A, m. p. 235°) is formed in small quantity when methoxymethyldihydrostrychnidine is heated with methyl iodide (see p. 1605), but is produced much more readily and in larger quantity under the following conditions. The base (6 g.) dissolves in methyl alcohol (60 c.c.) and methyl iodide (8 c.c.) in the cold. When the solution is boiled under reflux for 3 hours and then kept for a week, glistening scales (3 g.) separate; after boiling for 3 hours and being concentrated, the mother-liquor deposits a further small quantity. The crystals are washed with methyl alcohol containing a little ammonia to remove traces of iodine, and dried on the steam-bath (Found: C, 72·3; H, 7·9; N, 6·9; MeO, 8·6. $C_{23}H_{30}O_3N_2$ containing 1MeO requires C, 72·3; H, 7·8; N, 7·3; MeO, 8·1%).

Oxymethoxymethyldihydrostrychnidine (A) melts at 235° and dissolves with some difficulty in cold dilute hydrochloric acid. It is readily soluble in glacial acetic acid and is not reprecipitated by water. A solution in dilute sulphuric acid (60% by vol.) gives an intense crimson with dichromate or a drop of concentrated nitric acid; a solution in dilute hydrochloric acid gives no immediate coloration with ferric chloride, but, on warming, a deep crimson colour develops. The substance is apparently not changed when it dissolves in dilute

hydrochloric acid, since, if ammonia is added immediately, a gelatinous precipitate separates which becomes chalky on warming and melts at 220—225°. The substance dissolves readily on boiling with alcohol, semicarbazide hydrochloride, and sodium acetate, and on addition of ammonia and warming, a crystalline precipitate separates, m. p. 275° (decomp.), containing N, 7·7%, and is evidently the isomeride (B) (see below). When the dark brown mother-liquor of the substance (A), m. p. 235°, was evaporated to a small bulk and mixed with dilute ammonia, a sticky precipitate separated which soon became crystalline. On warming this with methyl alcohol, most of it dissolved, leaving a sparingly soluble, chalky substance consisting of the isomeride (B); this separated from much methyl alcohol as a rather indefinite, crystalline powder, m. p. about 275° (decomp.) (Found: C, 72·0; H, 7·7; N, 7·1. $C_{23}H_{30}O_3N_2$ requires C, 72·3; H, 7·8; N, 7·3%).

Conversion of Oxymethoxymethyldihydrostrychnidine (A) *into* (B).—This change takes place under the following conditions: (i) When the substance (A) was boiled with a little xylene, gradual change took place and a sandy, crystalline, very sparingly soluble powder was formed, which was washed with xylene; m. p. about 280—285° (decomp.) (Found: C, 73·0; H, 7·9; MeO, 7·8%). The xylene mother-liquor, after being concentrated, slowly developed a hard crust of octahedra, m. p. 285° (decomp.); (ii) when the isomeride (A) was boiled with alcohol for about an hour, the concentrated solution gradually deposited well-defined octahedra, m. p. 280° (decomp.), and the same result was obtained on boiling with acetone, the m. p. of the crystals being about 280° (decomp.). In the last case, analysis gave C, 72·3; H, 8·3; N, 7·3; MeO, 7·8%.

Oxymethoxymethyldihydrostrychnidine (B) was also obtained when methoxymethyldihydrostrychnidine (2 g.) was boiled with nitric acid (5 c.c.), diluted with water (50 c.c.). The pale pink solution became brown, and if, after about 20 minutes, ammonia was added, a sticky precipitate separated which contained some unchanged base. On crystallising it from much alcohol and then from xylene–alcohol, colourless prisms were obtained, m. p. about 285° (decomp.) (Found: C, 72·3; H, 8·1%). The isomeride (B) was also obtained when methoxymethyldihydrostrychnidine (1·5 g.) was boiled with acetic anhydride for 10 minutes, and the solution then kept for some days. The crystalline crust which separated consisted of some unchanged base mixed with the oxy-derivative (B), and there was no sign of the formation of an acetyl derivative; on boiling the mixture with alcohol, the unchanged base dissolved and the isomeride (B) remained in an almost pure condition.

Methyl-ψ-strychnidine and the Methylneostrychnidinium Salts.

Methyl-ψ-strychnidine is obtained (i) when the mother-liquors from the crystallisation of crude methoxymethyldihydrostrychnidine are distilled (p. 1603), (ii) when methyl*neo*strychnidinium chloride is heated (p. 1612), and (iii) by the action of heat on methoxymethyldihydrostrychnidine dimethochloride (A), during which this substance loses 2 mols. of methyl chloride and methyl alcohol. The last decomposition is best carried out with small quantities of material, which must be very pure and quite free from inorganic matter; otherwise much tar is produced, the yield of product is small, and the highly coloured mass very difficult to purify. When the dimethochloride (1 g.) is cautiously heated in a wide test-tube over a free flame, a gas is given off which has a very pungent, particularly unpleasant smell and burns with a smoky, green-edged flame, and a considerable crystalline sublimate forms on the sides of the tube. This melts at about 195° and is nearly pure methyl-ψ-strychnidine.

When the effervescence has ceased, the heating is discontinued; the liquid product should then be only slightly coloured and should crystallise completely. Several such tubes are broken up and their contents extracted with much boiling alcohol (in which the product is sparingly soluble), and the solution is digested with norite for an hour and concentrated to a small bulk; the new substance gradually separates in groups of striated, pale ochre needles which become almost colourless after recrystallisation (Found: C, 79·0; H, 7·8; N, 8·6. $C_{22}H_{26}ON_2$ requires C, 79·0; H, 7·8; N, 8·4%).

Methyl-ψ-strychnidine melts at 203—204° and appears to distil under reduced pressure almost without decomposition. It is very sparingly soluble in cold acetone and not readily on boiling; the solution may be concentrated and left for a considerable time without crystallisation setting in, and then groups of needles gradually form. It dissolves very readily in benzene or petroleum and separates very gradually from these in needles. It does not appear to be affected by heating with concentrated sulphuric acid on the steam-bath for ½ hour.

The base is readily soluble in dilute acids. The solution in dilute sulphuric acid is coloured crimson by dichromate, and the same colour develops when the substance is dissolved in concentrated nitric acid. The solution in dilute hydrochloric acid gives, with ferric chloride, a pale pink colour which becomes deep crimson on warming.

The *hydriodide*, $C_{22}H_{26}ON_2,HI$, was prepared by dissolving the base in a slight excess of warm dilute sulphuric acid and then adding warm sodium iodide; on rubbing, the cloudy liquid deposited the

hydriodide as a voluminous mass of colourless crystals; these were sparingly soluble in boiling water and the solution gradually deposited crusts, which melted at 265—270° with effervescence, leaving a black mass (Found: C, 56·8; H, 5·9. $C_{22}H_{27}ON_2I$ requires C, 57·1; H, 5·9%).

This hydriodide is sparingly soluble in boiling alcohol and separates therefrom in stars of prismatic needles. The solution in hot water gives with potash an immediate precipitate of the base.

The Methiodide, $C_{22}H_{26}ON_2$,MeI.—When the base (2 g.) was mixed with methyl iodide (5 c.c.), combination took place in the cold with rise of temperature and formation of the methiodide. After warming for a few minutes and cooling in ice, the solid was collected and crystallised from methyl alcohol, from which the substance separated in almost colourless needles. These scarcely darken at 270° and melt at about 312° with effervescence to a dark brown syrup (Found: C, 57·5; H, 6·1. $C_{23}H_{29}ON_2I$ requires C, 57·9; H, 6·1%).

The *methochloride*, prepared in the usual manner by heating the methiodide with water and silver chloride, was obtained, when the solution was concentrated to a small bulk, in long, flat prisms and was very readily soluble. When it was heated in a test-tube, it gave off water and methyl chloride, and a considerable sublimate formed; the residue, on crystallising from methyl alcohol, gave methyl-ψ-strychnidine in almost colourless needles, m. p. 202—203°.

In order to determine whether methyl-ψ-strychnidine could be reduced electrolytically, the base (2·5 g.), dissolved in dilute sulphuric acid (100 c.c. of 20%), was placed in the usual electrolytic cell (p. 1600) and a current of 4 amps. passed for 6 hours. The colourless solution was mixed with excess of ammonia, and the precipitate crystallised from methyl alcohol; colourless needles (2·2 g.) were then obtained which melted at 202° and at the same temperature in admixture with methyl-ψ-strychnidine. Identity was further established by analysis (Found: C, 79·2; H, 7·6. Calc. for $C_{22}H_{26}ON_2$: C, 79·0; H, 7·8%).

The Methylneostrychnidinium Salts.—The solution of the methyl-*neo*strychnidinium sulphates (A) and (B) from which the other salts were obtained was prepared as follows: Methoxymethyldihydrostrychnidine (p. 1602; 20 g.) was dissolved in dilute sulphuric acid (300 c.c. of 10% by vol.) and heated to boiling in a flask fitted with a long, ground-in condenser. In a short time, methyl alcohol could be detected at the open end of the tube, and when, after 2 hours, all of it had boiled away, a few drops of the liquid no longer gave a precipitate or cloudiness, due to unchanged base,

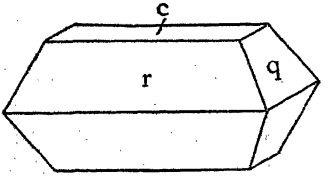
on being basified. The pale brown solution was made just alkaline with ammonia, a little sulphurous acid was added, and then a boiling solution of sodium iodide (25 g.). The clear solution was rapidly filtered and vigorously stirred; *methyl*neo*strychnidinium iodide* (A) then separated either as a heavy, crystalline precipitate or sometimes as a gum which soon crystallised. On standing, a mass of crystals separated from the supernatant liquid. The solid was collected and dissolved in boiling water containing a little sulphurous acid and the solution was rapidly filtered; the iodide (A) then separated, on standing, in characteristic, long needles. After recrystallisation from water (3 g. dissolve in about 75 c.c.), the substance was dried on the steam-bath (Found: C, 56·7; H, 6·0; I, 26·9. $C_{22}H_{27}ON_2I$ requires C, 57·2; H, 5·9; I, 27·4%).

This iodide (A) darkens at 295° and decomposes at about 300° to a black mass. It is very sparingly soluble in methyl alcohol. A piece of filter-paper soaked in the aqueous solution gradually becomes yellow and then orange on exposure to air. A hot aqueous solution of the iodide gives no precipitate with caustic potash (30%); even after heating for ½ hour on the steam-bath, the iodide separates unchanged on cooling. Although so sparingly soluble in water, it dissolves readily in cold dilute hydrochloric acid and in large quantities on boiling; the solution deposits, on slowly cooling, stars of prismatic needles of a substance which decomposes at 305° and is not a hydrochloride, as was expected, but consists of the unchanged iodide (Found: C, 57·5; H, 6·0%).

*Methyl*neo*strychnidinium Chloride* (A).—The iodide (A) was ground to a paste with warm water and heated on the steam-bath with a large excess of silver chloride for 2 hours with frequent shaking. The colourless filtrate and washings from the silver salts were concentrated to a small bulk by distillation under reduced pressure, and the solution was placed over sulphuric acid in a vacuum desiccator; the chloride then gradually separated in brilliant, colourless, prismatic needles. These, after being recrystallised from very little water and dried on porous porcelain in the air, appeared to contain $3H_2O$, since the loss on heating at 100° was 12·8% (Calc. for $C_{22}H_{27}ON_2Cl,3H_2O$: loss, 12·7%). When exposed over sulphuric acid in a vacuum desiccator, the crystals became opaque and lost the whole of their water of crystallisation, since there was no further loss at 100° (Found: C, 71·5; H, 7·3. $C_{22}H_{27}ON_2Cl$ requires C, 71·3; H, 7·3%). The chloride (A) melts at about 270° with vigorous effervescence (compare p. 1609) and is very readily soluble in water; the solution, which gives no precipitate either with ammonia or with caustic potash, is intensely bitter. The solution in dilute sulphuric acid gives, with concentrated nitric acid or

dichromate, a yellow coloration which changes to crimson on warming; ferric chloride added to a solution in dilute hydrochloric acid gives a pale yellow colour, which changes to crimson on boiling.

The crystals of the chloride (A) have been examined by Dr. T. V. Barker, who reports as follows :



The crystals are orthorhombic (pseudo-tetragonal). The habit is shown in Fig. 2, the list of forms being c (001), r (010), and q (011). The elements $a : b : c = 0{\cdot}998 : 1 : 1{\cdot}828$ were calculated from the following mean results of measurement of three crystals.

	c (001).	q (011).	r (010).
ϕ	Polar.	0° 0′	90° 0′
ρ	Face.	*61 18	*61 21

Optically the crystals are biaxial; birefringence, negative; axial angle, large; dispersion, strong; $\rho < \nu$.

The chloride (A) is very soluble in cold methyl alcohol. When the solution is mixed with methyl-alcoholic potash (25%), an immediate precipitation of potassium chloride occurs; after heating in the water-bath for ½ hour so that much methyl alcohol boils away, the product gives with water a caseous mass which separates from methyl alcohol in prisms, m. p. 125°, and consists of methoxymethyldihydrostrychnidine. The chloride, in quantities of 0·5 g., is cautiously heated in a test-tube over a free flame until effervescence has ceased; the pale yellow, syrupy residue solidifies on cooling, and separates from methyl alcohol in needles, m. p. 202°, which analysis and a mixed m. p. determination prove to be methyl-ψ-strychnidine (p. 1592). This decomposition affords perhaps the most ready method of preparing this substance in a pure condition.

FIG. 2.

*Methyl*neo*strychnidinium Iodide* (B).—The mother-liquors containing sodium iodide from which the iodide (A) originally separated (p. 1611) were concentrated considerably by distillation under reduced pressure, allowed to stand for a couple of days to deposit traces of the iodide (A), and then mixed with aqueous potash (50%) so long as turbidity was produced. After 2 days, the pale salmon, crystalline mass was collected, ground, washed with a little water, and left on porous porcelain to dry. The cake was then dissolved in boiling acetone [in which in this condition it, but not the iodide (A), is rather readily soluble], and the solution was rapidly filtered from the first small crop of crystals and then kept; a copious, colourless, sandy precipitate of the iodide (B) separated which was very sparingly soluble in cold acetone; further crops were

obtained by concentrating the mother-liquor. The iodide (B) begins to darken at 260° and melts and decomposes at about 277° to a black froth (Found: C, 57·3; H, 6·1. $C_{22}H_{27}ON_2I$ requires C, 57·2; H, 5·9%).

This iodide is moderately easily soluble in hot water and separates as a rather indefinite crust on standing; the aqueous solution gives no precipitate with ammonia or caustic potash. It dissolves very readily in warm dilute hydrochloric acid, but exhibits little tendency to crystallise from this solvent.

*Methyl*neo*strychnidinium Chloride* (B).—This was obtained by adding excess of silver chloride to a hot aqueous solution of the iodide (B), heating the mixture on the steam-bath for an hour, and filtering it. The filtrate was concentrated to a small bulk by distillation from the steam-bath under reduced pressure and then left over sulphuric acid in a vacuum desiccator; the pasty mass of minute crystals which gradually formed was left in contact with porous porcelain. The whole residue was dissolved in a very small amount of water, allowed to crystallise again, and transferred to porous porcelain. The colourless residue, dried at 100°, melted at about 255° with effervescence (Found: C, 68·3; H, 7·8. $C_{22}H_{27}ON_2Cl,H_2O$ requires C, 68·0; H, 7·5%). When this chloride is heated with methyl-alcoholic potash under the conditions described in the corresponding case of the chloride (B), a large yield of methoxymethyldihydrostrychnidine, m. p. 125°, is obtained.

In order to determine whether the product of the action of dilute sulphuric acid on methoxymethyldihydrostrychnidine was capable of electrolytic reduction, the solution prepared as explained on p. 1602 was placed in the usual apparatus (p. 1600), and a current of 5 amps. passed for 16 hours at 20°. The solution was then neutralised with ammonia, and a little sulphurous acid added, followed by a large excess of sodium iodide. The bulky precipitate which separated was recrystallised from water and found, by a comparison of properties and an analysis (Found: C, 57·6; H, 6·0. $C_{22}H_{27}ON_2I$ requires C, 57·2; H, 6·0%), to be methyl*neo*strychnidinium iodide (A), showing that reduction had not taken place.

Oxidation of Methyl-ψ-strychnidine. Formation of a Diketone termed Strychnidone.—Methyl-ψ-strychnidine (6 g.), dissolved in warm acetone (400 c.c.), was cooled to 15°, and very finely powdered and sieved permanganate (6 g.) added in small quantities at a time with constant shaking. When decolorisation was complete, the whole was heated on the steam-bath, the manganese precipitate * was

* When this manganese precipitate is extracted with hot water, a dark brown liquid is obtained containing a small quantity of the potassium salt of an acid which has not been obtained crystalline.

filtered off and well washed with acetone, and the combined acetone filtrate and extracts were evaporated on the steam-bath; the syrupy residue soon crystallised and did so immediately when stirred with methyl alcohol. The whole was dissolved in boiling methyl alcohol; from the solution, brilliant, almost colourless prisms separated, and further crops were obtained by concentrating the mother-liquor, the total yield being 5 g. After a second crystallisation from methyl alcohol, the substance was pure (Found: C, 71·3; H, 6·8; N, 8·0. $C_{21}H_{24}O_3N_2$ requires C, 71·6; H, 6·8; N, 7·9%). *Strychnidone* melts at about 152°, is slightly soluble in boiling water, and very sparingly soluble in cold methyl alcohol.

A solution in dilute sulphuric acid gives, with dichromate, a deep crimson colour; ferric chloride added to a solution in dilute hydrochloric acid gives a pale pink colour which becomes crimson on boiling. The powdered crystals dissolve in concentrated nitric acid to a most intense crimson solution, and the colour is not discharged on dilution. The diketone is remarkably resistant to oxidation, the solution even in boiling acetone decolorising permanganate very slowly.

The Disemicarbazone.—The diketo-derivative (2 g.), dissolved in hot dilute acetic acid, was mixed with a concentrated aqueous solution of semicarbazide hydrochloride (5 g.) and sodium acetate (4 g.) and heated on the steam-bath with gradual addition of potassium carbonate so as nearly to neutralise the acetic acid. After 2 hours, the whole was cooled, filtered from a little gum, and made strongly alkaline with ammonia; a chalky precipitate then separated which was well washed, dried on porous porcelain, and then on the steam-bath (Found: C, 58·1; H, 6·7; N, 24·4. $C_{23}H_{30}O_3N_8$ requires C, 59·1; H, 6·4; N, 24·0%). A further crop of this disemicarbazone (Found: N, 24·2%) slowly separated from the aqueous mother-liquor as a definitely crystalline crust, m. p. about 252° (efferv.).

The Oxime.—The diketo-derivative (2 g.) was dissolved in boiling methyl alcohol, a concentrated aqueous solution of hydroxylamine hydrochloride (4 g.) and sodium acetate (5 g.) added, and the whole heated to boiling; the clear solution then gradually became cloudy. After 3 hours, the product was cooled and mixed with water, ammonia was added until the liquid was alkaline, and the precipitate, which was at first syrupy but soon hardened, was ground with water to a paste, washed, and dried over sulphuric acid in a vacuum desiccator (Found: N, 11·1. $C_{21}H_{25}O_3N_3$ requires N, 11·4%). The oxime was very soluble in methyl alcohol; the solution, after addition of much ether, was washed with water, dried over potassium carbonate, and concentrated; the *oxime* then separated in fluffy

masses which had no definite melting point, shrinking at about 150° and effervescing at 170—175° (Found: N, 11·2%). Experiments made with the object of bringing about a Beckmann transformation by means of acetic anhydride or acetyl chloride led to no useful result.

An isomeride of strychnidone was obtained when this substance (6·5 g.), dissolved in the minimum quantity of boiling methyl alcohol, was mixed with methyl-alcoholic potash (25 c.c. of 25%). On heating on the steam-bath, the liquid clouded and a crystalline, chalky precipitate separated. This was collected, washed well with methyl alcohol, and crystallised from much boiling methyl alcohol, from which the substance separated as a colourless, crystalline powder (Found: C, 71·3; H, 7·0; N, 7·7. $C_{21}H_{24}O_3N_2$ requires C, 71·6; H, 6·8; N, 7·9%).

allo-*Strychnidone* shrinks at 245°, gradually becomes brown, and froths at about 260—265°. It dissolves with difficulty in dilute acids and shows the same colour reactions as the original diketo-derivative. It is moderately easily soluble in boiling acetone or xylene and is very stable to permanganate. The same substance appeared to be produced when the original diketo-derivative was left in contact with concentrated sulphuric acid for 2 hours and the brownish-yellow solution, after dilution, was precipitated by ammonia. The decomposing point after recrystallisation was about 265° (Found: C, 71·2; H, 6·9; N, 7·8%). When the methyl-alcoholic solution of the base was boiled with semicarbazide hydrochloride or with hydroxylamine hydrochloride and sodium acetate, under exactly the conditions described above in the case of the isomeride, m. p. 152°, the solution in both cases deposited, on cooling, a mass of crystals of the *allo*-derivative which was identified by the decomposing point, 260°, and by analysis.

Methoxymethylstrychnidonic Acid.—The best conditions for the formation of this substance seem to be the following. Finely powdered methoxymethyldihydrostrychnidine (6 g.), suspended in warm methyl alcohol (50 c.c.), is mixed with methyl-alcoholic potash (10 c.c. of 25%), and perhydrol (20 c.c.) is added all at once. The temperature is kept carefully at 43—44°; a slow effervescence then takes place and a slimy substance separates at first but gradually disappears. After about an hour the effervescence will have ceased. The pale yellow product is left over-night, then mixed with an equal volume of water, and the methyl alcohol removed by distillation under reduced pressure. The filtrate from a small amount of flocculent matter is extracted several times with ether, then with chloroform to remove a gum, which so far has not been investigated, and is again distilled in order to free it from ether and chloroform.

On being acidified with dilute sulphuric acid, the liquid clouds and crude methoxymethylstrychnidonic acid separates as a brown resin. A specimen of the amino-acid in a nearly pure condition was obtained by extracting the crude product with much ether, drying the extract over calcium chloride, distilling off most of the ether, and allowing most of the remainder to evaporate over sulphuric acid; the *amino-acid* then separated as a crust which was not definitely crystalline (Found: C, 64·8; N, 7·5; N, 7·2. $C_{21}H_{28}O_5N_2$ requires C, 65·0; H, 7·2; N, 7·2%).

Anhydromethoxymethylstrychnidonic Acid.—When the crude amino-acid obtained on acidifying the product of the action of perhydrol on methoxymethyldihydrostrychnidine (see above) is warmed with water, almost all dissolves, and on allowing the solution to evaporate at 70—80° it darkens considerably and deposits at first colourless nodules of the anhydro-amino-acid and then a dark tar containing some crystalline matter. The latter is dissolved in a little boiling methyl alcohol and after some days the sparingly soluble anhydro-acid separates as a crust. This is collected and washed with methyl alcohol, the nearly colourless residue mixed with the nodules, and the whole repeatedly crystallised from methyl alcohol (Found: C, 67·6; H, 7·0; N, 7·4; MeO, 8·1. $C_{21}H_{26}O_4N_2$ requires C, 68·1; H, 7·0; N, 7·6; MeO, 8·0%). This anhydro-acid melts at 222° and is sparingly soluble even in boiling methyl alcohol, from which it separates in stars of flat, prismatic needles; on heating in a test-tube, it chars, liberating the odour of indole. It is insoluble in water or cold dilute acids or in dilute caustic soda solution, but dissolves gradually in the last on boiling. The solution in dilute sulphuric acid (60%) gives with dichromate an intense crimson colour, and the solution in warm dilute hydrochloric acid gives with ferric chloride the same coloration. When the anhydro-acid is heated in a sealed tube with methyl iodide and methyl alcohol for a few minutes, a pale yellow solution is obtained which deposits the unchanged anhydro-acid on evaporation.

Ethoxymethyldihydrostrychnidine.—This substance is obtained when powdered strychnidine methosulphate (3 g.) is heated with a saturated solution (25 c.c.) of caustic potash in ethyl alcohol on the steam-bath. The methosulphate gradually dissolves and a cloudy liquid containing drops of oil forms. After 10 minutes, the whole is cooled, water and ice are added, and the chalky precipitate is collected, washed with ice-water, and left on porous porcelain. The substance is very soluble in alcohol; from the solution, after being concentrated and left in the ice-chest, a paste of needles separates which, in contact with porous porcelain, becomes quite colourless but has the tendency, characteristic also of methoxy-

methyldihydrostrychnidine (compare p. 1602), to become purple on exposure to the air. After being dried at 80°, the substance melts at about 98° (Found: C, 75·9; H, 8·4; N, 7·3. $C_{24}H_{32}O_2N_2$ requires C, 75·8; H, 8·4; N, 7·3%). *Ethoxymethyldihydrostrychnidine* is much more readily soluble in solvents than the corresponding methoxy-derivative and exhibits much less tendency to separate in well-defined crystals. It is very soluble in light petroleum and separates from the concentrated solution, on slow evaporation, in hard, lilac-brown prisms.

Methoxymethyltetrahydrostrychnidine.

The corresponding dihydro-derivative (p. 1602) (10 g.), as obtained directly by the addition of water to the product of the action of methyl-alcoholic potash on strychnidine methosulphate, is dissolved in dilute sulphuric acid (150 c.c. of 20%) and reduced, in the apparatus described on p. 1600, by a current of 5 amps. for 15 hours. The product is diluted and mixed with excess of concentrated caustic potash solution, and the solid is collected, dried on porous porcelain, and warmed with a little alcohol to remove traces of gum. The substance is then twice crystallised from xylene, from which it separates very characteristically in well-developed, glistening, short prisms (Found: C, 75·1; H, 8·6; N, 7·5; MeO, 8·1. $C_{23}H_{32}O_2N_2$ requires C, 75·0; H, 8·7; N, 7·6; MeO, 8·3%). *Methoxymethyltetrahydrostrychnidine* melts at 220° and distils at about 230—235°/1 mm. without any decomposition, since the colourless, crystalline distillate melts at 220—222° either alone or mixed with a specimen of the original substance. It is very sparingly soluble in boiling alcohol, and moderately easily soluble in boiling benzene, from which it crystallises well in plates. It dissolves readily in dilute acids. The solution in dilute sulphuric acid gives with dichromate a pink coloration which rapidly changes to reddish-purple. Acetic anhydride appears to be without action, since, after boiling with the anhydride and a drop of sulphuric acid for several minutes, the base was recovered unchanged on addition of ammonia after the acetic anhydride had been decomposed with water.

The *hydriodide* was prepared by dissolving the base in a slight excess of dilute hydrochloric acid, adding a few drops of sulphuric acid, heating the solution to boiling, and mixing it with a large excess of aqueous sodium iodide; from the milky solution thus produced, a gum separated which soon crystallised. The mass was well washed and dissolved in boiling water, and the solution rubbed with a glass rod; a meal of glistening prisms then separated, m. p. 235° (decomp.) (compare p. 1623) (Found: C, 56·0; H, 6·7. $C_{23}H_{32}O_2N_2$,HI requires C, 55·7; H, 6·7%). This hydriodide is

very sparingly soluble in boiling methyl alcohol and separates well, on cooling, in small, colourless needles. Its conversion into methyl-*neo*dihydrostrychnidinium iodide by the action of heat is described on p. 1623.

The Methiodide (*a*), $C_{23}H_{32}O_2N_2$,MeI.—The base, m. p. 220°, does not combine readily with methyl iodide and may indeed be recrystallised from methyl iodide without change. In an experiment in which the base was boiled with methyl alcohol and a large excess of methyl iodide for 12 hours, the clear solution, on being concentrated, deposited a large amount of the unchanged base. When, however, the powdered base (2·5 g.) was heated with methyl iodide (8 c.c.) in a sealed tube in the steam-bath for 5 hours, complete solution gradually took place and, on cooling, a mass of crystals separated, or in some experiments a syrup formed on the surface of the methyl iodide which became crystalline on being rubbed with methyl alcohol. In either case, the crystals were collected, washed with methyl iodide, and recrystallised from a little boiling alcohol, from which the *methiodide* separated, on slowly cooling, as a glistening crust of arrow-shaped prisms (Found: C, 56·0; H, 7·0; I, 24·5. $C_{24}H_{35}O_2N_2I$ requires C, 56·4; H, 6·9; I, 24·9%). This methiodide melts at about 227° with vigorous effervescence. In order to determine the nature of this decomposition, about a gram of the substance was heated in a test-tube at 250°; methyl iodide then condensed on the cold part of the tube. After effervescence had ceased, the nearly colourless gum was dissolved in much boiling methyl alcohol, and the solution concentrated; on cooling, methoxymethyltetrahydrostrychnidine separated in prisms, m. p. 220°. The methiodide is decomposed with great difficulty by methyl-alcoholic potash, since, after boiling for several minutes, most of the unchanged methiodide is recovered on the addition of water. The methyl iodide washings of the crude methiodide gave a syrup on evaporation; a solution of this in boiling methyl alcohol, on standing exposed to air, deposited thick prisms of methoxymethyltetrahydrostrychnidine, showing again the small tendency this base has to combine with methyl iodide.

The Methochloride (*a*).—This was prepared by warming the methiodide with water and excess of silver chloride on the steam-bath for 2 hours and then evaporating the filtrate from the silver salts; the methochloride separated as a waxy, crystalline mass, which was not analysed. When this substance was heated on the steam-bath with excess of methyl-alcoholic potash (20%), decomposition took place immediately with separation of potassium chloride, and, as the product was completely soluble in water, it is probable that the methohydroxide was present at this stage.

If, instead of diluting the mixture with water, the whole is heated at 140° until nearly all the methyl alcohol has evaporated, a crystalline precipitate of methoxymethyltetrahydrostrychnidine is obtained on the addition of water.

The Dimethosulphates, $C_{23}H_{32}O_2N_2,2Me_2SO_4$ (A) *and* (B).—Methoxymethyltetrahydrostrychnidine does not combine readily with methyl sulphate, as is shown by the fact that, if methyl sulphate is added to a boiling concentrated solution of the base in benzene, the unchanged substance crystallises on cooling. Combination takes place readily, however, under the following conditions and with the formation of the dimethosulphates. The base (8 g.), dissolved in specially purified and dried benzene (100 c.c.), is mixed with carefully purified methyl sulphate (20 c.c.) and boiled under reflux with exclusion of moisture; in about 2 hours, the liquid begins to cloud and a gelatinous mass to separate. The boiling is continued for 20 hours, and the hot benzene then decanted from the gummy mass. After several days, the benzene solution deposits a soft, crystalline crust, which is washed with benzene and dried over sulphuric acid in a vacuum desiccator (Found: C, 51·8; H, 6·9. $C_{23}H_{32}O_2N_2,2Me_2SO_4$ requires C, 52·2; H, 7·1%). That this substance is the *dimethosulphate* (A) was confirmed by the fact that the solution in boiling methyl alcohol gave, on the addition of sodium iodide and cooling, the dimethiodide (A), m. p. 315—320° (decomp.). In preparing this substance in quantity, the horny mass of dimethosulphate from which the benzene had been decanted was dissolved in warm water, and the solution was filtered from benzene and mixed with a considerable excess of hot concentrated sodium iodide; the clear solution, on rubbing, immediately began to deposit the *dimethiodide* (A) in flat prisms. After some hours, the crystalline mass was collected, well washed, and dried on porous porcelain and then on the steam-bath (Found: C, 45·8; H, 5·6. $C_{23}H_{32}O_2N_2,2MeI$ requires C, 46·0; H, 5·8%). This dimethiodide (A) does not discolour until 300° and melts and effervesces at about 315° to a reddish-brown froth. It dissolves readily in boiling water and separates on cooling in needles; in boiling methyl alcohol it is very sparingly soluble, but it dissolves in much boiling ethyl alcohol and separates on slow cooling in striated, quadrilateral plates.

The Dimethochloride (A).—A boiling aqueous solution of the dimethiodide (A) was readily decomposed by silver chloride and, on evaporating the filtrate from the silver salts to a small bulk and leaving it over sulphuric acid, a gummy mass was obtained which gradually crystallised but was not analysed. The solution in dilute sulphuric acid gives with dichromate a pink coloration which becomes crimson on warming. The conversion of this dimethoc

chloride (A) into methyl-ψ-dihydrostrychnidine, $C_{22}H_{28}ON_2$, by the action of heat is described on p. 1621.

Methoxymethyltetrahydrostrychnidine Dimethiodide (B), $C_{23}H_{32}O_2N_2,2MeI$.—When the solution of the dimethosulphate, prepared as described on p. 1619, was treated with sodium iodide, less than half the calculated amount of the dimethiodide (A) separated, and very little more was obtained on standing or concentration. On investigating the cause of this, it was found that the addition of caustic potash solution (50%) to the mother-liquor of (A) produced a heavy caseous precipitate. After alkali had been added until there was no further separation, the whole was warmed at 50°; the precipitate then melted and settled on the bottom of the beaker as a viscid gum. The supernatant alkaline solution was decanted, the syrup dissolved in boiling methyl alcohol, and the solution filtered and concentrated; on standing, a thick mass of colourless prisms gradually separated, and more was obtained by concentrating the mother-liquor. This dimethiodide (B) is very readily soluble in boiling methyl alcohol, but sparingly soluble in the cold, and separates in thick, four-sided, twin prisms which effervesce at about 165° owing to the escape of methyl iodide (see below) (Found: C, 46·7; H, 5·9. $C_{25}H_{38}O_2N_2I_2$ requires C, 46·0; H, 5·8%). The final methyl-alcoholic mother-liquors, from which no more of the dimethiodide (B) could be separated, on being concentrated and kept for months in the air, yielded a semi-solid paste; this, in contact with porous porcelain, gradually left a white, crystalline mass, a solution of which in methyl alcohol, when allowed to concentrate in the air, gradually deposited large, glistening prisms, m. p. 225° (vig. efferv.) (Found: C, 56·2; H, 7·0. $C_{23}H_{32}O_2N_2,MeI$ requires C, 56·4; H, 6·8%). Since this substance decomposed on heating into methyl iodide and methoxymethyltetrahydrostrychnidine, it is evident that it was the methiodide of this substance described on p. 1618, and its formation shows that the crude dimethosulphate prepared in benzene solution with a large excess of methyl sulphate contains some monomethosulphate in spite of the fact that a very large excess of methyl sulphate was used and the heating continued for 20 hours (p. 1619).

Methoxymethyltetrahydrostrychnidine Methiodide (*b*).—When the dimethiodide (B) just described is heated in a test-tube in a bath at about 220°, methyl iodide is eliminated and condenses on the cold sides of the tube. In a quantitative experiment, 0·2440 g., heated at 165°, rising to 230° until decomposition was complete, lost 0·1047 g. or 42·8%, whereas $C_{23}H_{32}O_2N_2,2MeI$ losing 2MeI requires a loss of 43·5%. On crystallising the residue from alcohol, colourless leaflets separated which melted at 220° and consisted of methoxy-

methyltetrahydrostrychnidine (Found: C, 74·9; H, 8·6. Calc. for $C_{23}H_{32}O_2N_2$: C, 75·0; H, 8·7%). The elimination of only 1 mol. of methyl iodide was accomplished under the following conditions. The dimethiodide (B) was gently boiled in a test-tube with carefully dried mesitylene; it then became spongy and granular but did not dissolve. The crystalline deposit was collected, washed with warm mesitylene, and crystallised from a large volume of methyl alcohol, in which it was very sparingly soluble and from which it separated as a sandy, crystalline powder (Found: C, 55·8; H, 6·7. $C_{23}H_{32}O_2N_2$,MeI requires C, 56·4; H, 6·9%). This methiodide (*b*) becomes brown at 300—320°, decomposes with effervescence at about 325° into methyl iodide and methoxymethyltetrahydrostrychnidine, and is readily soluble in boiling water. It is therefore isomeric with the methiodide (*a*) described on p. 1618, which melts at 227°, and it is interesting that both these isomerides lose methyl iodide on heating and yield methoxymethyltetrahydrostrychnidine.

Methoxymethyltetrahydrostrychnidine Dimethochloride (B).—The pure dimethiodide (B), m. p. 165°, was treated with water and silver chloride on the steam-bath in the usual way; the filtrate from the silver salts was evaporated to a small bulk on the steam-bath and then left over sulphuric acid in a vacuum desiccator, but there was no sign of crystallisation and the whole dried to a horny mass. This became brittle on the steam-bath and could be powdered, but the powder rapidly absorbed moisture and became sticky. When the dry substance was heated in a test-tube in a sulphuric acid bath, methyl chloride was eliminated; the effervescence being over, the residue was crystallised from xylene, colourless prisms being thus obtained which melted at 220—222° and consisted of methoxymethyltetrahydrostrychnidine [compare the action of heat on the dimethochloride (A),; see below].

Methyl-ψ-dihydrostrychnidine, $C_{22}H_{28}ON_2$.—This substance is obtained from the dimethochloride (A) of methoxymethyltetrahydrostrychnidine (p. 1619) or from methyl*neo*dihydrostrychnidinium chloride (p. 1623) by heating. The dimethochloride (A), in quantities of not more than 0·5 g., is cautiously heated in test-tubes over a free flame; it soon gives off steam and doubtless also methyl alcohol and then froths at a very high temperature, giving a very unpleasant smelling vapour, which burns with a smoky flame tinged with green, and a small amount of a colourless, crystalline sublimate forms on the sides of the tube. When the effervescence has ceased, the ochre-coloured residue, which crystallises on cooling, is dissolved in much boiling methyl alcohol; the solution, on being concentrated considerably and left in the ice-chest, deposits the new substance in colourless spangles, but the yield is poor even after the mother-

liquors have been worked up (Found: C, 78·1; H, 8·0; N, 8·5. $C_{22}H_{28}ON_2$ requires C, 78·6; H, 8·3; N, 8·3%).

Methyl-ψ-dihydrostrychnidine melts at 212° and is somewhat soluble in boiling water to a bitter solution which, on cooling, deposits the substance in flitters. It is sparingly soluble in cold methyl alcohol and very sparingly soluble in acetone even on boiling; it separates from the solution, on concentration, in glistening, colourless plates. It is also sparingly soluble in benzene or light petroleum. The solution in acetone does not decolorise permanganate except on the addition of a little water and then only on long standing. The resistance to oxidation was shown in an experiment in which the base (1 g.), dissolved in much boiling acetone and water (3 c.c.), was boiled under reflux, and permanganate (1·5 g.) gradually added. After some hours, decoloration was complete and the acetone filtrate from the manganese precipitate yielded, on being concentrated, 0·7 g. of unchanged substance. A solution of the base in dilute sulphuric acid gives with dichromate a yellow solution which becomes crimson on warming; a solution in dilute hydrochloric acid is coloured yellowish-pink by ferric chloride, the colour changing to crimson on warming. The base dissolves with effervescence in concentrated nitric acid to a reddish-brown solution.

The Methiodide, $C_{22}H_{28}ON_2$,MeI.—When the base, m. p. 212°, was mixed with methyl iodide, there was some rise of temperature. The chalky precipitate produced after the mixture had been heated in a sealed tube for 15 minutes was crystallised from methyl alcohol, in which it was very sparingly soluble and from which it separated in glistening groups of slender needles (Found: C, 57·6; H, 6·3. $C_{23}H_{31}ON_2I$ requires C, 57·7; H, 6·4%). This methiodide is very sparingly soluble in boiling water. It becomes brown at 290° and decomposes with effervescence at about 330—335° to a brown syrup, which crystallises on cooling; this decomposition product was not further investigated.

The *methochloride*, prepared in the usual manner by boiling the methiodide with water and silver chloride, separated from the concentrated aqueous solution, on standing over sulphuric acid, in colourless, very readily soluble needles and was not analysed. It darkens at 260° and effervesces at about 315° to a black syrup. The solution in dilute sulphuric acid gives with permanganate a pink coloration which becomes an intense crimson on standing or warming.

*The Methyl*neo*dihydrostrychnidinium Salts.*

Methoxymethyltetrahydrostrychnidine, unlike the corresponding dihydro-derivative (p. 1610), is not acted on by boiling dilute sulphuric

acid: the tetrahydro-base (5 g.) was boiled with sulphuric acid (20% by vol.) for 3 hours, but there was no sign of any elimination of methyl alcohol and on addition of ammonia a caseous precipitate separated which was found to be the unchanged base, practically the whole being recovered. The only way in which the methyl*neo*-dihydrostrychnidinium salts could be prepared was from methoxymethyltetrahydrostrychnidine hydriodide (p. 1617) by the action of heat. The air-dried substance, in quantities of 0·5 g., was spread evenly over the lower surface of large test-tubes and these were heated by a sulphuric acid bath gradually to 230° and kept at this temperature for about 3 minutes; the vapours which came off during the decomposition were apparently water and methyl alcohol. After effervescence had ceased, the residual syrup crystallised, on cooling, as a hard, pale brown crust. This was very sparingly soluble in boiling water, but dissolved very readily in warm dilute hydrochloric acid (compare p. 1611). The solution, after being decolorised with norite, was mixed with excess of ammonia, left for 24 hours, filtered from a small, fluffy, brown precipitate, and concentrated on the steam-bath to a small bulk. The solution of ammonium chloride was decanted from the sparingly soluble, brown crusts which had separated, and the crusts were dissolved in much boiling water. On concentrating the solution considerably, the iodide separated in well-developed, pale brown prisms (Found: C, 57·2; H, 6·4. $C_{22}H_{29}ON_2I$ requires C, 56·9; H, 6·3%).

*Methyl*neo*dihydrostrychnidinium iodide* melts at about 350° with effervescence and is sparingly soluble in alcohol, xylene, or glacial acetic acid. This iodide was rubbed into a paste with hot water and heated on the steam-bath for 2 hours with excess of silver chloride. The filtrate from the silver salts was evaporated to a small bulk and the solution placed over sulphuric acid in a vacuum desiccator; a paste of crystals then formed. In contact with porous porcelain, the mother-liquor was readily absorbed, leaving a hard, colourless mass of *methyl*neo*dihydrostrychnidinium chloride* (Found in material dried at 100°: C, 70·7; H, 8·1. $C_{22}H_{29}ON_2Cl$ requires C, 70·8; H, 7·9%). This chloride is very readily soluble in water. The solution in dilute sulphuric acid gives with dichromate an intense crimson coloration in the cold. The dry substance changes colour at 300° and decomposes at about 345° with effervescence, leaving a brown syrup. In investigating this change, the dry substance (0·5 g.) was very cautiously heated in a large test-tube by a free flame until effervescence had ceased; during this decomposition a very pungent and unpleasant smelling vapour was given off which tinged a flame green. The brown syrup solidified, on cooling, to a very hard crust. A solution of this in much boiling

methyl alcohol was decolorised by boiling with norite for an hour and then concentrated; a mass of colourless plates then gradually separated which melted at 210—212° and consisted of methyl-ψ-dihydrostrychnidine, as a comparison of properties and a mixed melting point demonstrated. This is probably the most convenient method of preparing this base, but the yield in this case also is not good.

Methylstrychnine.—This substance may be quickly and conveniently prepared in good yield by the following process. Strychnine (100 g.), finely powdered and passed through a 40-mesh sieve, is stirred in a mortar with the gradual addition of pure methyl sulphate (68 c.c.); the whole soon sets to a solid mass of strychnine methosulphate. This is broken up, left over-night, and dissolved in warm water (300 c.c.), the solution is filtered from unchanged methyl sulphate (about 2 c.c.), and then caustic potash (170 c.c. of 50%) added with shaking. Crystallisation soon sets in and after remaining over-night the crystals are collected and dissolved in boiling water (260 c.c.), and the solution is filtered from unchanged strychnine (about 2 g.) and allowed to cool; the stout, colourless prisms of methylstrychnine, $C_{22}H_{24}O_2N_2,4H_2O$, that separate are collected and dried on the steam-bath. The colourless powder (93 g.) melts and decomposes at about 318—320°. The aqueous mother-liquors are used for the recrystallisation of another batch of crude methylstrychnine.

Normethylstrychnine.—When methylstrychnine, powdered and dried on the steam-bath, is heated in a distilling flask under 1 mm. by a metal bath kept at 200—205°, it gradually melts, there is much effervescence and some sublimation, and the loss is about 15%. The heating is continued for about ½ hour, and the residual resin is then dissolved in a slight excess of dilute hydrochloric acid, ammonia is added until there is a slight precipitation, and the filtered solution is mixed with excess of ammonia and warmed at 50° on the steam-bath. The pale brown, granular precipitate is collected and dissolved in excess of warm oxalic acid; after 2 days, a small amount of a dark crust separates. The filtrate from this is vigorously shaken while dilute ammonia is carefully added so long as a dark-coloured precipitate forms. After being filtered, the solution is shaken with norite and filtered, and excess of ammonia is added to the pale yellow filtrate. A voluminous, pale ochre precipitate separates which becomes granular on warming at 50°, and this is collected, washed, and dried over sulphuric acid in a vacuum desiccator (Found in two different preparations: C, 75·7 and 75·2; H, 6·8 and 6·7; N, 8·2. $C_{21}H_{22}O_2N_2$ requires C, 75·4; H, 6·6; N, 8·4%). This base, which is isomeric with strychnine, has so far

not been obtained in a crystalline condition. A solution in dilute sulphuric acid (60% by vol.) gives with dichromate an intense bluish-purple colour, fading to a port wine tint; a solution in dilute hydrochloric acid gives with ferric chloride no coloration in the cold and there is little change on warming.

The Methiodide.—The base was heated in a sealed tube in the steam-bath with a large excess of methyl iodide for 5 hours. Next day, the crust of prisms which had separated on the sides of the tube was scraped off, washed with methyl iodide, and dried on the steam-bath. The old-gold, crystalline mass became opaque at 180°, darkened at 290°, and frothed at about 315° (Found: C, 54·9; H, 5·5. $C_{21}H_{22}O_2N_2$,MeI requires C, 55·4; H, 5·3%). This methiodide of normethylstrychnine was digested with water and silver chloride on the steam-bath, and the pale green filtrate concentrated to a small bulk; a soft, satiny mass separated on standing. This became colourless on porous porcelain and melted at about 285° (Found: C, 68·9; H, 6·6; N, 7·2. $C_{21}H_{22}O_2N_2$,MeCl requires C, 68·7; H, 6·5; N, 7·3%). A solution of this methochloride in dilute sulphuric acid (60% by vol.) gives with dichromate an intense indigo-blue colour, fading to brown. Methylstrychnine (10 g.) mixed with phenol (15 g.) was heated at 240° for an hour; the distillate, on treatment with dilute potash, yielded anisole (1·2 g.), which was recognised by its boiling point and other properties.

Action of Caustic Potash on Methylstrychnine.—Methylstrychnine (10 g.), mixed with methyl-alcoholic potash (60 c.c. of 20%), was heated on the steam-bath for 15 minutes with stirring, powdered potash (30 g.) was then added, and the decomposition continued at 150—200° for 20 minutes with frequent stirring; the temperature was then raised to 250° for 30 minutes. The product from five such operations was steam-distilled, the oil that passed over was extracted with ether, and the extract was dried over potassium carbonate and fractionated. The portion that distilled between 148° and 155°/15 mm., on remaining in the ice-chest, deposited crystals which were collected, drained on porous porcelain, and recrystallised from petroleum. The colourless plates thus obtained in considerable quantity melted at 52° and consisted of indole, as a mixed melting-point determination and a careful comparison of properties conclusively proved. The reddish-brown solution in the steam-distillation flask was cooled, sulphur dioxide passed in, and the precipitate collected, dried, and distilled in quantities of 3 g. with soda-lime under reduced pressure. The distillate, containing oily drops, was extracted with ether, and the extract steam-distilled; a further quantity of indole then passed over. Finally, the residue in the steam-distillation flask was extracted with benzene and distilled,

and the fraction, b. p. 240—280°/16 mm., was dissolved in low-boiling petroleum; from the solution a pasty mass of crystals separated which, after recrystallisation, melted at 236°, and this substance was found, by an examination of its colour reactions and other properties and by a mixed m. p. determination, to be carbazole.

Decomposition by soda-lime. Methylstrychnine (2·5 g.) was mixed with soda-lime (10 g.) and heated in a hard glass tube under 20 mm. to about 400°. The distillate from several such operations was steam-distilled, the pale yellow oil extracted with ether, and the extract dried over potassium carbonate and fractionated; an oil passed over at 93°/25 mm. which was insoluble in dilute hydrochloric acid, gave an intense purple colour with *p*-dimethylaminobenzaldehyde, and yielded a picrate, m. p. 168°. The amount obtained was too small to allow of its constitution being determined.

The residue from the steam distillation yielded a small amount of a substance which separated from light petroleum in glistening plates, m. p. 236°, and was recognised as carbazole.

Electrolytic Reduction of Methylstrychnine.—Methylstrychnine (20 g.), dissolved in dilute sulphuric acid (100 c.c. of 60%), was reduced in the usual apparatus (p. 1600) by a current of 5 amps. for 16 hours, the pale pink solution diluted with water and heated on the steam-bath, and barium carbonate added until the sulphuric acid had been removed. The strongly alkaline solution from the barium sulphate was evaporated to dryness; the almost colourless, crystalline methylstrychnidinium hydrogen carbonate that remained was purified by dissolving it in methyl alcohol, in which it was readily soluble, and fractionally precipitating it with ether. The second fraction, after drying on porous porcelain over sulphuric acid in a vacuum desiccator, gave analytical results agreeing approximately with those required for the formula

$$C_{22}H_{27}ON_2,HCO_3,H_2O$$

(Found: C, 65·8; H, 6·9; N, 6·8. Calc.: C, 66·6; H, 7·2; N, 6·8%). When this carbonate was heated at 100° it lost 4·4% (Calc., 4·3%) (Found: C, 69·0; H, 7·4; N, 7·0. $C_{23}H_{28}O_4N_2$ requires C, 69·7; H, 7·1; N, 7·1%). This carbonate is readily soluble in hot water and effervesces with acids; the dry substance also effervesces, when it is heated at 200°, with formation of a colourless syrup. It was readily soluble in hot methyl-alcoholic potash (25%), and after heating in an open flask on the steam-bath for 15 minutes so that considerable concentration had taken place, the milky liquid gave, on dilution with water, a caseous precipitate which separated from methyl alcohol in glistening prisms, m. p. 124—125°, and proved to be methoxymethyldihydrostrychnidine (Found: C, 75·0; H,

8·2. Calc. for $C_{23}H_{30}O_2N_2$: C, 75·4; H, 8·2%). When the carbonate was treated with hydrochloric acid, it yielded a horny methochloride which appeared to be identical with the substance obtained from strychnidine methiodide by treatment with silver chloride (p. 1601).

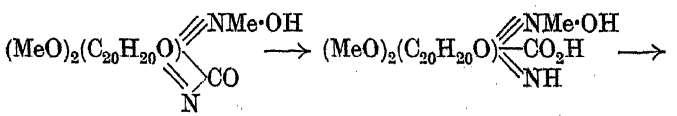
CCXI.—*Strychnine and Brucine. Part V.*

By JOHN MASSON GULLAND, WILLIAM HENRY PERKIN, jun., and ROBERT ROBINSON.

THE present communication contains the description of part of a general investigation of the reduction products of brucine, our knowledge of which is comparatively scanty. Reduction by hydrogen in presence of colloidal palladium yields dihydrobrucine (Skita and Franck, *Ber.*, 1911, **44**, 2864), and Tafel and Naumann (*Ber.*, 1901, **34**, 3291) have described the preparation by electrolytic reduction of a substance which they designate "tetrahydrobrucine."

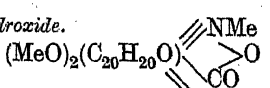
The starting point of the research now to be described is brucidine, a substance which Tafel and Naumann (*loc. cit.*) claim to have prepared from "tetrahydrobrucine" by the elimination of water at 215°. The two substances were thus considered to be analogous to tetrahydrostrychnine and strychnidine and were represented by the scheme:.

$$(MeO)_2(C_{20}H_{20}O)(:N)\leqslant^{CH_2\cdot OH}_{NH} \longrightarrow (MeO)_2(C_{20}H_{20}O)(:N)\leqslant^{CH_2}_{N}$$



Tetrahydrobrucine. *Brucidine.*

The properties of these substances as described by Tafel are extremely similar, and he was unable to demonstrate by the preparation of a nitrosoamine the presence of an imino-group in the secondary amine, tetrahydrobrucine. We have repeated the electrolytic reduction of brucine, using the modified apparatus described in a previous communication (J., 1924, **125**, 1798), and our results show that Tafel's "tetrahydrobrucine," m. p. 200—201°, should be re-named brucidine. It is clear, however, that his "brucidine," m. p. 198°, was correctly named, although it was not quite homogeneous and was identical with his supposed "tetrahydrobrucine." We have now obtained two products, (i) *brucidine*, m. p. 203—203·5°, which shows all the properties of Tafel's "tetrahydrobrucine," and (ii) *tetrahydrobrucine*, m. p. 177°, which is a secondary amine yielding a *nitrosoamine*. The second substance, moreover, yields brucidine when dehydrated by means of phosphorus



oxychloride, and the two compounds are thus entirely analogous to the corresponding derivatives of strychnine. Tafel's analyses of " tetrahydrobrucine " are in agreement with the theory for brucidine containing a molecule of methyl alcohol, and we have found that the base when crystallised from methyl alcohol does in fact retain one molecule of the solvent.

Tetrahydrobrucine and brucidine are di-acid bases each of which forms a *dihydrochloride* and a *dihydriodide*, but only a monomethiodide when heated with an excess of methyl iodide in boiling methyl alcohol.

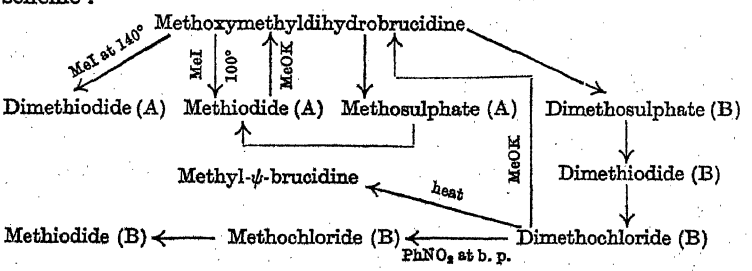
The starting materials in the experiments described in this communication are the brucidine metho-salts, and of these the *methosulphate*, prepared by the direct combination of the base with methyl sulphate, is the most easily obtained in practice. Brucidine metho-salts, however, have also been prepared by the electrolytic reduction of methylbrucine. This substance was first obtained (Moufang and Tafel, *Annalen*, 1899, **304**, 42) by the decomposition of brucine methiodide with silver sulphate, followed by the removal of the sulphuric acid by baryta, and Tafel represented it as a betaine according to the scheme :

Brucine methohydroxide.

Methylbrucine.

Leuchs and Anderson (*Ber.*, 1911, **44**, 3046), however, prepared this compound more simply by the action of sodium hydroxide on brucine methosulphate, and we have employed a slight modification of their method. The electrolytic reduction of methylbrucine in dilute sulphuric acid is followed by the removal of the sulphuric acid by means of barium carbonate. In this way, *brucidine methohydrogencarbonate* is obtained, and from it may be prepared *brucidine methohydroxide* by the action of alkali, and also *brucidine methiodide* by means of sodium iodide. This methiodide is identical with a specimen prepared by the interaction of the base with methyl iodide, and it is therefore evident that the nitrogen atom which is involved in the production of brucidine metho-salts is not that which forms part of the group $-CO-N:$ of brucine.

When brucidine methochloride or methosulphate,



$$C_{22}H_{28}O_3N_2,Me_2SO_4,$$

is digested with methyl-alcoholic potassium hydroxide it is converted into *methoxymethyldihydrobrucidine*, $C_{25}H_{34}O_4N_2$, m. p. 115°, which is derived from brucidine by the introduction of a methyl group and the addition of methyl alcohol. Unlike the corresponding derivative of strychnidine, this substance is a di-acid base, yielding a *dihydriodide*, but here, as in the case of brucidine, one molecule only of methyl iodide enters easily into combination with the base. The formation of this *methiodide* (A) by the action of methyl iodide at 100° takes place smoothly in the absence of a solvent, but when methyl alcohol is employed in the preparation, a small quantity of *oxymethoxymethyldihydrobrucidine*, $C_{25}H_{34}O_5N_2$, m. p. 277°, is produced, and a little of the same substance may be isolated from the mother-liquors when the methiodide, prepared in the absence of a solvent, is recrystallised from methyl alcohol. By far the greater proportion of the product of the action of methyl iodide on methoxymethyldihydrobrucidine under either set of conditions is the methiodide (A), and in this the brucidine derivative differs greatly from the parallel strychnidine one (compare this vol., p. 1591). Indications have been obtained of the formation in these reactions of a second iodine-free *base*, melting at about 218°, which may correspond to oxymethoxymethyldihydrostrychnidine (A), but this substance has not been obtained in a pure condition, because recrystallisation from methyl alcohol converts it into oxymethoxymethyldihydrobrucidine, m. p. 277°. Oxymethoxymethyldihydrobrucidine is probably formed by an atmospheric oxidation which is catalysed by small quantities of iodine, since it has recently been obtained in much greater yield when an ethyl-alcoholic solution of methoxymethyldihydrobrucidine containing a few small crystals of iodine is exposed to the air for some days. A parallel experiment in which the iodine was omitted yielded no oxymethoxymethyldihydrobrucidine in the same space of time.

Further atmospheric oxidation takes place in boiling methyl-alcoholic solution, and a *dioxymethoxymethyldihydrobrucidine* (X), $C_{25}H_{34}O_6N_2$, m. p. 270°, has been isolated. This substance is isomeric with two *dioxymethoxymethyldihydrobrucidines*, namely (Y) and (Z) (p. 1631), which are produced by oxidation of methoxymethyldihydrobrucidine by permanganate. The investigation into the constitution of these substances, their relationship, and the significance of their formation has not yet been completed.

Methoxymethyldihydrobrucidine combines readily at 100° with one molecule of methyl iodide, as has been stated above, but when the temperature is raised to 140° and the reaction prolonged for some hours, the *dimethiodide* (A), m. p. 215°, is formed. In a similar way, methoxymethyldihydrobrucidine reacts slowly with methyl

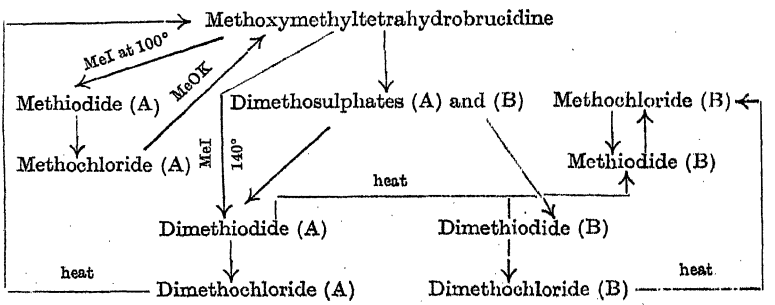
sulphate at 100° to form the *monomethosulphate* (A), but if the reaction is continued for a day the base is converted quantitatively into the *dimethosulphate* (B). This substance has not been obtained in a crystalline form, but when sodium iodide is added to its aqueous solution the *dimethiodide* (B), m. p. 290°, is precipitated and easily obtained in a pure condition. The *dimethochloride* (B), prepared from the dimethiodide by the action of silver chloride, is a horny mass which has been decomposed in three different ways. When boiled with methyl-alcoholic potassium hydroxide, it loses two molecules of methyl chloride, and methoxymethyldihydrobrucidine is regenerated. When the dimethochloride is heated for a short time in boiling nitrobenzene, the chief product is *methoxymethyldihydrobrucidine methochloride* (B), produced by the liberation of one molecule of methyl chloride. Sodium iodide converts this substance into the *methiodide* (B), which is isomeric with the methiodide (A) mentioned above. When, thirdly, the dry dimethochloride (B) is heated, it loses two molecules of methyl chloride and one of methyl alcohol and yields *methyl-ψ-brucidine* (p. 1631). It will be observed that methoxymethyldihydrobrucidine not only forms two series of metho-salts, depending probably upon which of the two nitrogen atoms is involved, but also two series of dimetho-salts, which are probably stereoisomeric. The relationships existing in this complex group of substances are readily understood from the following scheme:

A consideration of the colour reactions of the reduced brucidine derivatives, especially that given with ferric chloride (see p. 1661), leads to the conclusion that the methiodide (A) has the formula $(MeO)_2(C_{20}H_{20}O)(OMe)(:NMe)\left\langle \begin{matrix} CH_2 \\ | \\ NMe \end{matrix} \right\rangle I$, whilst the methiodide (B) is $(MeO)_2(C_{20}H_{20}O)(OMe)(:NMe_2)\left\langle \begin{matrix} CH_2 \\ | \\ N \end{matrix} \right\rangle I$. This is noteworthy and implies that the more basic of the two nitrogen atoms of brucidine becomes the less basic of the two nitrogen atoms of methoxymethyldihydrobrucidine.

Dilute nitric acid has apparently little oxidising action on

methoxymethyldihydrobrucidine, as this reagent at 100° yields only *nitromethoxymethyldihydrobrucidine*, $C_{25}H_{33}O_6N_3$. When, however, the oxidation is brought about by means of potassium permanganate in acetone, two isomeric *dioxymethoxymethyldihydrobrucidines*, $C_{25}H_{34}O_6N_2$, are produced, namely (Y), m. p. 185—186°, and (Z), m. p. 110—111°. The first of these substances (Y) is a base and yields a *methiodide*, which has the interesting property of existing simultaneously in two interconvertible forms; one contains solvent of crystallisation, the other does not. This base is not altered by boiling for a short time with acetic anhydride, and attempts to form a semicarbazone resulted in a dark red, uncrystallisable oil. The second substance (Z) shows more feebly basic properties, since, although it is readily soluble in dilute hydrochloric acid, it does not react with methyl iodide at 100°.

In order to determine whether a process similar to the formation of methoxymethyldihydrobrucidine would occur if ethyl alcohol were substituted for the methyl alcohol used in the preparation of this substance, brucidine methosulphate was digested with sodium ethoxide in ethyl alcohol. A sandy powder was obtained which showed no tendency to crystallise, and was therefore analysed in the form of its crystalline methiodide. This proved to be *ethoxymethyldihydrobrucidine methiodide*, $C_{26}H_{36}O_4N_2,MeI$. The reaction thus follows a course similar to that observed when methyl alcohol is used, but the product was not further investigated.



When methoxymethyldihydrobrucidine is boiled with dilute sulphuric acid, methyl alcohol is eliminated, and as no precipitate is formed on the addition of ammonia or sodium hydroxide the solution evidently contains a quaternary sulphate. On addition of an excess of sodium iodide *methyl*neo*brucidinium iodide*, $C_{24}H_{31}O_3N_2I$, m. p. 298°, is precipitated, and the investigation of the mother-liquors yielded only a further quantity of the same iodide. It would thus appear that, in contrast to the behaviour of methoxymethyldihydrostrychnidine under similar conditions (this vol., p. 1593), only one iodide is formed, which, it should be noted, is isomeric with brucidine methiodide, m. p. 322°. *Methyl*neo*brucidinium chloride*, prepared from the iodide by means of silver chloride, may be decomposed in two ways. When digested with methyl-alcoholic potassium hydroxide, it gains methyl alcohol and loses hydrogen chloride, forming methoxymethyldihydrobrucidine. On the other hand, if the dry chloride is heated it loses hydrogen chloride, forming *methyl-ψ-brucidine*.

Methyl-ψ-brucidine, $C_{24}H_{30}O_3N_2$, m. p. 198—199°, is obtained either in the manner described above, or by heating methoxymethyldihydrobrucidine dimethochloride (B). It is a base, forming a

dihydriodide, but only a *methiodide* when combined directly with methyl iodide in the cold. Small quantities of the base and also of its methochloride are formed during the decomposition of methoxymethyldihydrobrucidine dimethochloride (B) in boiling nitrobenzene; the methochloride, which was not isolated, yields the above-mentioned methiodide when treated with sodium iodide. Methyl-ψ-brucidine is unchanged by electrolytic reduction or by shaking in an atmosphere of hydrogen in presence of colloidal palladium, but it is readily oxidised by potassium permanganate to brucidone, $C_{23}H_{28}O_5N_2$, one atom of carbon being lost during the process. This most interesting substance, the analogue of strychnidone, is unfortunately an oil, but a crystalline *monosemicarbazone* was obtained and analysed. The stability of methyl-ψ-brucidine towards reducing agents is noteworthy and cannot, at present, be explained.

Methoxymethyltetrahydrobrucidine, $C_{25}H_{36}O_4N_2$, m. p. 133—135°, is derived from methoxymethyldihydrobrucidine by electrolytic reduction. It is characterised by the facility with which it crystallises, and also shows greater stability to light and air than the methoxydihydro-derivative. It is a di-acid base yielding a *dihydrochloride* and a *dihydriodide*, and like the methoxydihydro-derivatives it forms two series of metho-salts, namely (A) and (B), and also two series of dimetho-salts, namely (A), which are comparatively low-melting, and (B), which are high-melting. The *methiodide* (A) is produced by the direct combination of the base with methyl iodide at 100°, and in contrast to the behaviour of methoxymethyldihydrobrucidine under similar conditions no oxidation accompanies this reaction (compare p. 1629). This methiodide yields the *methochloride* (A) by the action of silver chloride, and it was observed that both of these substances readily revert to the parent base. The methiodide loses methyl iodide quantitatively at 170°, whilst methyl chloride is eliminated when the methochloride is boiled with methyl-alcoholic potassium hydroxide. Methoxymethyltetrahydrobrucidine combines slowly with methyl sulphate when heated with an excess of the reagent in dry benzene for 24 hours, and yields a glassy mass which is a mixture of two *dimethosulphates*, namely, (A) and (B). These have not been separated, but the addition of sodium iodide to their aqueous solution precipitates the *dimethiodide* (B), m. p. 287°, the isomeride (A) remaining in solution. The dimethiodide (B) and the *dimethochloride* (B), which is prepared from it by means of silver chloride, each lose one molecule of methyl iodide, or methyl chloride, when heated, and yield respectively the *methiodide*, or *methochloride*, of the series (B). Attempts to prepare methyl-ψ-dihydrobrucidine by further decomposition of the dimethochloride (B) or the metho-

chloride (B) were unsuccessful, because decomposition of the rest of the molecule precedes the elimination of methyl chloride; this behaviour is in marked contrast to that of the corresponding strychnidine derivatives (compare this vol., p.1592). *Methoxymethyltetrahydrobrucidine dimethiodide* (A), m. p. 230—232°, is precipitated in a very crude condition by the addition of a large excess of potassium hydroxide to the mother-liquors from the preparation of the dimethiodide (B). It may also be obtained by the direct combination of the base with methyl iodide at 140°. When heated at its melting point, it loses one molecule of methyl iodide with the formation of the methiodide (B), and it is converted by silver chloride into the *dimethochloride* (A). When this substance is heated, two molecules of methyl chloride are liberated and methoxymethyltetrahydrobrucidine is regenerated. The relationships of these substances are illustrated by the following scheme :—

The ferric chloride reactions suggest that the metho-salts (A) and (B) are constituted analogously to the related series from methoxymethyldihydrobrucine.

The methiodide (A) will have the formula

$$(MeO)_2(C_{20}H_{22}O)(OMe)(:NMe)\left\langle \begin{matrix} CH_2 \\ NMe \end{matrix} \right\rangle I,$$

whilst the methiodide (B) should be

$$(MeO)_2(C_{20}H_{22}O)(OMe)(:NMe_2)\left\langle \begin{matrix} CH_2 \\ N \end{matrix} \right\rangle I.$$

This is in agreement with the production of the methiodide (B) from each of the stereoisomeric dimethiodides (A) and (B), since the decomposition, on the suggested hypothesis, occurs at the nitrogen atom which becomes asymmetric (*Nabcd*) on the formation of the dimethiodides. A glance at the formula of the dimethiodides, $(MeO)_2(C_{20}H_{22}O)(OMe)(:NMe_2)\left\langle \begin{matrix} CH_2 \\ NMe \end{matrix} \right\rangle I_2$, will show that the $:NMe_2$ group is not a new asymmetric centre, whilst the nitrogen atom of the

$-CH_2-\overset{\diagup}{\underset{\diagdown}{N}}Me$ group can give rise to enantiomorphism. If the formulæ for the methiodides (A) and (B) were transposed, we should anticipate that the dimethiodides (A) and (B) would give rise to stereoisomeric methiodides on decomposition.

The *methyl*neo*dihydrobrucidinium salts* could not be prepared directly from methoxymethyltetrahydrobrucidine because this substance, unlike the methoxydihydro-base, is unaffected by boiling dilute sulphuric acid. Attempts to obtain these salts by the reduction of the methyl*neo*brucidinium salts were unsuccessful, as the sulphate was unchanged by electrolytic reduction. Methoxymethyltetrahydrobrucidine dihydrochloride, however, decomposes above its melting point in boiling mesitylene, yielding hydrogen chloride, methyl alcohol, and *methyl*neo*dihydrobrucidinium chloride*. This substance is amorphous, and its aqueous solution forms no precipitate with ammonia or potassium hydroxide. When the dry chloride is heated, it decomposes without producing methyl-ψ-dihydrobrucidine (compare this vol., p. 1592). The crystalline *methyl*neo*dihydrobrucidinium iodide* is prepared from the chloride by means of sodium iodide.

A number of efforts were made to prepare *methyl-ψ-dihydrobrucidine* by heating either (i) methoxymethyltetrahydrobrucidine methochloride (B), or (ii) methoxymethyltetrahydrobrucidine dimethochloride (B), or (iii) methyl*neo*dihydrobrucidinium chloride In each case, it was evident that decomposition of the rest of the molecule preceded the liberation of methyl chloride or of hydrogen chloride as the case might be, although the corresponding derivatives of strychnidine yield methyl-ψ-dihydrostrychnidine. We hoped, therefore, that the less stable *methoxymethyltetrahydrobrucidine dimethohydrogencarbonates* would decompose more readily, and this proved to be the case. The *dimethohydrogencarbonates* (A) and (B) may be prepared by evaporating in an open basin aqueous solutions of the corresponding *dimethohydroxides*, prepared by the action of silver hydroxide on the dimethiodides (A) and (B). They are also obtained by the action of silver carbonate on the dimethiodides. When heated over a flame, the dimethohydrogencarbonate (A) regenerates methoxymethyltetrahydrobrucidine, whilst the dimethohydrogencarbonate (B) yields methyl-ψ-dihydrobrucidine, $C_{24}H_{32}O_3N_2$, m. p. 220—221°, which has been characterised further by the preparation of a *dihydriodide*. When heated less vigorously (at 135°), the dimethohydrogencarbonate (B) loses only one molecule of carbon dioxide and forms *methoxymethyltetrahydrobrucidine methohydrogencarbonate* (B), which was not purified, but was isolated in the form of the methiodide (B) by the action of sodium iodide.

EXPERIMENTAL.

Brucine Methosulphate.—Leuchs and Anderson (*Ber.*, 1911, **44**, 3046) have described the preparation of small quantities of this substance by the combination of brucine with methyl sulphate in chloroform. The following process was found convenient for large-scale operations. Pure methyl sulphate (50 c.c.) is added to a suspension of brucine (125 g.) in methyl alcohol (200 c.c.). The base dissolves with evolution of heat, and the methosulphate, which separates over-night, is collected, washed with a little methyl alcohol, and dried first in a vacuum and then at 100°. A further quantity is obtained on concentrating the mother-liquors (total yield, about 90%). The methosulphate crystallises from ethyl alcohol in colourless needles, m. p. 278° (decomp.) (Found: C, 58·2; H, 6·5. Calc.: C, 58·5; H, 6·5%). Leuchs and Anderson give m. p. 268°.

Brucine methiodide is obtained by adding sodium iodide solution to an aqueous solution of the methosulphate. It crystallises from water in needles, m. p. 295° (decomp.), after drying at 100° (Found: C, 53·4; H, 5·4. Calc.: C, 53·7; H, 5·4%). Claus and Röhre (*Ber.*, 1881, **14**, 772) prepared this compound by the interaction of brucine and methyl iodide, and give the melting point as 290° (decomp)., whereas Hanssen (*Ber.*, 1884, **17**, 2267) gives 270°.

Brucine methohydrogencarbonate is prepared from the methiodide by shaking a hot aqueous solution with excess of silver carbonate, evaporating the filtrate to dryness under reduced pressure on the water-bath, and crystallising the residue from ethyl alcohol. It forms creamy-yellow plates, m. p. 202—203° (decomp.), which retain a molecule of alcohol after drying in a vacuum desiccator, and dissolve readily in water (loss at 120°, 10·5. 1EtOH requires loss, 9·8%. Found in dried material: C, 63·6; H, 6·5. $C_{23}H_{26}O_4N_2$, $MeHCO_3$ requires C, 63·8; H, 6·4%).

The Electrolytic Reduction of Brucine. Brucidine and Tetrahydrobrucine.

The success of this reduction depends largely on the temperature of the cathode chamber. Thus at 18°, the lowest temperature at which the battery of cells could be kept during a prolonged period in the absence of ice-cooling, about 68% of the weight of brucine used was isolated in the form of practically pure brucidine and tetrahydrobrucine. If, on the other hand, the temperature rose to 21°, the yield dropped to about 55% of the weight of brucine, and further the isolation of the tetrahydrobrucine was made more difficult by the presence of gummy substances, which caused the products to

become red when exposed to light and air. The formation of these could never be entirely avoided, but their amount was diminished considerably at the lower temperature. Tafel and Naumann (*loc. cit.*) were troubled by similar unstable by-products if their reduction was carried out above 15°.

The following is a description of a typical experiment, but it must be realised that variations occurred in the yields from different preparations. A solution of brucine (100 g.) in dilute sulphuric acid (300 g. of concentrated acid in 300 c.c. of water) is reduced in the usual apparatus (J., 1924, **125**, 1798) for 16 hours by a current of 5 amps., while the temperature is maintained at 17—18° by immersing the cells in running water. The contents of the cathode chambers and the aqueous washings of the cells are diluted to about twice the volume of the original solution, filtered in order to remove some lead sulphate, mixed with ice, and rendered alkaline by ammonia (*d* 0·880). Any rise of temperature is carefully avoided by the addition of ice and by cooling in a freezing mixture. A pale pink gum separates and adheres to the walls of the vessel. The liquid is decanted, extracted three times with chloroform (300 c.c. in all), and the mixed extracts are then used to dissolve the gum. The chloroform solution is washed with water, dried by potassium carbonate, and distilled. In order to remove the last traces of chloroform, the gummy residue is dissolved in boiling methyl alcohol (150 c.c.), and the solution evaporated to dryness on the water-bath. The product (100 g.), now a solid, is dissolved in boiling methyl alcohol (250 c.c.), and, on cooling, an almost colourless mass of crystals separates; this is collected and dried on the water-bath (45 g.). It melts at about 199° and is practically pure brucidine (see below). The mother-liquors are evaporated to dryness on the water-bath, the last traces of solvent being removed under reduced pressure; on boiling the semi-solid mass with pure ethyl acetate, a part remains undissolved, and after cooling is collected, washed with ethyl acetate, and dried in a vacuum (23 g.). It melts at 174° and is practically pure tetrahydrobrucine (see below). The mother-liquors contain the oily by-products, together with some crystalline substances, and their investigation is in progress.

Brucidine.—The product obtained from the reduction is crystallised from methyl alcohol, from which it separates in colourless needles, which, after being dried in a vacuum desiccator, shrink at 188—190° and melt at 203—203·5° without decomposition. On drying at 105° brucidine loses one molecule of methyl alcohol of crystallisation, and then melts at 203—203·5° without decomposition (loss at 105°, 7·7. 1MeOH requires loss, 7·9%. Found in dried material: C, 72·7; H, 7·3. $C_{23}H_{28}O_3N_2$ requires C, 72·6; H, 7·4%). It is

very slightly soluble in boiling water, and the solution reacts alkaline to litmus. It dissolves readily in chloroform, less easily in methyl alcohol and ethyl acetate, and only very sparingly in ether. The colourless solution of a pure specimen in dilute hydrochloric acid slowly acquires a faint olive-green colour; on addition of a few drops of sodium nitrite a dark green coloration appears, which becomes reddish-brown on standing. When now excess of sodium carbonate is added, the colour changes to a very intense claret, which passes entirely into chloroform when the liquid is shaken with that solvent. These properties agree well with the reactions of the substance which Tafel and Naumann describe as "tetrahydrobrucine." A solution of brucidine in 60% sulphuric acid * to which a drop of an aqueous solution of potassium dichromate has been added becomes green on standing. The addition of ferric chloride to a solution in dilute hydrochloric acid produces a dark blue-green colour, which appears pink when examined in thin layers. These colour reactions are also shown by many derivatives of brucidine (see p. 1661) and in many cases dilute nitric acid causes the development of a similar green-pink colour.

The corresponding colour reactions of brucine may be given here for comparison. A drop of dichromate imparts a deep red colour to a solution in 60% sulphuric acid, but the addition of ferric chloride to brucine in dilute hydrochloric acid does not produce a coloration.

The *dihydrochloride* is formed when a little concentrated hydrochloric acid is added to a solution of the base in hot methyl alcohol. On cooling, the liquid sets to a mass of needles, which are collected and recrystallised from methyl alcohol. This salt forms colourless needles which begin to darken at 285°, and melt at 310° (decomp.) after drying in a vacuum desiccator. A satisfactory analysis of this substance was not obtained, as it appears to lose hydrogen chloride on drying. There is no doubt, however, that the base combines with two molecules of hydrogen chloride. A solution of the dihydrochloride in methyl alcohol is colourless, but on exposure for a short time to air it becomes green; the solution then appears pink when examined in thin layers.

The *dihydriodide*, prepared by adding sodium iodide to a solution of the base in dilute hydrochloric acid, crystallises from water in shining, grey needles, m.p. 255° (decomp.), which are only very sparingly soluble in hot water.

The methosulphate. A short, vigorous reaction occurs when pure methyl sulphate (8 c.c.) is added to a slightly warm suspension of

* In the case of brucine and its derivatives the colour reactions are well shown in dilute sulphuric acid of 60% by weight, and not by volume (compare Part IV, this vol., p. 1599).

powdered brucidine (20 g.) in methyl alcohol (80 c.c.), and when this has subsided the mixture is heated on the water-bath for a few moments until the base has completely dissolved. On cooling the green solution in ice, the methosulphate separates in excellent yield as a mass of colourless needles, which are collected, washed with methyl alcohol, and dried in a vacuum desiccator. It is essential that the methyl sulphate should be pure and freshly distilled; the presence of acid greatly reduces the yield. When prepared in this way, the methosulphate is sufficiently pure for most purposes. It may be recrystallised from methyl alcohol in colourless needles which begin to darken at 270° and melt at 291° (decomp.), are readily soluble in water, and become purple or green when kept for some time.

The *methiodide* is obtained either by the addition of sodium iodide to an aqueous solution of the methosulphate, or by adding methyl iodide to an ethyl-alcoholic solution of the base. In either case, the crystals which separate are recrystallised from water. The methiodide forms colourless needles, m. p. 322° (decomp.), which are sparingly soluble in methyl or ethyl alcohol (Found: C, 55·1; H, 6·0. $C_{23}H_{28}O_3N_2$,MeI requires C, 55·2; H, 5·9%).

Tetrahydrobrucine.—The product obtained from the electrolytic reduction (p. 1636) is recrystallised from ethyl acetate, in which it is sparingly soluble. When prepared in this way, tetrahydrobrucine forms colourless needles, m. p. 177° (Found: C, 69·1; H, 7·7. $C_{23}H_{30}O_4N_2$ requires C, 69·4; H, 7·5%), but one of its characteristic properties is the power of retaining solvent of crystallisation with the resulting production of comparatively low-melting crystalline forms. It melts in boiling water, dissolves fairly readily to a solution which is alkaline to litmus, and on cooling crystallises in colourless needles; after drying for a short time in a vacuum desiccator, these melt to a pasty mass at 90—92°, and evolve water briskly at 100° (loss at 100°, 14·8. $4H_2O$ requires loss, 15·3%). It is rather easily soluble in methyl alcohol, but when a concentrated solution is cooled, it crystallises in colourless needles, which, after being dried in a vacuum desiccator, melt to a pasty mass at 90—95° (loss at 100°, 10·4. MeOH requires loss, 10·8%), harden on further heating, and melt again at 177°. When crystallised from ethyl alcohol, tetrahydrobrucine forms colourless needles, which soften at 115° and melt at 120° after drying in a vacuum desiccator. These contain one molecule of ethyl alcohol which is not lost at 90° (Found in material dried at 90°: C, 68·4; H, 8·3. $C_{23}H_{30}O_4N_2$,EtOH requires C, 68·2; H, 8·2%), but is liberated at 120° (loss at 120°, 10·0. 1EtOH requires loss, 10·4%). A solution of a pure specimen in dilute hydrochloric acid is colourless, but becomes bright green

on the addition of a few drops of ferric chloride; this solution does not, however, show the pink tinge in thin layers which is characteristic of brucidine and its derivatives.

The *dihydrochloride* is rather readily soluble, but is obtained when a little concentrated hydrochloric acid is added to a concentrated solution of the base in methyl alcohol. On standing over-night, it separates in colourless needles, which are collected, washed with methyl alcohol, and dried at 100°. This salt darkens at 280° and melts at 305° (decomp.) (Found: C, 58·4; H, 7·0. $C_{23}H_{30}O_4N_2,2HCl$ requires C, 58·6; H, 6·8%).

The *dihydriodide* is prepared by adding sodium iodide to a solution of tetrahydrobrucine in dilute hydrochloric acid. The green colour of the solution disappears, and a yellow gum separates which slowly crystallises on rubbing. When recrystallised from ethyl alcohol, it forms colourless plates, which darken at 220° and melt at 225° (decomp.).

The *methiodide* is readily obtained by warming a solution of the base and an excess of methyl iodide in methyl alcohol for a few moments until crystallisation begins. After cooling, the colourless needles of the methiodide are collected, washed, and dried in a vacuum desiccator; they then melt at 290° (decomp.) (loss at 100°, 5·3. 1MeOH requires loss, 5·5%. Found in material dried at 100°: C, 53·5; H, 6·3. $C_{23}H_{30}O_4N_2,MeI$ requires C, 53·3; H, 6·1%).

The nitrosoamine. Sodium nitrite (0·5 g.) in a little water is added gradually to a cooled solution of tetrahydrobrucine (2 g.) in hydrochloric acid (20 c.c. of 2*N*). The yellow crystals are collected, washed with dilute hydrochloric acid, and recrystallised from ethyl alcohol. *Tetrahydrobrucine nitrosoamine hydrochloride* forms buff-coloured needles, which, after drying in a desiccator, darken and shrink at 190°, have become black at 250°, and melt at 288° (decomp.) (loss at 100°, 8·5. 1EtOH requires loss, 9·0%. Found in material dried at 100°: Cl, 7·5. $C_{23}H_{29}O_5N_3,HCl$ requires Cl, 7·6%).

When sodium carbonate is added to an aqueous solution of the hydrochloride, the *nitrosoamine* separates in needles. It is collected, washed, and recrystallised from dilute ethyl alcohol, separating in lemon-yellow needles which shrink at 205° and melt at 213—214° (decomp.) (Found: C, 64·2; H, 6·7. $C_{23}H_{29}O_5N_3$ requires C, 64·6; H, 6·8%). It is readily soluble in ethyl alcohol, and gives Liebermann's nitroso-reaction.

The Conversion of Tetrahydrobrucine into Brucidine.

A mixture of tetrahydrobrucine (5 g.) and phosphorus oxychloride (50 g.) is warmed on the water-bath for about 30 minutes; hydrogen chloride is evolved, whilst the base becomes gummy, partly dissolves,

and soon changes to a mass of crystals. The excess of phosphorus oxychloride is removed by distillation on the water-bath under reduced pressure, and the residue is dissolved in water (25 c.c.), much heat being produced. After cooling and addition of ice, the solution is mixed with potassium hydroxide, and the semi-solid precipitate is collected on a glass rod, drained as thoroughly as possible, and boiled with a little methyl alcohol. The product becomes crystalline, and after cooling it is collected, washed with methyl alcohol, and dried at 100° (yield 3·6 g.; 75% of that theoretically possible). The crystals melt at 203—203·5° either alone or when mixed with a specimen of brucidine.

The Electrolytic Reduction of Methylbrucine. Brucidine Metho-hydroxide and Metho-salts.

Methylbrucine.—The conversion of brucine methosulphate into methylbrucine does not take place under conditions similar to those under which strychnine methosulphate yields methylstrychnine (this vol., p. 1624), because the methosulphate is precipitated unchanged by the alkali. If, however, a higher temperature and more concentrated potassium hydroxide are used, the liquid sets to a gelatinous mass, which certainly contains methylbrucine, but which can be neither crystallised nor purified. Methylbrucine was therefore prepared by a modification of the method of Leuchs and Anderson (*loc. cit.*, p. 3047), who used less concentrated alkali. Hot, dilute sodium hydroxide solution (200 c.c. of 2·5*N*) is added in one batch to a hot solution of brucine methosulphate (10 g.) in water (50 c.c.), and the mixture is heated on the water-bath for 5 minutes. On cooling, the yellow solution does not gelatinise (compare Leuchs and Anderson); sodium hydroxide (20 c.c. of 30%) is now added, and the mixture set aside. Next day, the needles, which fill the liquid, are collected, and are sufficiently pure for the purpose of the reduction described below. When purified by the addition of acetone to a concentrated aqueous solution, and dried at 100°, methylbrucine forms colourless needles, m. p. 300° (decomp.) when heated quickly. Leuchs and Anderson give the melting point as 300° (decomp.).

The reduction. A solution of methylbrucine (20 g.) in sulphuric acid (100 c.c. of 60%) is reduced in the usual apparatus for 6 hours with a current of 5 amps., while the temperature is kept at 18° by cooling in running water. The liquid is diluted with an equal volume of water, heated on the water-bath, and neutralised by an excess of barium carbonate. The deep red filtrate, mixed with the washings of the barium precipitate, is evaporated to dryness under reduced pressure on the water-bath. The dark red, glassy residue

dissolves readily in water or methyl or ethyl alcohol, and shows very little tendency to crystallise. A small specimen, however, was obtained in a crystalline condition from methyl alcohol by cooling in ice. It was recrystallised once from that solvent in colourless nodules of needles, m. p. 265° (decomp.) after drying in a vacuum desiccator, and appears from analysis to be *brucidine methohydrogencarbonate* containing two molecules of water (Found: C, 60·3; H, 7·1. $C_{25}H_{32}O_6N_2,2H_2O$ requires C, 61·0; H, 7·3%). This view is confirmed by the conversion of this substance into brucidine methiodide and methohydroxide (see below), and also by its interaction with dilute hydrochloric acid. Carbon dioxide is evolved, and the substance dissolves to a green solution; the addition of ferric chloride intensifies this colour, and gives it the pink tinge in thin layers which is characteristic of brucidine and its derivatives.

When sodium iodide is added to an aqueous solution of the methohydrogencarbonate, brucidine methiodide is formed. It separates from water in colourless needles, m. p. 322° (decomp.), and is identical with a specimen prepared from brucidine (p. 1638).

Brucidine methohydroxide is obtained by grinding the crude methohydrogencarbonate with 30% potassium hydroxide solution. The resulting crystalline paste is filtered, and the solid recrystallised twice from water, in which it dissolves very readily. Brucidine methohydroxide forms colourless, hair-fine needles, m. p. 268° (decomp.), which retain two molecules of water after drying in a vacuum desiccator (Found: C, 64·1; H, 7·6. $C_{23}H_{28}O_3N_2,MeOH,2H_2O$ requires C, 64·3; H, 8·0%). The same substance was prepared for comparison from brucidine methiodide. An aqueous solution of the methiodide was shaken with an excess of silver carbonate, and the dark red filtrate evaporated to dryness under reduced pressure on the water-bath. The residual dark red glass (not purified) was dissolved in water, and mixed with 50% potassium hydroxide solution; brucidine methohydroxide then separated in crystalline form, and was recrystallised from a little water in colourless needles, m. p. 268° (decomp.).

The specimen obtained from the reduction of methylbrucine was converted into brucidine methiodide either (i) by adding sodium iodide to a solution in dilute hydrochloric acid, or (ii) when a solution of the methohydroxide (4 g.) and methyl iodide (10 c.c.) in ethyl alcohol (30 c.c.) was boiled for 10 minutes, and then cooled. In either case, the crystalline precipitate which separated was recrystallised from water, and formed colourless needles, m. p. 322° (decomp.) (Found: C, 55·1; H, 6·1. $C_{23}H_{28}O_3N_2,MeI$ requires C, 55·2; H, 5·9%). The identity of this substance with brucidine methiodide was confirmed by converting it into methoxymethyldihydrobrucidine

(see below), which is formed by heating brucidine metho-salts with methyl-alcoholic potassium hydroxide. Brucidine methochloride (not purified), prepared by shaking with an excess of silver chloride an aqueous solution of the methiodide obtained above, and evaporating the filtrate to dryness under reduced pressure on the water-bath, was heated with a large excess of 25% methyl-alcoholic potassium hydroxide for 30 minutes, cooled, mixed with water, and the precipitate collected. Crystallisation from ethyl alcohol yielded colourless needles, m. p. 115° either alone or mixed with an authentic specimen of methoxymethyldihydrobrucidine.

Methoxymethyldihydrobrucidine.—A mixture of brucidine methosulphate (30 g.) and methyl-alcoholic potassium hydroxide (150 c.c. of 25%) is heated on the water-bath for 30 minutes in an open flask so that the methyl alcohol partly evaporates. The initial yellow solution gradually clouds and deposits a solid precipitate which increases on cooling in running water. Water (500 c.c.) is added, and the precipitate is collected after 1 hour, washed with water, and dried roughly on porous tile. The crude product is crystallised from ethyl alcohol, from which about 20 g. of pure material separate, and the addition of water to the mother-liquor yields a further quantity of practically pure substance (total yield, *ca.* 90%). *Methoxymethyldihydrobrucidine* forms colourless needles, m. p. 115° without decomp. after drying in a vacuum [Found: C, 70·2; H, 7·8; OMe, 21·9. $C_{25}H_{34}O_4N_2$ requires C, 70·4; H, 8·0; $(OMe)_3$, 21·8%]. It distils without decomposition at 265—267°/1·5 mm., and is rather readily soluble in the usual solvents except light petroleum. A solution in glacial acetic acid is not precipitated on addition of water. The base and its solutions become red on keeping, especially if exposed to laboratory fumes.

The dihydriodide. The addition of sodium iodide to a solution of methoxymethyldihydrobrucidine in dilute sulphuric acid produces a red, uncrystallisable oil, which rapidly oxidises, but when concentrated sodium iodide solution is added slowly with constant stirring to a solution of the base (5 g.) in 2*N*-sulphuric acid (20 c.c.), saturated with sulphur dioxide, an additive compound separates as a brick-red oil which soon crystallises on rubbing. This is collected (approximately 8 g.), and boiled with water until the orange colour of the solution and the smell of sulphur dioxide have disappeared; the dihydriodide then crystallises on cooling in colourless leaflets, m. p. 217—218° (decomp.) (loss at 100°, 3·5. $1\frac{1}{2}H_2O$ require loss, 3·8%. Found in material dried at 100°: C, 43·8; H, 5·3. $C_{25}H_{34}O_4N_2,2HI$ requires C, 44·0; H, 5·3%). The crystals become yellow on keeping, on exposure, or on drying, and when heated char and evolve hydrogen iodide.

The methiodide (*A*). This substance is obtained under the following conditions. (i) Methoxymethyldihydrobrucidine (10 g.) and pure methyl iodide (15 c.c.) are heated together at 100° in a sealed tube for 5 minutes. The solution becomes purple and fills with crystals, which are collected after cooling, washed with methyl iodide, and dried in a vacuum (12 g.). The mother-liquors deposit a further amount (1 g.) on standing over-night. The yield is about 98%. (ii) A mixture of methoxymethyldihydrobrucidine (15 g.) and methyl iodide (15 c.c.) is boiled under reflux for 15 minutes, and next day 13—15 g. of crude product are collected. The methiodide obtained by either method separates from methyl alcohol in creamy tablets which become chalky when dried in a vacuum; m. p. 190° (loss at 100°, 2·6. 0·5MeOH requires loss, 2·8%. Found in material dried at 100°: C, 55·1; H, 6·5; N, 4·9. $C_{25}H_{34}O_4N_2$,MeI requires C, 55·0; H, 6·5; N, 4·9%). It crystallises from water in stout prisms, m. p. 190°, or from ethyl alcohol in rectangular plates, m. p. 179°, which contain alcohol of crystallisation (loss at 100°, 3·6. 0·5EtOH requires loss, 3·9%. Found in dried material: C, 55·2; H, 6·7%). It yields the methochloride (A) when treated with silver chloride (see below).

The methyl-alcoholic mother-liquors gradually deposit a very small amount of crystalline material which does not contain iodine. This is recrystallised by dissolving it in much methyl alcohol and concentrating the solution; *oxymethoxymethyldihydrobrucidine* then separates in pink bipyramids, which shrink at 270° and melt at 277° (decomp.) (Found: C, 67·3; H, 7·6. $C_{25}H_{34}O_5N_2$ requires C, 67·9; H, 7·7%). The same substance may be obtained in greater quantity by a simpler method. When a solution of methoxymethyldihydrobrucidine in ethyl alcohol containing a few crystals of iodine is exposed to the air for some days, the solution becomes deep crimson, and gradually deposits oxymethoxymethyldihydrobrucidine as pale pink, perfectly formed prisms, which soften at 270°, melt at 277°, and are analytically pure (Found: C, 67·6; H, 7·8; N, 6·1. $C_{25}H_{34}O_5N_2$ requires N, 6·3%). It is very sparingly soluble in ethyl alcohol or acetone, but dissolves in warm benzene, and is readily soluble in chloroform. It is insoluble in boiling water or sodium hydroxide, but dissolves readily in dilute hydrochloric acid. When it is boiled with methyl alcohol (charcoal) and the filtered solution is concentrated, a slightly more soluble base separates in irregular, boat-shaped crystals, m. p. 270° (decomp.), which appear from the analysis to be *dioxymethoxymethyldihydrobrucidine* (X) (compare pp. 1647, 1648) (Found: C, 65·5; H, 7·4. $C_{25}H_{34}O_6N_2$ requires C, 65·5; H, 7·4%).

When methoxymethyldihydrobrucidine and methyl iodide inter-

act in methyl-alcoholic solution the reaction follows a course very similar to that, described above, in the absence of methyl alcohol, and the chief product is the monomethiodide (A), accompanied by small quantities of oxymethoxymethyldihydrobrucidine (compare Part IV, this vol., p. 1607). In addition to these substances, an intermediate *base*, m. p. about 210—218°, appears to be formed. This does not contain iodine, and changes into oxymethoxymethyldihydrobrucidine in boiling methyl alcohol or acetone, in which solvents it is sparingly soluble. This substance was not obtained sufficiently pure for analysis, and the change evidently takes place so readily that the intermediate product did not appear in some experiments, but had been completely converted into oxymethoxymethyldihydrobrucidine. The following is an account of an experiment in which the intermediate base was formed. A mixture of methoxymethyldihydrobrucidine (5 g.) and methyl iodide (5 c.c.) in methyl alcohol (25 c.c.) was boiled under reflux for 3 hours, and then concentrated to half its volume. The residue was cooled for several hours in ice and salt, and the crystals which had separated were collected, washed with methyl alcohol, and dried (3 g.). The mother-liquors were examined separately (see below). The crude crystals were extracted with boiling methyl alcohol (20 c.c.), and the insoluble portion was collected, washed thoroughly with methyl alcohol, and dried (0·2 g.). It consisted of indefinite crystals, m. p. 210°, which did not contain iodine. The methyl-alcoholic extract contained practically pure methiodide (A).

The methyl-alcoholic mother-liquors (see above) were mixed with water, and the solid was collected and extracted with boiling methyl alcohol. The insoluble portion (0·1 g.) formed indefinite crystals, m. p. 218°, which did not contain iodine. Oxymethoxymethyldihydrobrucidine separated in the characteristic bipyramids, m. p. 277°, when a solution of the mixed fractions, m. p. 210° and 218°, in much boiling methyl alcohol was concentrated and cooled.

The Action of Methyl-alcoholic Potassium Hydroxide on the Methiodide (*A*) *and the Methochloride* (*A*).—The reaction follows the same course in both cases, but takes place more readily with the methochloride. This is prepared from the methiodide by heating an aqueous solution with excess of silver chloride for 1 hour, and evaporating the filtrate to dryness on the water-bath under reduced pressure. The gummy *methochloride* crystallises in colourless needles on standing for some days. The methochloride (7 g.) and methyl-alcoholic potassium hydroxide (60 c.c. of 25%) are heated in an open flask on the water-bath for 40 minutes, and after cooling and addition of water, the precipitate is collected and dried in a desiccator (5 g.). Recrystallisation of this crude material from ethyl alcohol

yields colourless needles; m. p. 115°, either alone or mixed with a specimen of methoxymethyldihydrobrucidine (Found: C, 70·6; H, 7·8; OMe, 21·4%). A careful examination of the mother-liquors yields no other product.

Methoxymethyldihydrobrucidine methochloride (*B*) cannot be obtained directly from methoxymethyldihydrobrucidine, but it is formed when methoxymethyldihydrobrucidine dimethochloride (B) (compare p. 1647) (15 g.) is heated in boiling nitrobenzene (30 c.c.) until all has dissolved and the evolution of gas appears to have ceased—10 to 15 minutes. After standing over-night, the crystals which have separated are collected, washed with light petroleum, dried in a desiccator (10 g.), and crystallised from acetone, being thus obtained in colourless prisms, m. p. 164° (decomp.) (Found: C, 64·9; H, 7·4. $C_{25}H_{34}O_4N_2$,MeCl requires C, 65·5; H, 7·8%). This substance yields methyl-ψ-brucidine when heated gently in a test-tube over a free flame (compare p. 1651). The nitrobenzene mother-liquors contain both methyl-ψ-brucidine and methyl-ψ-brucidine methochloride; their examination is described on p. 1652.

The *methiodide* (*B*) is prepared from the methochloride with sodium iodide, but has not been obtained in any other way. It crystallises from water in colourless, coarse prisms, m. p. 291° (decomp.), and is less soluble in water and methyl or ethyl alcohol than the isomeric methiodide (A).

The *dimethiodide* (*A*) is obtained when methoxymethyldihydrobrucidine (5 g.) and pure methyl iodide (10 c.c.) are heated in a sealed tube in an oil bath at 135—140° for 7½ hours. After removal of the methyl iodide by distillation, the brown, sandy powder (8·5 g.) is crystallised from methyl alcohol (charcoal), from which the dimethiodide (4·5 g.) separates in pink leaflets which become colourless at 110°, form a pasty mass at 215°, and evolve gas freely at 230° (loss at 110°, 8·6. 2MeOH requires loss, 8·3%. Found in material dried at 110°: C, 45·3; H, 5·5. $C_{25}H_{34}O_4N_2$,2MeI requires C, 45·6; H, 5·6%).

The *methosulphate* (*A*) is formed when a solution of methoxymethyldihydrobrucidine (3 g.) and pure methyl sulphate (10 c.c.) in dry benzene (70 c.c.) is boiled under reflux for 4 hours and allowed to remain over-night. A mixture of stellar aggregates of coarse crystals and a purple gum separates, and the crystals of the monomethosulphate are easily detached and pressed on porous tile (1·7 g.). The gum consists essentially of the dimethosulphate (B) (see below). The methosulphate is crystallised from ethyl alcohol, in which it is rather readily soluble, and forms colourless, rectangular plates, m. p. 231—232° (decomp.) (Found: S, 6·0. $C_{25}H_{34}O_4N_2$,Me_2SO_4 requires S, 5·8%). This substance is

very soluble in water and is converted by sodium iodide into the methiodide (A), m. p. 190°.

The Dimethosulphate (*B*) *and the Dimethiodide* (*B*).—A solution of carefully dried methoxymethyldihydrobrucidine (60 g.) and pure methyl sulphate (150 c.c.) in dry benzene (500 c.c.) is boiled for 9 hours under reflux, carefully protected from moisture. It rapidly becomes purple, and after some time a brown gum forms slowly and increases steadily with diminution of the purple colour. After the benzene has been decanted, the gum is washed with benzene, and freed from excess of the solvent by a current of air. It undoubtedly consists essentially of the *dimethosulphate* (*B*), although traces of benzene and methyl sulphate are still present, but all attempts to crystallise it are unsuccessful, and it is therefore converted into the corresponding dimethiodide by sodium iodide. Sodium iodide (100 g.) in warm water (40 c.c.) is added to the dimethosulphate in warm water (100 c.c.) and, after cooling, the mixture is scratched and set aside over-night. The crystalline precipitate is collected, washed with water, dried in a vacuum desiccator (84 g.), and recrystallised from water. The *dimethiodide* (*B*) forms colourless columns, m. p. 290° (decomp.), with darkening below this, and is sparingly soluble in alcohol (loss at 105°, 1·0. $\frac{1}{2}H_2O$ requires loss, 1·2%. Found in dried material: C, 45·0; H, 5·5. $C_{25}H_{34}O_4N_2.2MeI$ requires C, 45·6; H, 5·6%).

The mother-liquors from the precipitation with sodium iodide are mixed with 50% potassium hydroxide solution; the caseous precipitate then soon hardens. It is washed roughly with water, and boiled with alcohol, which causes it to crystallise without passing into solution. After cooling, the crystals are collected (13 g.), and recrystallised from water, being obtained in colourless columns, m. p. 290° (decomp.), identical with those obtained by direct precipitation from the solution of the dimethosulphate with sodium iodide (loss at 105°, 1·1%. Found in dried material: C, 45·5; H, 5·4%). The total yield is 97 g., or 96% of that theoretically possible.

The dimethiodide is stable to 25% methyl-alcoholic potassium hydroxide at 120°, but reaction takes place with the corresponding dimethohydrogensulphate obtained by means of silver sulphate. The dimethiodide (10 g.) in water (75 c.c.) is heated on the water-bath for 1 hour with excess of silver sulphate, the filtrate is evaporated to dryness under reduced pressure on the water-bath, the residue taken up in methyl alcohol to eliminate silver sulphate, and the solution again evaporated to dryness. The gummy dimethohydrogensulphate thus obtained (not isolated) is mixed with methyl-alcoholic potassium hydroxide (100 c.c. of 25%) and heated in an

oil-bath for 45 minutes while the temperature is gradually raised from 110° to 130°. After cooling and addition of water, the roughly dried, sandy powder is crystallised from ethyl alcohol, and shown to be identical with methoxymethyldihydrobrucidine by mixed m. p., and by conversion into the methiodide (A), m. p. 190°.

The *dimethochloride* (*B*), prepared in the usual way from the dimethiodide by silver chloride, is a colourless glass which could not be crystallised.

Nitromethoxymethyldihydrobrucidine.—A solution of methoxymethyldihydrobrucidine (3 g.) in water (75 c.c.) and nitric acid (*d* 1·4; 7·5 c.c.) is heated under reflux on the water-bath for 2 hours. From the cooled mixture, ammonia (*d* 0·880) precipitates a negligible quantity of a base, which is discarded, and the addition of 50% potassium hydroxide solution yields a mixture of tar and crystals which is pressed on porous tile, crystallised twice from ethyl alcohol, and dried in a desiccator. *Nitromethoxymethyldihydrobrucidine* forms colourless needles, m. p. 276—278° (decomp.), which contain alcohol of crystallisation (loss at 110°, 9·6. 1EtOH requires loss, 9·8%. Found in material dried at 110°: C, 63·9; H, 7·0; N, 9·2. $C_{25}H_{33}O_6N_3$ requires C, 63·7; H, 7·1; N, 8·9%). It is rather curious that this substance exhibits the brucidine reaction with 60% sulphuric acid and potassium dichromate.

Permanganate Oxidation of Methoxymethyldihydrobrucidine. The Isomeric Dioxymethoxymethyldihydrobrucidines (*Y*) and (*Z*).

A number of experiments showed the necessity of adhering to the conditions described below. Powdered (80-mesh) potassium permanganate (20 g.; 4 atoms of oxygen) is added gradually to a solution of methoxymethyldihydrobrucidine (20 g.) in purified acetone (800 c.c.), stirred mechanically, and cooled in ice and salt so that the internal temperature remains at −10°. The manganese precipitate, collected and washed with acetone, yields with water a solution in which only oxalic acid can be detected.

The removal of the acetone by distillation yields 12—15 g. of thick, brown oil. When this is dissolved in warm alcohol (15 c.c.), cooled, and scratched, 2·5—2·8 g. of fairly pure crystalline material separate. (The examination of the mother-liquors, called M, is described on p. 1648.) Recrystallisation from ethyl alcohol yields colourless prisms, m. p. 185—186°, which appear from the analyses to be *dioxymethoxymethyldihydrobrucidine* (called Y; compare p. 1643) (loss at 100°, 4·4. ½EtOH requires loss, 4·8%. Found in dried material: C, 65·3; H, 7·6; N, 6·3. $C_{25}H_{34}O_6N_2$ requires C, 65·5; H, 7·4; N, 6·1%). This substance is insoluble in water or alkali, but readily dissolves in dilute hydrochloric acid, giving a green solution;

on addition of ammonia, the base is precipitated and the colour changes to red. The compound is recovered unchanged after boiling for a few minutes with acetic anhydride, and attempts to form a semicarbazone resulted in a dark red, uncrystallisable oil.

The *methiodide* is prepared by heating the base (2 g.) and methyl iodide (3 c.c.) in a sealed tube at 100° for 5 hours. The residue is pressed on porous tile, and separates from ethyl alcohol as a mixture of plates and needles, m. p. 223°. On recrystallisation from ethyl alcohol, both forms separate again, but when the mixture is boiled with insufficient alcohol for complete solution, the needles dissolve more rapidly, and ultimately the undissolved portion consists of plates only. These are collected and recrystallised, by seeding, from ethyl alcohol, separating in colourless plates, m. p. 225—226°, which lose nothing at 110° (Found: C, 52·3; H, 6·4. $C_{25}H_{34}O_6N_2$,MeI requires C, 52·0; H, 6·2%). When the hot alcoholic solution from the separation of plates and needles is cooled and set aside, it begins to deposit needles only, and on scratching, the material separates entirely in that form; but if allowed to remain undisturbed, the mixture of crystals again separates. The needles are recrystallised in the same form, m. p. 223—224°, from ethyl alcohol, and contain 2 molecules of alcohol of crystallisation after drying in a vacuum desiccator (loss at 110°, 12·1. 2EtOH requires loss, 13·3%. Found in material dried at 110°: C, 52·2; H, 6·4%). Both forms are sparingly soluble in ethyl alcohol, and a hot solution of each in that solvent, when cooled and seeded with the other form, deposits only that by which it has been seeded. A mixture of the two pure forms melts at 223°.

The alcoholic mother-liquors (M; p. 1647) are evaporated to dryness, and a filtered, aqueous solution of the residue is made strongly alkaline with potassium hydroxide. The oil thus precipitated is extracted as far as possible with ether, and the extract dried with potassium carbonate. The oil which remains undissolved in the ether yields no crystalline product, and is discarded. The oily residue from the evaporation of the ether is dissolved in ethyl alcohol (5 c.c.), cooled in ice and salt, and scratched frequently; crystals (3·2 g.) then separate slowly. Three recrystallisations from ethyl alcohol yield colourless, square plates, m. p. 110—111° after drying in a vacuum desiccator, which appear from analysis to be a *dioxymethoxymethyldihydrobrucidine* (called Z) (loss at 100°, 4·0. ½EtOH requires loss, 4·8%. Found in material dried at 100°: C, 65·0, 65·1; H, 7·6, 7·5; N, 5·8. $C_{25}H_{34}O_6N_2$ requires C, 65·5; H, 7·4; N, 6·1%). This substance is sparingly soluble in cold water, dissolves readily on heating to give a neutral solution, and on cooling separates in colourless, rectangular prisms. It is readily soluble in

the usual organic solvents except light petroleum, from which it crystallises when a hot solution is cooled, and gives the same colour reactions as methoxymethyldihydrobrucidine. It dissolves rapidly in cold dilute hydrochloric acid, but no iodide separates with sodium iodide. The compound is recovered unchanged after heating with excess of methyl iodide in a sealed tube at 100° for 4 hours, and an alcoholic solution does not form a sparingly soluble picrate.

Ethoxymethyldihydrobrucidine.—This substance was prepared in order to ascertain whether alkyloxy-groups other than methoxyl can be introduced into brucidine. The action between brucidine methosulphate and sodium ethoxide follows a similar course to that described on p. 1642 with methyl-alcoholic potassium hydroxide, but the isolation of the product was not successful, and further investigation was abandoned. Brucidine methosulphate (15 g.) and a solution of sodium (10 g.) in ethyl alcohol (150 c.c.) were heated in an open flask for 1 hour on the water-bath and then for 1 hour in an oil-bath at 120°. After cooling and addition of water, the sticky precipitate was pressed on porous tile. Attempts to crystallise the sandy powder (10 g.) thus obtained were fruitless, although it probably consisted of ethoxymethyldihydrobrucidine, and it was converted into the methiodide by boiling with excess of methyl iodide in ethyl alcohol (15 c.c.) for 20 minutes. On cooling, the purple solution set to a mass of crystals, which were washed with alcohol until they became colourless. *Ethoxymethyldihydrobrucidine methiodide*, recrystallised from ethyl alcohol, forms colourless needles, m. p. 176° (decomp.) (Found: C, 55·6; H, 7·1. $C_{26}H_{36}O_4N_2$,MeI requires C, 55·6; H, 6·9%).

*Methyl*neo*brucidinium Salts.*

*Methyl*neo*brucidinium Iodide.*—When a solution of methoxymethyldihydrobrucidine (25 g.) in sulphuric acid (250 c.c. of 10% by weight) is boiled gently under reflux for 2½ hours it becomes red, and methyl alcohol is evolved and can be burnt at the neck of the flask. The solution is cooled, rendered alkaline with ammonia (no precipitate), and just acidified with sulphur dioxide. The careful addition of concentrated sodium iodide precipitates a crystalline *iodide* (22 g.), which separates from water in stout, pink columns, m. p. 298° (decomp.) (Found: C, 55·3; H, 6·0. $C_{24}H_{31}O_3N_2I$ requires C, 55·2; H, 5·9%). When prepared in this way, the salt is always red; it may, however, be obtained practically colourless by crystallisation from aqueous potassium carbonate, or from ethyl alcohol, from which it separates in leaflets, m. p. 298° (decomp.). It is sparingly soluble in cold water, acetone, or methyl or ethyl

alcohol, and crystallises unchanged when a boiling solution in 30% potassium hydroxide is cooled.

The mother-liquors from the precipitation by sodium iodide (see above) were investigated in the expectation of isolating an isomeric iodide (compare methyl*neo*strychnidinium iodide, this vol., p. 1612), but only a further quantity of the same methyl*neo*brucidinium iodide was obtained, the total yield being 90% of that theoretically possible. The mother-liquors are concentrated to quite a small volume under reduced pressure on the water-bath, and after cooling, the aqueous layer is decanted from the oil which has separated during the distillation. This oil crystallises on being boiled with a little acetone; part dissolves, crystallisation begins suddenly, and the oil soon changes into a mass of colourless needles. After cooling, these are collected, washed with acetone, and dried (5 g.); m. p. 295° (decomp.). One recrystallisation from water yields the iodide in colourless, prismatic columns, m. p. 298° (decomp.). The identity of this substance with the methyl*neo*brucidinium iodide obtained above was shown by seeding an aqueous solution with a crystal of the authentic material.

*Methyl*neo*brucidinium chloride* is prepared from the iodide in the usual way by silver chloride. When sulphur dioxide is passed into the dark red filtrate after this has been concentrated on the water-bath under reduced pressure, slightly sticky, yellow needles separate; these are triturated with hot acetone, which causes the compound to crystallise in beautiful prisms. Methyl*neo*brucidinium chloride crystallises from absolute alcohol, in which it is rather readily soluble, in colourless, anhydrous needles, m. p. 188°, which absorb moisture on keeping and then melt at about 163°. On addition of ether to an alcohol–acetone solution, the chloride forms pale yellow, waxy prisms, m. p. 163°, which retain a molecule of water of crystallisation after being heated at 100° (Found: C, 63·9; H, 7·5. $C_{24}H_{31}O_3N_2Cl,H_2O$ requires C, 64·2; H, 7·4%). It dissolves readily in water, and is precipitated unchanged as a rapidly-crystallising oil by 50% potassium hydroxide solution. The colour reactions with ferric chloride in hydrochloric acid are identical with those given by methoxymethyldihydrobrucidine, and are also produced by silver nitrate in dilute nitric acid, whilst the addition of a drop of potassium dichromate to a solution in 60% sulphuric acid develops a yellowish-brown colour which does not alter on standing. After the chloride has been heated with 25% methyl-alcoholic potassium hydroxide on the water-bath for 30 minutes in the usual way, the addition of water precipitates a base, which crystallises from ethyl alcohol in colourless needles, m. p. 115°; the base melts at the same temperature in admixture with methoxy-

methyldihydrobrucidine. The chloride yields methyl-ψ-brucidine when heated (see p. 1652). In order to test the possibility of reducing methyl*neo*brucidinium salts, the sulphuric acid solution obtained directly from methoxymethyldihydrobrucidine was reduced in the usual apparatus for 18 hours with a current of 4·5 amps. The contents of the colourless solution, which began to redden as soon as the current was switched off, were isolated as the iodide in the manner described above. This iodide formed colourless prisms, m. p. 298° (decomp.), which were identical with a very pure specimen of methyl-*neo*brucidinium iodide (Found: C, 55·6; H, 6·0%). The fact that reduction had not taken place was confirmed by converting the corresponding chloride, m. p. 188°, into methyl-ψ-brucidine by heating.

Methyl-ψ-brucidine.—This substance is prepared either (i) from methoxymethyldihydrobrucidine dimethochloride (B) or (ii) from methyl*neo*brucidinium chloride.

(i) Methoxymethyldihydrobrucidine dimethochloride (B) (27 g.), free from inorganic material, is heated gently over a flame in test-tubes in batches of 3 g. until the evolution of methyl chloride and inflammable gas ceases. The clear, glassy residue is dissolved in benzene, the solution filtered from a little charred material, and the solvent distilled; the crystalline solid (16·5 g.), m. p. 194°, thus obtained is recrystallised from ethyl alcohol. Pure *methyl-ψ-brucidine* forms colourless tablets, m. p. 198—199° without decomposition [Found: C, 72·8; H, 7·7; N, 7·4; OMe, 15·7; *M*, in camphor, 430. $C_{24}H_{30}O_3N_2$ requires C, 73·1; H, 7·6; N, 7·1; $(OMe)_2$, 14·9%; *M*, 394]. It is, however, often green, melting at about 196°, but in this condition is sufficiently pure for most purposes. It is insoluble in water, readily soluble in benzene, acetone, and dilute acetic acid, and is stable to boiling 20% potassium hydroxide solution. A solution in dilute sulphuric acid instantly decolorises permanganate, forming the characteristic green solution with the pink tinge which is also produced by ferric chloride in dilute hydrochloric acid or ethyl alcohol. The base is recovered unchanged after being electrolysed in 25% sulphuric acid for 9 hours with a current of 4·5 amps. in the usual apparatus, or after being shaken in cold dilute acetic acid solution in an atmosphere of hydrogen in presence of reduced palladous chloride and gum arabic.

The *dihydriodide*, prepared by adding sodium iodide to a solution of the base in dilute hydrochloric acid, crystallises from water in leaflets, m. p. 259° (decomp.) (Found in material dried at 100°: C, 44·1; H, 4·9. $C_{24}H_{30}O_3N_2,2HI$ requires C, 44·3; H, 4·9%).

The *methiodide* is formed (*a*) directly from methyl-ψ-brucidine, or (*b*) from methoxymethyldihydrobrucidine dimethochloride (B).

(*a*) Powdered methyl-ψ-brucidine (1 g.) and methyl iodide (3 c.c.) react at once in the cold to form a jelly which rapidly crystallises. The methiodide, obtained thus in theoretical yield, separates from methyl alcohol in colourless plates, m. p. 297° (decomp.) (Found: C, 55·8; H, 6·1. $C_{24}H_{30}O_3N_2$,MeI requires C, 55·9; H, 6·1%). Occasionally it crystallises in needles, m. p. 297°, which change slowly into plates in presence of methyl alcohol.

(*b*) The nitrobenzene mother-liquors from the action of boiling nitrobenzene on methoxymethyldihydrobrucidine dimethochloride (B) (compare p. 1645) contain a small quantity of methyl-ψ-brucidine methochloride and also a little methyl-ψ-brucidine, and these are removed separately by extraction first with water and then with dilute hydrochloric acid. The methochloride was not isolated from the aqueous extract, but was converted by sodium iodide into the methiodide. The crystalline solid thus formed crystallised from ethyl alcohol in colourless needles, m. p. 297° (decomp.) (Found: C, 56·1; H, 6·2%).

The identity of these two specimens of the methiodide was shown by causing a solution of (*b*) in methyl alcohol to deposit plates on seeding with (*a*), and also by seeding an ethyl-alcoholic solution of (*a*) with (*b*), when the methiodide separated in needles.

The Formation of a By-product by the Action of Heat on Methoxymethyldihydrobrucidine Dimethochloride (*B*).—When the dimethochloride is contaminated by inorganic matter, *e.g.*, sodium chloride if the silver chloride used in its formation has been prepared from sodium chloride, the yield of methyl-ψ-brucidine is lowered, pyridine bases are formed during the heating, and a *by-product* is obtained. For example, the dimethochloride (30 g.), containing some sodium chloride, yielded a benzene extract containing pure methyl-ψ-brucidine (10 g.) together with a residue insoluble in benzene (4 g.). The investigation of this substance is at present in progress and the results already obtained show that we have encountered here an important degradation by fission of the brucine molecule.

Methyl-ψ-brucidine (ii). This base is also obtained by heating methyl*neo*brucidinium chloride in an oil-bath at 200—210° until effervescence ceases. The dark brown glass is dissolved in dilute acid, and the base is precipitated by potassium hydroxide and crystallised from ethyl alcohol. It forms tablets, melting, either alone or mixed with an authentic specimen of methyl-ψ-brucidine, at 198°.

Permanganate Oxidation of Methyl-ψ-brucidine.

Brucidone Semicarbazone.—Powdered potassium permanganate (6·8 g.: 5 atoms of oxygen) is added gradually to methyl-ψ-brucidine (5 g.) in ice-cold, mechanically-stirred acetone (500 c.c.); the colour

of the permanganate disappears slowly, and oxidation seems to be complete at the end of the addition. The manganese precipitate is filtered off, but yields no solid product. Removal of the acetone leaves a pale yellow, gummy residue (4 g.), which has not been obtained crystalline, and which yields only oily products when heated with methyl-alcoholic potassium hydroxide, or when dissolved in concentrated sulphuric acid (compare strychnidone, this vol., p. 1615). It is therefore converted into the semicarbazone by boiling a solution of the gum, semicarbazide hydrochloride (3·4 g.), and potassium acetate (3·4 g.) in aqueous alcohol under reflux for 1½ hours. Water is added, the alcohol distilled off under reduced pressure, and the crystalline precipitate, which forms during the distillation, is recrystallised from ethyl alcohol, being obtained in colourless needles which shrink at 210° and evolve gas at 226°, without complete fusion (loss at 100°, 13·1. 1½EtOH requires loss, 12·8%. Found in dried material: C, 60·8; H, 7·0; N, 15·1. $C_{24}H_{31}O_5N_5$ requires C, 61·4; H, 6·6; N, 14·9%). This *semicarbazone* is very sparingly soluble in cold methyl or ethyl alcohol. From the analyses, it appears to be the monosemicarbazone of a ketone derived from methyl-ψ-brucidine by the loss of CH_2 and its replacement by O, and the further introduction of one oxygen atom.

The unsharp melting point suggested that this material might be a mixture, and fruitless efforts were made to obtain pure components by repeated crystallisation from methyl or ethyl alcohol. The melting point remained unaltered. Purification was also attempted by extracting the substance with boiling methyl alcohol in sufficient quantity to dissolve only half, filtering the hot solution from the residue *A*, allowing it to deposit a second fraction *B* on cooling, and obtaining a third fraction *C* when the mother-liquor had remained over-night. *A* was recrystallised, and the mother-liquor yielded a very small fraction, *D*, on standing over-night. These fractions all formed colourless needles, which were dried in a vacuum desiccator, and the analyses agreed well with the formula already suggested (see below). On the other hand, the specimens differ in melting point and contain different amounts of solvent of crystallisation. (*A*) shrinks at 200°, melts at 220—225° (decomp.), and is not changed by recrystallisation (loss at 100°, 2·3. ½MeOH requires loss, 3·3%. Found in material dried at 100°: C, 62·0; H, 6·5%). (*B*) shrinks at 245°, melts at 257° (decomp.), and is not changed by recrystallisation (loss at 100°, 11·4. 2MeOH requires loss, 12·0%. Found in dried material: C, 61·6; H, 6·6%). (*C*) shrinks at 200° and melts at 235° (decomp.); there was not enough for recrystallisation (loss at 100°, 7·5. 1MeOH requires loss, 6·4%. Found in dried material: C, 61·4; H, 6·7%). (*D*), only

0·0327 g., shrinks at 195° and melts at 245° (decomp.) (loss at 100°, 10·4%. Found in dried material: C, 59·7; H, 6·5%).

It is possible that brucidone is a mixture of isomerides or that the semicarbazone group introduces geometrical isomerism.

Methoxymethyltetrahydrobrucidine.—A solution of methoxymethyldihydrobrucidine (20 g.) in sulphuric acid (200 c.c. of 20%) is reduced in the usual apparatus for 16 hours with a current of 5 amps., the temperature being kept at 18° by cooling in water. The methoxymethyldihydrobrucidine may be used in the crude condition in which it is obtained when water is added to the product of the interaction of brucidine methosulphate and methyl-alcoholic potassium hydroxide. After the reduction, excess of ammonia (*d* 0·880) is added while the liquid is stirred and cooled in ice; the product is thus obtained as a finely divided solid, whereas precipitation without cooling yields a caseous mass which solidifies to a single hard lump. The precipitate is collected, washed, dried (18 g.), and crystallised from methyl alcohol, from which it separates in colourless needles (Found: C, 70·2; H, 8·3. $C_{25}H_{36}O_4N_2$ requires C, 70·0; H, 8·4%).

Methoxymethyltetrahydrobrucidine melts at 133—135° and distils without decomposition at 253°/2 mm. It is somewhat soluble in the usual solvents and crystallises in beautiful needles from light petroleum (b. p. 60—80°). It dissolves readily in dilute acetic or mineral acid, and does not redden on exposure nearly so quickly as methoxymethyldihydrobrucidine. Acetic anhydride seems to be without action; after the mixture has been boiled for a few minutes and water and excess of ammonia have been added, the base is recovered unchanged.

The *dihydriodide* is prepared by adding concentrated sodium iodide solution to a solution of the base in 2*N*-sulphuric acid. On scratching, the dihydriodide separates in practically quantitative yield; it crystallises from water in colourless needles, which melt at 212° to a yellow froth (Found: I, 37·3. $C_{25}H_{36}O_4N_2,2HI$ requires I, 37·1%). It is sparingly soluble in ethyl alcohol, and becomes yellow on keeping.

When a hot aqueous solution of the dihydriodide is treated with excess of silver chloride, and the filtrate is evaporated to dryness under reduced pressure on the water-bath, the *dihydrochloride* is obtained as a colourless glass, which crystallises when ether is added carefully to a solution in alcohol–acetone. It forms rectangular plates, which are very soluble in water and evolve gas at 150° without melting completely. The residue is probably methyl*neo*-dihydrobrucidinium chloride, which is produced when the dihydrochloride is decomposed in boiling mesitylene (b. p. 165°) (see p. 1659).

The *methiodide* (*A*) is prepared by heating the base (4 g.) and methyl iodide (5 c.c.) under reflux on the water-bath for 20 minutes; a crystalline precipitate is soon formed. The methyl iodide is distilled away, and the residue separates from ethyl alcohol in colourless leaflets (Found: C, 54·9; H, 7·2. $C_{25}H_{36}O_4N_2$,MeI requires C, 54·7; H, 6·8%). The methiodide dissolves rather readily in water. It melts at 166—167°, losing methyl iodide quantitatively (loss in an oil-bath at 165—170°, 24·9. $C_{25}H_{36}O_4N_2$,MeI requires loss, 24·9%), and regenerating the base, m. p. 134°, which was identified by the mixed melting-point method.

The *methochloride* (*A*), prepared in the usual way from the methiodide and silver chloride, forms a glassy mass. When it was heated with an excess of methyl-alcoholic potassium hydroxide at 120° for 1 hour, and water was added, methoxymethyltetrahydrobrucidine was regenerated, and identified by the mixed melting-point method.

The *methiodide* (*B*) is obtained by heating either (i) the dimethiodide (A) (p. 1658) or (ii) the dimethiodide (B) (p. 1656).

(i) When methoxymethyltetrahydrobrucidine dimethiodide (A) is heated in an oil-bath at 230°, it melts and evolves methyl iodide quantitatively. The glassy residue crystallises from ethyl alcohol in flattened needles or leaflets, m. p. 298° (decomp.) (Found: C, 54·9; H, 6·7. $C_{25}H_{36}O_4N_2$,MeI requires C, 54·7; H, 6·8%). This substance is sparingly soluble in ethyl alcohol and in water and crystallises from the latter in characteristic prisms, m. p. 298° (decomp.), which become chalky when dried in a vacuum desiccator.

(ii) Methoxymethyltetrahydrobrucidine dimethiodide (B) (1 g.) is heated gently in a test-tube over a flame until the evolution of methyl iodide ceases. If the heating becomes too vigorous, deep-seated decomposition takes place, and gases are evolved which burn with a luminous flame, partly condense on the cold part of the tube, and smell strongly of pyridine bases. The residue is crystallised from ethyl alcohol, and this purification is repeated if necessary until leaflets, m. p. 298° (decomp.), are obtained. This *methiodide* (*B*) separates from water in colourless, characteristic prisms, m. p. 298° (decomp.) (Found: C, 55·1; H, 6·9; I, 22·4. $C_{25}H_{36}O_4N_2$,MeI requires I, 22·3%). The identity of the specimens of the methiodide (B) obtained from the dimethiodides (A) and (B) was shown by seeding an aqueous solution prepared in one way with a crystal prepared in the other way.

The *methochloride* (*B*), prepared in the usual way from the methiodide and silver chloride, forms a colourless glass. When this is heated in a test-tube over a flame, it decomposes before methyl

chloride is split off, and no methyldihydrobrucidine can be isolated from the charred residue. When exposed to water vapour in a bell-jar, the glassy methochloride crystallises in sticky needles, which after being pressed on porous tile and dried in a vacuum desiccator, decompose without melting at about 210.°

Methoxymethyltetrahydrobrucidine Dimetho-salts.

The Dimethosulphates (A) and (B).—Methoxymethyltetrahydrobrucidine reacts with methyl sulphate even more slowly than does methoxymethyldihydrobrucidine. In this case no monomethosulphate has been isolated. A solution of dried methoxymethyltetrahydrobrucidine (46 g.) and pure methyl sulphate (100 c.c.) in dry benzene (300 c.c.) is boiled on the water-bath under reflux for 24 hours, carefully protected from moisture. The hot benzene is decanted, but the residual mixture of brown gum and needles (90 g.) still retains some methyl sulphate and a little solvent, even after being washed as thoroughly as possible with benzene, which is then blown away in a current of air. This mixture must contain two dimethosulphates, (A) and (B), since it is converted into two dimethiodides, but attempts to isolate the dimethosulphates have been fruitless, and the mixture is therefore converted into the dimethiodides (A) and (B) by sodium iodide.

The *dimethiodide* (*B*) is prepared by adding sodium iodide (100 g.) in warm water (40 c.c.) to a warm solution of the above mixture of dimethosulphates in water (60 c.c.). On cooling and scratching, crystallisation begins, and after 24 hours the solid is collected, washed with water, and dried in a vacuum (31 g.). (The mother-liquors contain the dimethiodide A together with a small quantity of the dimethiodide B, and their investigation is described on p. 1658.) One recrystallisation from water (filter : see below) is usually sufficient for the purification of this product, although on a few occasions it had an unpleasant smell, which was first removed by grinding with cold ethyl alcohol. The dimethiodide (B) crystallises from water in prismatic needles, m. p. 287° (decomp.) (Found : C, 45·3, 45·4; H, 5·5, 5·7. $C_{25}H_{36}O_4N_2,2MeI$ requires C, 45·5; H, 5·9%). It is sparingly soluble in cold water or methyl or ethyl alcohol, but dissolves readily in hot water. When an aqueous solution is saturated with sulphur dioxide, a yellow oil is formed which crystallises on standing. This additive product, which contains sulphur dioxide, is very sparingly soluble in cold water, but readily forms an orange solution on warming, which evolves sulphur dioxide when boiled and then becomes colourless. When the colourless solution is cooled, the dimethiodide separates in a pure condition. The dimethiodide is very stable to alkali, and was

recovered in good yield after being heated with a large excess of 25% methyl-alcoholic potassium hydroxide at 140° for 30 minutes.

The crude precipitate of the dimethiodide is usually mixed with a small quantity of an ochreous, amorphous substance, which remains undissolved on recrystallisation of the precipitate from water. The amount of this by-product increases to about one-tenth of the weight of the dimethiodide if the solutions of the dimethosulphates and sodium iodide are boiling when mixed. The insoluble solid from the recrystallisation of the dimethiodide (see above) is crystallised fom methyl alcohol, in which it is very sparingly soluble, by dissolving it in much boiling solvent (charcoal), concentrating the solution until crystallisation begins, and allowing it to cool. The substance thus obtained in purple-red, glistening prisms melts at 230° (decomp.) and is a *periodide* of the dimethiodide (B) (Found: I, 55·6. $C_{25}H_{36}O_4N_2,2MeI,I_2$ requires I, 52·6%). This periodide is slowly decomposed by boiling water; it is stable to cold dilute nitric acid, but is instantly decomposed on boiling, iodine being liberated. When sulphur dioxide is passed into an aqueous suspension, the crystals change into a red gum, which is collected, and boiled with water until the solution becomes colourless and the smell of sulphur dioxide is no longer perceptible; on cooling, the dimethiodide (B) separates in colourless prisms, m. p. 287°.

The *dimethochloride* (*B*) is prepared by heating an aqueous solution of the dimethiodide (B) with excess of silver iodide, and evaporating the filtrate to dryness on the water-bath under reduced pressure. The colourless, crystalline mass thus obtained separates from ethyl alcohol in plates which melt to a froth and lose solvent at 138°, after drying in a vacuum desiccator. On further heating, the froth hardens and melts at 214°. After drying at 100°, the dimethochloride has m. p. 214° (decomp.) (loss at 100°, 8·5. 1EtOH requires loss, 8·0%. Found in dried material: Cl, 13·7. $C_{25}H_{36}O_4N_2,2MeCl$ requires Cl, 13·4%).

The dimethochloride loses a molecule of methyl chloride when it melts at 214°, forming methoxymethyltetrahydrobrucidine methochloride (B). After heating at 245° in an oil-bath until the evolution of methyl chloride ceased, the residual glass, consisting of the methochloride (B), was converted into the methiodide by adding sodium iodide to an aqueous solution, and crystallising the precipitate from water. The methiodide (B) separated in the characteristic prisms, m. p. 298° (decomp.), which became chalky on drying (Found: C, 54·5; H, 6·8%).

When the dimethochloride was heated in a test-tube at 300°, further decomposition took place. No methyl-ψ-dihydrobrucidine could be isolated from the residue, which consisted only of charred material.

if the heating was sufficiently prolonged to allow complete elimination of the methyl chloride.

The *dimethiodide* (*A*) is obtained either (i) from the mother-liquors of the preparation of the dimethiodide (B), or (ii) by the direct combination of the base and methyl iodide.

(i) The mother-liquors from the preparation of the dimethiodide (B) (p. 1656) are mixed with 50% potassium hydroxide solution; a caseous mass then separates, and soon hardens sufficiently to be pressed between porous tiles in order to remove as much alkali as possible. On boiling with a little ethyl alcohol, it becomes colourless and completely crystalline, without passing into solution to any great extent. The crystals are collected after several hours, washed with alcohol, and dried in a vacuum desiccator (33 g.). This product is essentially the dimethiodide (A), but contains also a little of the dimethiodide (B). In the first experiment, these were separated by fractional crystallisation from methyl alcohol, but later, when the properties of the dimethiodide (A) became known, the following process was found to be much more satisfactory. The mixture is dissolved in a little boiling water, and the solution is cooled, seeded with the dimethiodide (B), and set aside over-night. The remainder of the dimethiodide (B) separates in a practically pure state, and is collected, washed, and dried (5 g.). The filtrate now contains the dimethiodide (A), which is very soluble in water. It is saturated with sulphur dioxide while stirred continuously, and the yellow, crystalline additive compound which is formed is collected, washed with a little sulphurous acid, and dissolved in boiling methyl alcohol. After boiling for about 15 minutes, the solution becomes colourless, and is then concentrated to about 100 c.c. On cooling, the *dimethiodide* (*A*) crystallises in an almost pure condition, m. p. 230° (25 g.). (The yield of the combined dimethiodides A and B is about 81% of that theoretically possible.) One recrystallisation from methyl alcohol gives the pure product in stout prisms, which melt at 230—232° to a colourless froth (see below) (Found: C, 45·1; H, 5·8. $C_{25}H_{36}O_4N_2,2MeI$ requires C, 45·5; H, 5·9%). It dissolves readily in cold water, but only very sparingly in methyl or ethyl alcohol. When it is heated at its melting point, a molecule of methyl iodide is liberated smoothly; the glassy residue crystallises from water in the characteristic prisms of the methiodide (B) (see p. 1655).

(ii) A preliminary experiment showed that methoxymethyltetrahydrobrucidine combines with only one molecule of methyl iodide at 100°, even when heated for long periods. When, however, the base (5 g.) and methyl iodide (10 c.c.) are heated in a sealed tube at 140° for 24 hours, and the methyl iodide is distilled off, the

residual solid is the *dimethiodide* (*A*). After two recrystallisations from methyl alcohol, it forms stout prisms, m. p. 230°, which are identical in every way with the substance described above (Found: C, 45·6; H, 6·0; I, 35·4. $C_{25}H_{36}O_4N_2$,2MeI requires I, 35·7%).

The *dimethochloride* (*A*), prepared from the dimethiodide in the usual way by silver chloride, forms a colourless glass which cannot be crystallised. When it is heated gently in a test-tube over a flame, methyl chloride is evolved smoothly; the colourless residue, crystallised from methyl alcohol, forms needles, melting, either alone or when mixed with a specimen of methoxymethyltetrahydrobrucidine, at 133°.

*Methyl*neo*dihydrobrucidinium Salts.*

Methoxymethyltetrahydrobrucidine is not attacked by boiling 10% sulphuric acid under the conditions in which methoxymethyldihydrobrucidine yields methyl*neo*brucidinium sulphate. After the acid solution had been boiled for 2½ hours, ammonia precipitated 98% of the base used. Nor were successful results obtained when methoxymethyltetrahydrobrucidine dihydriodide or dihydrochloride was heated in a test-tube, since a much wider decomposition evidently took place. Ultimately, however, it was found possible to obtain the iodide in the following way.

The iodide. A suspension of methoxymethyltetrahydrobrucidine dihydrochloride (5 g.) in mesitylene (40 c.c.) is heated in an oil-bath at 180°. The solid becomes gummy and evolves hydrogen chloride, which is blown away from time to time in a current of air. After 20 minutes, the light brown gum hardens and is broken up, and the heating is continued for 10 minutes more in order to ensure complete decomposition. Ether is added to the cooled product, and the glassy solid is collected and dried at 100° (3·9 g.). Attempts to crystallise this chloride were unsuccessful (compare below), and it was therefore converted into the iodide. A solution of the chloride in water (25 c.c.) is saturated with sulphur dioxide, and concentrated sodium iodide is added drop by drop until no more oil separates. This additive product solidifies after a short time, and the orange mass thus obtained is boiled with water until the smell of sulphur dioxide has disappeared. On cooling, *methyl*neo*dihydrobrucidinium iodide* (3 g.) separates; it crystallises from water in colourless bipyramids, m. p. 283° (decomp.) (Found: C, 54·9; H, 6·4. $C_{24}H_{33}O_3N_2I$ requires C, 55·0; H, 6·3%). It is rather sparingly soluble in cold water or ethyl alcohol and crystallises in plates from the latter. An aqueous solution is not precipitated by ammonia or dilute alkali solution; concentrated potassium hydroxide solution precipitates the iodide unchanged.

The *chloride*, prepared by heating an aqueous solution of the

iodide with silver chloride and evaporating the filtrate under reduced pressure on the water-bath, is a colourless glass which does not crystallise. An aqueous solution is not precipitated by ammonia or dilute alkali solution. On heating in a test-tube over a flame, charring occurs very readily; the residue dissolves in water to a red solution, which becomes deep red on addition of ammonia, and then bright green on addition of a few drops of potassium hydroxide; much concentrated potassium hydroxide solution precipitates a green oil, which has not been examined. No methyl-ψ-dihydrobrucidine is formed.

Methoxymethyltetrahydrobrucidine Dimethohydrogencarbonates (A) and (B) and their Decomposition by Heat. Methyl-ψ-dihydrobrucidine.

The Dimethohydrogencarbonate (*A*).—This substance is prepared by shaking a hot aqueous solution of methoxymethyltetrahydrobrucidine dimethiodide (A) with an excess of either silver hydroxide or silver carbonate. In either case, the alkaline filtrate is evaporated as far as possible in an open basin on the water-bath, and then left in a vacuum desiccator over-night. The gummy residue crystallises on being rubbed with acetone containing a little ethyl alcohol, and is recrystallised by the cautious addition of ether to an ethyl-alcoholic solution. The *dimethohydrogencarbonate* (*A*) forms almost colourless, hygroscopic crystals, m. p. 92—94°, or 103—104° when heated in a sealed capillary tube (Found in material dried in a vacuum desiccator: C, 52·5; H, 8·3. $C_{25}H_{36}O_4N_2,2MeHCO_3,5H_2O$ requires C, 51·9; H, 8·1%). It is very soluble in water or ethyl alcohol, and evolves carbon dioxide on treatment with dilute hydrochloric acid. When a small quantity is heated gently in a test-tube over a flame, carbon dioxide is eliminated; the light brown, glassy residue crystallises from methyl alcohol in colourless needles, which, either alone or when mixed with methoxymethyltetrahydrobrucidine, melt at 134°.

The *dimethohydrogencarbonate* (*B*) is prepared from the dimethiodide (B) exactly in the manner described above in the case of the isomeride (A). It is crystallised by the careful addition of ether to a filtered solution in ethyl alcohol, and forms colourless prisms, which are hygroscopic and melt at 109° after drying in a vacuum desiccator (Found: C, 50·3; H, 8·3. $C_{25}H_{36}O_4N_2,2MeHCO_3,6H_2O$ requires C, 50·6; H, 8·1%). It is very soluble in water or ethyl alcohol, and evolves carbon dioxide on treatment with acids.

When it is heated at 135° in an oil-bath, carbon dioxide is evolved. The heating is continued for 30 minutes until the frothing has ceased, and the clear, glassy residue is dissolved in water. As the solution gives no precipitate with ammonia and evolves carbon dioxide on

treatment with acids, it must contain a methohydrogencarbonate. Sodium iodide is therefore added; the precipitate formed crystallises from water in colourless prisms, m. p. 298°, and is identical with methoxymethyltetrahydrobrucidine methiodide (B). The product of the decomposition is therefore the *methohydrogencarbonate* (*B*).

Methyl-ψ-dihydrobrucidine. The dimethohydrogencarbonate (B) (1 g.) is heated gently in a test-tube over a flame. It melts to a froth while gradually losing carbon dioxide, and the methyl alcohol which is evolved may be burnt at the mouth of the tube; when the effervescence has ceased, the light brown residue is quite mobile. After cooling, the tubes are broken and the contents extracted with boiling ethyl alcohol. The filtrate is concentrated to small volume; *methyl-ψ-dihydrobrucidine,* which then separates in moderate yield, recrystallises from ethyl alcohol in colourless tablets, m. p. 220—221° [Found: C, 72·5; H, 8·2; OMe, 15·8. $C_{24}H_{32}O_3N_2$ requires C, 72·7; H, 8·1; $(OMe)_2$, 15·6%]. This substance is soluble in dilute hydrochloric or acetic acid; it is sparingly soluble in ethyl alcohol, moderately easily soluble in acetone, and dissolves readily in benzene. It is extremely stable to oxidation by permanganate in acetone.

The *dihydriodide*, prepared by the addition of sodium iodide to a solution of the base in dilute hydrochloric acid, crystallises from water in small, wart-like granules, which melt at 215—217° to a yellow froth (Found in material dried at 100°: C, 44·0; H, 5·2. $C_{24}H_{32}O_3N_2,2HI$ requires C, 44·2; H, 5·2%). It separates from ethyl alcohol in stout prisms, and is sparingly soluble in this solvent and in water.

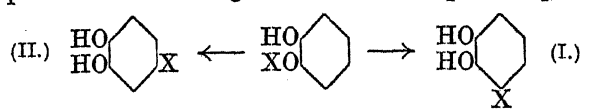
Colour Reactions of the Brucidine Derivatives.

The most useful reaction is that with ferric chloride in dilute hydrochloric acid, and a positive result is a deep green or bluish-green coloration, pink in thin layers, becoming red on boiling; when the reaction is negative, no colour is produced even on heating. The following substances give the reaction: brucidine, brucidine methosulphate, tetrahydrobrucine and its methochloride, methoxymethyldihydrobrucidine and its methochloride (B), methoxymethyltetrahydrobrucidine and its methochloride (B), methyl-ψ-brucidine and its methochloride prepared by either method, methyl*neo*brucidinium chloride, methyl-ψ-dihydrobrucidine, and methyl*neo*dihydrobrucidinium chloride. The substances which do not give the reaction are: methoxymethyldihydrobrucidine methosulphate (A) and methochloride (A), methoxymethyltetrahydrobrucidine methochloride (A), methoxymethyldihydrobrucidine dimethochlorides (A) and (B), methoxymethyltetrahydrobrucidine dimethochlorides (A) and (B), dioxymethoxymethyldihydrobrucidine (Y) methochloride, and

as already mentioned, brucine itself.* Since both strychnidine and brucidine give characteristic but entirely different ferric chloride reactions, the latter must be concerned with the only part of the molecule which is not identical in the two substances, namely, the aromatic nucleus, and this view is confirmed in the case of strychnidine by the observation that those derivatives which give a negative or feeble ferric chloride reaction are the only strychnidine derivatives which do not couple with diazonium salts. It then becomes apparent that the occurrence of the reaction in a particular case is dependent on the condition of the nitrogen atom bound to the aromatic nucleus. When this is salt-forming, the reaction is positive, whilst a negative reaction is due to its inclusion in the group –N–CO– as in brucine, or in a quaternary ammonium salt grouping as in the various dimethochlorides (and dihydrochlorides) described in this and the preceding communications. These views are in complete harmony with experience of simpler aromatic amine derivatives; thus dimethylaniline couples with diazonium salts, whereas *N*-methylacetanilide and phenyltrimethylammonium chloride do not. It is on this basis that we have allocated formulæ to the methochlorides (A) and (B) of methoxymethyldihydrobrucidine and methoxymethyltetrahydrobrucidine respectively (see pp. 1630 and 1633) and have drawn the important inference that the conversion of brucidine into methoxymethyldihydrobrucidine is accompanied by a transposition of the function of the nitrogen atoms in respect of their basic character.

The dichromate test in 60% sulphuric acid is of inferior diagnostic value. It is given by all the brucidine derivatives, but the green colour appears much more slowly in the cases where the ferric chloride reaction is negative.

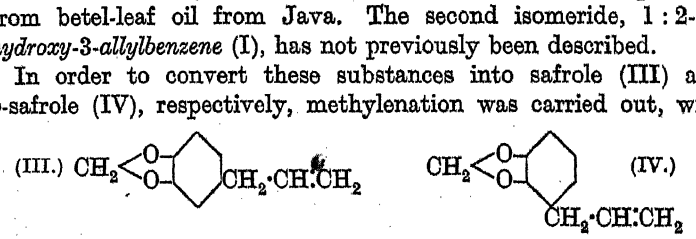
We are indebted to Mr. R. I. E. Hall, M.A., for preparing the large quantities of material required in these two researches and also to Mr. F. Hall for carrying out, with his usual skill, the whole of the analyses. One of us (W. H. P.) is indebted to the Government Grant Committee of the Royal Society for repeated grants which have covered much of the expense of these investigations.



UNIVERSITIES OF OXFORD AND
MANCHESTER. [*Received, May 24th*, 1927.]

* The brucidine derivatives do not exhibit the reaction in concentrated hydrochloric acid solution. In the cases when the reaction is positive, however, the colour appears on dilution, and this behaviour is clearly due to the formation and hydrolysis of dihydrochlorides.

CCXII.—*A Synthesis of Safrole and o-Safrole.*



By WILLIAM HENRY PERKIN, jun., and VICTOR MARTIN TRIKOJUS.

No direct synthesis of safrole has been recorded, the most recent attempt being that of Baker and Robinson (J., 1925, **127**, 1424), who distilled the product of the action of silver oxide and water upon γ-piperonylpropyltrimethylammonium iodide, but obtained *iso*safrole, the double bond moving into the position of greater stability. Kawai (*Sci. Papers Inst. Phys. Chem. Res.*, 1925, **3**, 263) has shown that the monoallyl ether of pyrocatechol undergoes the Claisen rearrangement to give an oil which he considered to be a mixture of 3- and 4-allyl-1 : 2-dihydroxybenzene, the change taking place in the following manner (X = $CH_2{\cdot}CH{:}CH_2$) :

This matter has now been reinvestigated and, by repeated fractionation of the product of the rearrangement, both of the above isomerides have been isolated in a pure state as colourless, crystalline solids melting at 28° and 48° respectively. As further confirmation of the course of the Claisen migration, it has been found that the properties of the higher-melting isomeride (II) are in accord with those assigned to the "4-allylbrenzcatechin" which Schimmel and Co. (*Centr.*, 1907, II, 1741) isolated in small quantity from betel-leaf oil from Java. The second isomeride, 1 : 2-*dihydroxy*-3-*allylbenzene* (I), has not previously been described.

In order to convert these substances into safrole (III) and *o*-safrole (IV), respectively, methylenation was carried out, with

moderately good yields, by gently refluxing them with methylene iodide and anhydrous potassium carbonate in dry acetone solution. By employing such mild conditions, any change into the isomeric *iso*safroles during the course of the reaction was inhibited. The identity of the synthetic product with naturally occurring safrole has been established by preparing the pentabromo-derivative (m. p. 169°) and the acetamido-derivative (m. p. 162—163°) and comparing these with the same derivatives from natural safrole. The properties of the hitherto unknown isomeride *o-safrole* (IV)

(which resembles safrole in odour and in many other ways) have been recorded.

The process of methylenation described above takes place very smoothly without formation of tarry products and may prove to be valuable in other cases of this kind.

EXPERIMENTAL.

Mono- and Di-allyl Ethers of Pyrocatechol.—Pyrocatechol (132 g.) and pure allyl bromide (144 g.) were dissolved in pure dry acetone (220 c.c.), finely powdered, freshly heated potassium carbonate (170 g.) was added gradually with constant shaking, and the whole refluxed for 6—8 hours on the water-bath, the condenser being fitted with a calcium chloride tube (compare Kawai, *loc. cit.*). After removal of the acetone, addition of water and dilute sulphuric acid, and extraction with ether, the monoallyl ether and unchanged pyrocatechol were removed by washing the extract with dilute alkali solution, and the ethereal solution was then dried with anhydrous sodium sulphate and evaporated. The yield of pure diallyl ether was 43 g. (b. p. 124—125·5°/13 mm.). The alkali washings were immediately acidified and the oil was taken up in chloroform. After being repeatedly washed with water to remove pyrocatechol, the chloroform was evaporated and the oil distilled, yielding 90 g. of pure monoallyl ether, b. p. 107·5—109°/15 mm. The yields of both ethers were considerably higher than those recorded by Kawai under almost analogous conditions.

Molecular rearrangement. The monoallyl ether (92 g.) was heated in a flask, fitted with a ground-in condenser, in a paraffin bath at 170—180°; the inner temperature suddenly rose to 265° with momentary boiling, the colour of the liquid changing to red. After cooling, the product was fractionated under 15—16 mm. and fractions, b. p. 142—152° (66·2 g.) and 152—160° (17·2 g.), were collected, leaving a resinous, non-volatile residue (9 g.). The second fraction solidified on standing and consisted chiefly of 1 : 2-dihydroxy-4-allylbenzene, melting at 40—41° with previous softening. Kawai noticed the formation of some crystals in his higher fraction (b. p. 155—160°/16 mm.) and suggested that they were due to pyrocatechol which had been set free during the rearrangement (compare Claisen, *Annalen*, 1913, **401**, 21). In the present instance, however, no pyrocatechol was observed and it is probable that his crystals were those of 1 : 2-dihydroxy-4-allylbenzene.

After repeated systematic refractionation of the above two fractions, both isomerides were isolated in a pure condition, the proportion of 1 : 2-dihydroxy-3-allylbenzene to its isomeride in the rearranged product being approximately 5 to 4.

1 : 2-*Dihydroxy*-4-*allylbenzene* (II) is a colourless, waxy, crystalline solid soluble in water and most other solvents, but sparingly soluble in petroleum. It forms colourless needles, m. p. 48°, from benzene–light petroleum and boils at 147—149°/10 mm. and at 156—158°/16 mm. (Found: C, 72·1; H, 6·8. $C_9H_{10}O_2$ requires C, 72·0; H, 6·7%). The dibenzoyl derivative (Schotten-Baumann) separates from light petroleum in colourless prisms, m. p. 71°. These properties clearly indicate that the substance is identical with the "allylbrenzcatechin" isolated from Java betel-leaf oil (*loc. cit.*).

1 : 2-*Dihydroxy*-3-*allylbenzene* (I) is best purified by distillation under reduced pressure and has b. p. 143·5—145°/15 mm. If allowed to crystallise slowly, it separates in large, colourless, flat prisms, m. p. 28°, but it has a tendency to remain liquid below this temperature. Owing to this property, it was not found possible to recrystallise it satisfactorily. It dissolves readily in most solvents except petroleum, whilst in water it is not as soluble as its isomeride (Found: C, 72·1; H, 6·5. $C_9H_{10}O_2$ requires C, 72·0; H, 6·7%).

It resembles its isomeride in having a phenolic odour and in aqueous solution it gives with ferric chloride an olive-green colour, changing to wine-red on addition of sodium carbonate.

The *dibenzoyl* derivative separates from light petroleum in colourless prisms, m. p. 60—61° (Found: C, 77·1; H, 5·2. $C_{23}H_{18}O_2$ requires C, 77·1; H, 5·0%).

Safrole (III).—1 : 2-Dihydroxy-4-allylbenzene (10 g.) and methylene iodide (18 g.) were dissolved in pure dry acetone (35 c.c.) and finely powdered, freshly ignited potassium carbonate (20 g.) was gradually added with shaking to prevent caking. After gently refluxing on the water-bath for 12 hours, the acetone was removed, the product was made acid with dilute sulphuric acid and extracted with ether, and the ethereal solution was repeatedly washed with dilute aqueous sodium hydroxide and finally with water, dried over sodium sulphate, and evaporated. On carefully distilling the residue under reduced pressure, methylene iodide first passed over; when this had been completely removed, a fraction, b. p. 100—101·5°/10—11 mm., consisting of 2·5 g. of a clear, colourless oil, was collected. This was identified as safrole by its characteristic odour and by preparing its *pentabromo*-derivative by gradually adding excess of bromine below 0° and allowing the mixture to stand for some hours; the solid substance which had separated, after recrystallising from ethyl alcohol, melted at 169°, and a mixed melting point with the derivative prepared from ordinary safrole showed no depression. The oil had $n_D^{20°}$ 1·5381 (Found: C, 74·2; H, 6·4. Calc. for $C_{10}H_{10}O_2$: C, 74·1; H, 6·2%). As an additional

proof of identity, 1·35 g. of the synthetic substance were nitrated under the conditions laid down by Foulds and Robinson (J., 1914, **105**, 1963), the nitro-derivative was reduced with tin and hydrochloric acid, and the crude 6-aminosafrole acetylated; the acetyl derivative crystallised from methyl alcohol in colourless needles, m. p. 162—163° (Found: C, 65·5; H, 6·0. Calc. for $C_{12}H_{13}O_3N$: C, 65·7; H, 5·9%), and a mixed melting-point determination with the corresponding derivative from naturally occurring safrole showed no depression.

o-Safrole (IV).—1 : 2-Dihydroxy-3-allylbenzene (20 g.), methylene iodide (36 g.), potassium carbonate (40 g.), and acetone (70 c.c.) were gently refluxed for 14 hours, and the product was treated in a manner similar to that described above in the synthesis of safrole. Methylene iodide was removed under reduced pressure, and the remainder (boiling over 1·5°) collected separately. Yield, 7 g. It was redistilled and collected at 102·5—103°/13 mm. (Found: C, 74·3; H, 6·2. $C_{10}H_{10}O_2$ requires C, 74·1; H, 6·2%). It boils at 106—107°/16 mm. and at 226—227°/762 mm.

o-Safrole is a colourless, mobile oil which does not crystallise at −20° and has $n_D^{20°}$ 1·5359. It has an agreeable odour, similar to, but not so pronounced as, that of safrole (compare the respective odours of *o*-piperonal and piperonal; Perkin and Trikojus, J., 1926, 2927). On the addition of excess of bromine to *o*-safrole cooled below 0°, a vigorous reaction occurs; the product, which solidifies on standing over-night, is washed with ethyl alcohol and crystallised from the same solvent, in which it is only sparingly soluble. The resulting *pentabromo*-derivative separates in colourless prisms, m. p. 154°, and the yield is almost quantitative (Found: Br, 71·8. $C_{10}H_7O_2Br_5$ requires Br, 71·6%).

One of us (V. M. T.) is indebted to the Royal Commissioners of the 1851 Exhibition for a scholarship which enabled him to take part in this investigation.

CCXIII.—*Monothioethylene Glycol. Part III. Nitrophenyl Thioethers.*

By GEORGE MACDONALD BENNETT and WILLIAM AMBLER BERRY.

IN continuation of the examination of monothioethylene glycol and its derivatives (J., 1921, **119**, 1860; 1922, **121**, 2139), we have now prepared the three isomeric nitrophenyl β-hydroxyethyl

sulphides and a number of related substances. The direct conversion of the parent mercaptan into each of these nitrophenyl thioethers was realised, the *o*-isomeride being obtained in good yield by the action of *o*-bromonitrobenzene and alcoholic potassium hydroxide, and the *m*- and *p*-isomerides by the action of the respective nitrobenzenediazonium salts (compare Stadler, *Ber.*, 1884, **17**, 2073). The most economical method for preparing each of these substances is, however, by the action of ethylene chlorohydrin upon the salt of the nitrothiophenol. The corresponding *p*-nitrobenzyl thioether was obtained in a similar manner from *p*-nitrobenzyl mercaptan, the preparation of which has been improved. The isomeric *p*-nitrophenyl γ-hydroxypropyl sulphide is also described.

From these hydroxy-sulphides, the chloro-, bromo-, and iodosulphides have been produced by known methods. The replacement of the hydroxyl group by chlorine was appreciably less easy in *p*-nitrophenyl γ-hydroxypropyl sulphide than in the β-series (compare Bennett and Hock, J., 1925, **127**, 2671; this vol., p. 477).

The isolation of three of these compounds has been announced by other authors during the course of our work—*o*-nitrophenyl β-chloroethyl sulphide by Lecher and Simon (*Ber.*, 1925, **58**, 409) and *p*-nitrophenyl β-hydroxy- and β-bromo-ethyl sulphides by Waldron and Reid (*J. Amer. Chem. Soc.*, 1923, **45**, 2399).

The results of a crystallographic examination of some of these compounds are summarised in the following table:

Substance.	*a* : *b* : *c*.	β.	Cleavage.
1 : 2$(NO_2)C_6H_4\cdot S\cdot C_2H_4\cdot OH$	0·5445 : 1 : 1·1416	—	(010)
1 : 2$(NO_2)C_6H_4\cdot S\cdot C_2H_4Cl$	0·9584 : 1 : 0·5126	—	(010)

EXPERIMENTAL.

Action of Sodium and Potassium Salts of Monothioethylene Glycol on o- *and* p-*Chloro- and Bromo-nitrobenzenes.*—The *o*-nitrophenyl thioether was first isolated from the products of the interaction of *o*-nitrochlorobenzene and monothioethylene glycol. o-*Nitrophenyl β-hydroxyethyl sulphide* was thus obtained in deep yellow, orthorhombic tables, m. p. 100° (Found: C, 48·2; H, 4·5; N, 7·1. $C_8H_9O_3NS$ requires C, 48·2; H, 4·5; N, 7·05%).

A better yield and a purer product were obtained by gradually heating *o*-nitrobromobenzene in spirit with monothioethylene glycol and potassium hydroxide, but the most convenient method

of preparation of this substance is through *o*-nitrothiophenol as described below.

When these preparations were repeated using *p*-chloronitrobenzene and *p*-bromonitrobenzene, reduction or some other subsidiary reaction was still more marked; the yellow product isolated, being practically indifferent to phosphorus pentachloride, was not *p*-nitrophenyl β-hydroxyethyl sulphide.

Preparation of the p-*Nitrophenyl Thioether of Monothioethylene Glycol.*—The *p*-compound was first isolated by a reaction analogous to that noted by Stadler (*loc. cit.*). The product was an oil, but it solidified after 3 weeks. It was dried on porous earthenware and recrystallised from dilute alcohol, and was identical with the material obtained more conveniently by the following method: *p*-Nitrochlorobenzene (31·5 g.) was covered with alcohol, a warm solution of sodium sulphide (48 g. of $Na_2S,9H_2O$) in dilute alcohol (60 c.c., 1 : 1) was added, and the mixture heated on the steam-bath until a vigorous reaction occurred. When this reaction had subsided, the mixture was heated for a further 5 minutes. Prolonged heating at this stage causes a decrease in the yield owing to oxidation of the thiophenol to disulphide (compare Willgerodt, *Ber.*, 1885, **18**, 331). The mixture was then poured into about 500 c.c. of water and cooled in a coal-gas atmosphere until the precipitated unchanged *p*-nitrochlorobenzene had solidified, and the liquid was rapidly filtered into an excess of sulphurous acid to precipitate the thiophenol and prevent oxidation. The thiophenol was quickly filtered off, dissolved in alcohol (30 c.c.), and added to a solution of potassium hydroxide (6 g. in 40 c.c. of water). The mixture was heated under reflux on the steam-bath with ethylene chlorohydrin (15 c.c.) until the dark colour faded, and the alcohol and volatile impurities were then removed in steam. The product (18 g.), which solidified on cooling, was *p*-nitrophenyl β-hydroxyethyl sulphide, which crystallised well from ether or carbon disulphide–petroleum as a pale yellow, finely crystalline solid, m. p. 62° (Found: C, 48·0; H, 4·6; N, 7·25. Calc.: C, 48·2; H, 4·5; N, 7·05%). Waldron and Reid (*loc. cit.*) give m. p. 59°.

Convenient Method of Preparation of the o-*Nitrophenyl Thioether.*—The analogous method can be shortened satisfactorily for the preparation of *o*-nitrophenyl β-hydroxyethyl sulphide. *o*-Nitrochlorobenzene and sodium sulphide are heated as described above and the product is poured into water. The precipitated nitrochlorobenzene, which does not solidify readily, is extracted with benzene, and the remaining solution is heated with the requisite amount of ethylene chlorohydrin for 15 minutes. It is not advisable to heat for longer than this, owing to the possible reduction of the

nitro-group by the sodium sulphide present in the solution. The yield is 17 g.

Preparation of m-*Nitrophenyl* β-*Hydroxyethyl Sulphide.*—An attempt to prepare this compound by the Stadler diazo-reaction (*loc. cit.*) gave an oil which did not crystallise. The *m*-nitrophenyl thioether was therefore made from *m*-nitrothiophenol, prepared as described by Leuckart (*J. pr. Chem.*, 1890, **41**, 179). The awkward diazotisation at great dilution was avoided thus: *m*-Nitroaniline (50 g.), dissolved in 150 c.c. of concentrated hydrochloric acid and 750 c.c. of water and cooled to 10°, was diazotised by adding sodium nitrite (26·5 g. in a little water) all at once, the temperature not being allowed to rise above 15°. This mixture was kept in ice for about 30 minutes, and the liquid was then filtered into a solution of potassium xanthate (75 g.) and borax (150 g.) in water (750 c.c.) at 70—75°. (It is necessary to add the diazo-solution cautiously, otherwise an explosive evolution of gas may be caused.) The mixture was finally heated until effervescence ceased. After cooling, the precipitated oil was removed in ether, the ether evaporated, and the crude xanthogenic ester hydrolysed. The dinitrodiphenyl disulphide, obtained by adding potassium ferricyanide to the resulting solution, was purified by recrystallisation and reduced with glucose and alkali (compare Lecher and Simon, *Ber.*, 1922, **55**, 2427), and the resulting thiophenol was converted into *m*-nitrophenyl β-hydroxyethyl sulphide in the same way as the *o*- and *p*-isomerides. The crude product was a dark oil which did not solidify. As the compound could not be distilled, even at pressures of 1 mm., it was heated at 150° with the equivalent of *p*-nitrobenzoyl chloride. The product solidified and, after recrystallising from toluene, m-*nitrophenyl* β-(p-*nitrobenzoyl*)*oxyethyl sulphide* was obtained as a pale yellow solid, m. p. 86° (Found: N, 8·25. $C_{15}H_{12}O_6N_2S$ requires N, 8·05%). This nitrobenzoyl derivative was hydrolysed by boiling alcoholic sodium hydroxide, the mixture poured into water, the oil which separated removed in ether, the extract dried, and the ether evaporated. The remaining oil solidified on being cooled in a freezing mixture, and m-*nitrophenyl* β-*hydroxyethyl sulphide* was obtained in pale yellow needles, m. p. 42·5°, by crystallisation from light petroleum (b. p. 40—60°) or warm water (Found: C, 48·0; H, 4·7; N, 7·0. $C_8H_9O_3NS$ requires C, 48·2; H, 4·6; N, 7·0%).

Little difficulty was encountered in getting the *mm'*-dinitrodiphenyl disulphide into a solid workable condition during the winter months, but when the preparation was repeated in warmer weather the disulphide solidified so slowly that it could not easily be obtained pure in quantity. The preparation of the *m*-compound has there-

fore been carried out without the isolation of the disulphide, as follows: The xanthogenic ester (20 g.) was hydrolysed with an alcoholic solution of sodium hydroxide (5 g. of sodium, 50 c.c. of alcohol, and 10 c.c. of water), and the reaction liquor was poured into water and extracted with carbon tetrachloride. The remaining solution was filtered, the filtrate dropping into water saturated with sulphur dioxide, and the precipitated thiophenol was removed in ether. The filtered ethereal solution was extracted with a solution of potassium hydroxide (10 g.) in two portions, and the extract heated on the steam-bath with ethylene chlorohydrin (10 c.c.) until the solution became clear. The precipitated oil, after being steam-blown, solidified when cooled and nucleated (yield, 9 g. of dry crude product).

Preparation of p-*Nitrobenzyl* β-*Hydroxyethyl Sulphide.*—*p*-Nitrobenzyl thiocyanate (m. p. 84°; compare Henry, *Ber.*, 1869, **2**, 638) was converted into *p*-nitrobenzyl thiocarbamate by Meyer's method ("Analyse und Konstitutions Ermittlung Organischen Verbindungen," 3rd Ed., p. 678), but it was subsequently found more convenient to use the method described by Gabriel and others (*Ber.*, 1895, **28**, 1027; 1896, **29**, 160: compare also Poggi, *Atti R. Accad. Lincei*, 1925, **2**, 423). A solution of the thiocyanate (50 g.) in concentrated sulphuric acid (250 c.c.) was kept in the ice-chest for 10 hours and then poured on ice. The precipitated thiocarbamate was filtered off and purified (m. p. 146°). The thiocarbamate was hydrolysed by boiling it under reflux with hydrochloric acid (10 parts of 20% acid) for 2 hours (compare Gabriel and Stelzner, *Ber.*, 1896, **29**, 160). On cooling, the oil, *p*-nitrobenzyl mercaptan, solidified.

The alternative method of preparation of *p*-nitrobenzyl mercaptan described by Price and Twiss (J., 1909, **95**, 1725) was found to be less satisfactory than the description would lead one to expect and certainly gave a product inferior both in yield and in purity to that obtained by the method described above.

The conditions for the condensation of the sodium salt of *p*-nitrobenzyl mercaptan and ethylene chlorohydrin are important, in that too great a concentration of alkali and heating to too high a temperature must be avoided, or else subsidiary reactions occur. The method used was as follows: To the mercaptan prepared from the thiocarbamate (12 g.) as described above, a solution of sodium hydroxide (3 g. in 60 c.c. of water) and ethylene chlorohydrin (7 c.c.) were added and the mixture was heated, in a flask provided with a stirrer, to 50° (thermometer dipping into the reaction liquid). The mixture was kept at this temperature for 15 minutes, during which an oil separated. 2*N*-Sodium hydroxide (10 c.c.) and ethylene chlorohydrin (3 c.c.) were then added and the mixture was heated

for a further 10 minutes. The reaction liquid was steam-blown to remove volatile impurities and cooled, the oil removed in ether, the extract dried, and the ether evaporated. After being kept for several days in a desiccator, the oil solidified (9 g.).

p-*Nitrobenzyl* β-*hydroxyethyl sulphide*, which is soluble in alcohol, ether, and benzene and slightly soluble in water, crystallises best from a mixture of equal volumes of carbon disulphide and light petroleum (b. p. 40—60°) in almost colourless needles, m. p. 37·5° (Found: C, 50·6; H, 5·4; N, 6·5. $C_9H_{11}O_3NS$ requires C, 50·7; H, 5·2; N, 6·6%).

In subsequent preparations, this compound was obtained as a solid by inoculating the steam-blown reaction liquor.

Preparation of p-*Nitrophenyl* γ-*Hydroxypropyl Sulphide.*—This compound was prepared by a method analogous to that used for the *p*-nitrophenyl β-hydroxyethyl sulphide and was isolated as an oil which solidified after a few days. It was recrystallised from carbon disulphide–light petroleum and obtained in pale yellow needles, m. p. 41·5°, which are slightly soluble in water and easily soluble in ether, alcohol, benzene, and acetone (Found: C, 50·5; H, 5·5; N, 6·6. $C_9H_{11}O_3NS$ requires C, 50·7; H, 5·2; N, 6·6%).

Preparation of Halogen Derivatives.

I. *Chloro-compounds.*—The *o*- and *p*-nitrophenyl β-chloroethyl sulphides were prepared by the action of phosphorus pentachloride on the hydroxy-compound (yield, 75%).

When this method was used for the preparation of *p*-nitrophenyl γ-chloropropyl sulphide, the yield was poor (45%), owing to a large amount of phosphoric ester being formed as a by-product. The preparation of this compound was therefore repeated using the Darzens reaction (*Compt. rend.*, 1911, **152**, 1314). The hydroxy-compound was dissolved in dimethylaniline (1·5 mols.), and thionyl chloride (1·5 mols.) gradually added, the mixture being kept cool. After 15 minutes, the mixture was heated on the steam-bath for 15 minutes and poured into dilute hydrochloric acid. The chloro-compound separated, and solidified on being cooled and scratched (yield, 87%). It was subsequently found that this method was preferable to the phosphorus pentachloride reaction for the preparation of the β-chloroethyl sulphides, in that the reaction product was much cleaner and solidified more readily (yield, 80—85%).

These ω-chloroalkyl sulphides are soluble in alcohol, acetone, benzene, and glacial acetic acid, and are best recrystallised from light petroleum or methyl alcohol.

Preparation of the Sulphoxides of the Halogenated Sulphides.—After the halogenated sulphide had been boiled for 15 minutes

with concentrated nitric acid (*d* 1·40), the product obtained on neutralising the solution had, even after several recrystallisations, an indefinite melting point.

The sulphide was dissolved in a little glacial acetic acid, and bromine (a slight excess above 1 mol.) added to the warm solution. As a dibromide (R·SBr_2·R′) did not crystallise, the solution was neutralised and a slight excess of aqueous sodium hydroxide added. The product in this case also had a diffuse melting point.

By adding a slight excess of hydrogen peroxide (30%) to a glacial acetic acid solution of the sulphide and keeping the mixture for 24 hours, compounds of sharp melting points were obtained. The sulphoxides crystallise well from either light petroleum or dilute acetic acid.

When oxidation of the iodoethyl sulphides was attempted with hydrogen peroxide, iodine was liberated and the pure sulphoxide was not isolated.

o-Nitrophenyl β-chloroethyl sulphide crystallises in deep yellow, orthorhombic needles, m. p. 51° (Found: C, 44·0; H, 3·8; Cl, 16·3. Calc.: C, 44·1; H, 3·7; Cl, 16·3%). The *sulphoxide* forms pale yellow needles, m. p. 84° (Found: N, 6·0. $C_8H_8O_3NClS$ requires N, 6·0%).

p-*Nitrophenyl* β-*chloroethyl sulphide* crystallises in pale yellow, monoclinic needles, m. p. 62° (Found: Cl, 16·3, 16·2. $C_8H_8O_2NClS$ requires Cl, 16·3%). The *sulphoxide* crystallises in colourless needles, m. p. 80° (Found: C, 41·2; H, 3·6; N, 6·0. $C_8H_8O_3NClS$ requires C, 41·1; H, 3·4; N, 6·0%).

m-*Nitrophenyl* β-*chloroethyl sulphide* forms pale yellow needles, m. p. 31° (Found: Cl, 16·2%).

p-*Nitrophenyl* γ-*chloropropyl sulphide* forms pale yellow needles, m. p. 50° (Found: N, 6·1; Cl, 15·4. $C_9H_{10}O_2NClS$ requires N, 6·1; Cl, 15·4%).

p-*Nitrobenzyl* β-*chloroethyl sulphide* forms almost colourless needles, m. p. 46—47° (Found: N, 6·1; Cl, 15·2. $C_9H_{10}O_2NClS$ requires N, 6·1; Cl, 15·4%).

H. *Bromo-compounds.*—These compounds were prepared by the action of phosphorus pentabromide on the hydroxy-compounds (see corresponding preparation of the chloro-compounds; p. 1671.) They are soluble in alcohol, benzene, acetone, and ether, and are best recrystallised from light petroleum.

o-*Nitrophenyl* β-*bromoethyl sulphide* crystallises in deep yellow, orthorhombic needles, m. p. 63° (Found: Br, 30·3. $C_8H_8O_2NBrS$ requires Br, 30·45%), and the *sulphoxide* in pale yellow needles, m. p. 112° (Found: N, 5·0%).

p-Nitrophenyl β-bromoethyl sulphide forms pale yellow, mono-

clinic needles, m. p. 59° (Found: Br, 30·1. Calc.: Br, 30·45%). Waldron and Reid (*loc. cit.*), who prepared this compound by the action of hydrobromic acid on the hydroxy-compound, give the melting point as 58°. The *sulphoxide* forms colourless needles, m. p. 100° (Found: Br, 28·6. $C_8H_8O_3NBrS$ requires N, 5·0; Br, 28·7%).

m-*Nitrophenyl* β-*bromoethyl sulphide* forms almost colourless, orthorhombic plates, m. p. 32° (Found: Br, 30·3%).

III. *Iodo-compounds.*—The interaction of phosphorus tri-iodide or phosphorus and iodine with the hydroxy-sulphides causes reduction and not simple replacement of the hydroxyl group. o- and p-*Nitrophenyl* β-*iodoethyl sulphides* have been obtained by heating the bromo-compound with a slight excess of sodium iodide in acetone solution for about 8 hours. They crystallise well from either methyl alcohol or light petroleum. The former crystallises in deep yellow plates, m. p. 64° (Found: I, 40·8. $C_8H_8O_2NIS$ requires I, 41·0%), and the latter in pale yellow plates, m. p. 67° (Found: I, 40·8%).

m-Nitrophenyl β-iodoethyl sulphide was obtained in a similar manner as a dark brown oil which did not crystallise and was not analysed. After it had been kept for a long time in the expectation of its solidifying, it was found in fact to be depositing crystals. These, on recrystallisation from petroleum (b. p. 90—120°), gave pale yellow plates, m. p. 136°, which contained sulphur and nitrogen but no iodine (Found: N, 8·2%; *M*, cryoscopic in molten camphor, 393). Sufficient of this substance was not obtained for a more detailed examination, but it seems probable that it was *di*-m-*nitrodiphenylthiol*cyclo*butane*, $\begin{matrix} NO_2\cdot C_6H_4\cdot S\text{—}CH\text{—}CH_2 \\ \qquad\qquad\quad\ \ \vert \qquad\ \vert \\ \qquad\qquad\quad CH_2\text{—}CH\cdot S\cdot C_6H_4\cdot NO_2 \end{matrix}$, which requires N, 7·7%; *M*, 362.

Crystallographic Measurements.

o-*Nitrophenyl* β-*hydroxyethyl sulphide* crystallises from acetone in deep yellow, orthorhombic crystals with $a : b : c = 0{\cdot}5445 : 1 : 1{\cdot}1416$. The forms observed are *b*(010), *c*(001), *r*(101) and *q*(011), the habit being tabular with *c* large (Fig. 1). The mean angular values obtained by measurement of seven crystals on a single-circle goniometer are: *cq**48° 47′, *cr**64° 30′, *rq* 73° 37′ (calc. 73° 31′), *bc* 89° 59′. There is a perfect cleavage in the plane (010). $d_4^{15°}$ (vac.) 1·472. The substance has strong positive double refraction. The plane of the optic axes is (100), the acute bisectrix emerging perpendicular to (010), and there is large dispersion of the axes.

o-*Nitrophenyl* β-*chloroethyl sulphide* was obtained in suitable crystals, after many trials, by slow crystallisation from cold ethyl

alcohol or from ethylene dichloride–ethylene chlorohydrin, in orthorhombic crystals with $a : b : c = 0{\cdot}9584 : 1 : 0{\cdot}5126$. The following are the forms observed and the respective mean angular values from eight crystals:

	a (100).	m (110).	x (21$\bar{2}$).	y (232).
ϕ	0° 0′	*43° 47′	*24° 47′	57° 54′
ρ	90° 0′	90° 0′	*29° 27′	43° 2′

The crystals are uniterminal and of prismatic habit similar to that shown in Fig. 2. $d^{18°}$, 1·480.

There is an excellent cleavage in the plane (010). Examination of cleavage planes in convergent polarised light shows that the substance has strong crossed axial dispersion. The optic picture is apparently uniaxial for the D line of sodium: red light (lithium flame) gives a biaxial picture with the axes well separated in the

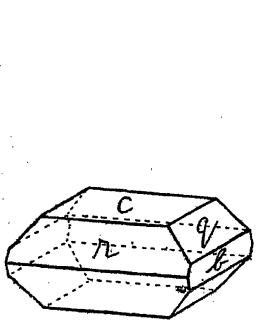

Fig. 1.

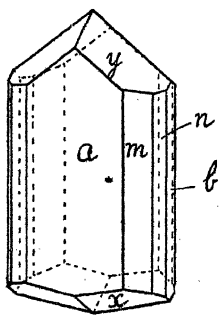

Fig. 2.

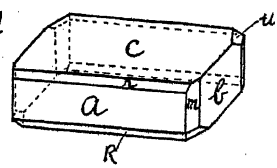

Fig. 3.

plane (100), whilst for green light (thallium) they are in the plane (001), the acute bisectrix remaining normal to (010) throughout.

o-*Nitrophenyl* β-*bromoethyl sulphide* separates from acetone in prisms (Fig. 2) belonging to the hemimorphic class of the orthorhombic system isomorphous with the foregoing, having $a : b : c = 0{\cdot}9590 : 1 : 0{\cdot}5250$. The following are the mean angular values (from six crystals):

	a (100).	m (110).	n (120).	b (010).	x (21$\bar{2}$).	y (232).
ϕ	0° 0′	*43° 48′	62° 25′	90° 0′	*23° 53′	56° 57′
ρ	90° 0′	90° 0′	90° 0′	90° 0′	*29° 52′	43° 10′

There is an excellent cleavage in the plane (010). $d^{17°}$ 1·742. A straight extinction was observed on (100). The acute bisectrix emerges perpendicular to (010), the axes being widely separated in the plane (001). The dispersion is large.

o-*Nitrophenyl* β-*iodoethyl sulphide* separates from acetone in large, deep yellow, monoclinic crystals (Fig. 3) with $a : b : c =$

3·143 : 1 : 2·513; β = 99° 16′. The following are the mean angular values (four crystals):

	a (100).	*m* (110).	*b* (010).	*r* (101).	*c* (001).	*R* (1̄01).	*u* (1̄12).
φ.....	0° 0′	*72° 8′	90° 0′	0° 0′	0° 0′	180° 0′	100° 32′
ρ.....	90° 0′	90° 0′	90° 0′	*44° 13′	9° 16′	33° 45′	47° 53′

There is a marked tendency for *b* to be replaced by a pair of vicinal faces. There are poor cleavages in the planes (010) and (100). $d^{16°}$ 2·026. The position of the optic axes could not be observed.

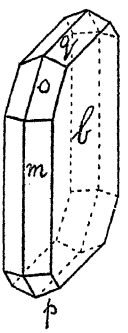

FIG. 4.

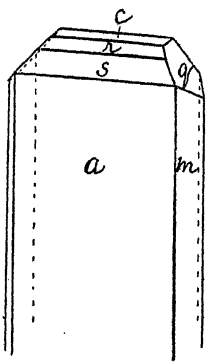

FIG. 5.

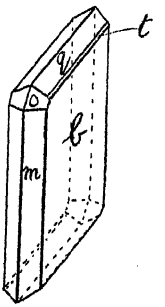

FIG. 6.

p-*Nitrophenyl* β-*chloroethyl sulphide* crystallises in the monoclinic system with *a* : *b* : *c* = 0·4752 : 1 : 0·4026; β = 96° 54′. The following are the mean angular values (4 crystals), the habit being as in Fig. 4.

	b (010).	*m* (110).	*q* (011).	*o* (111).	*p* (11
φ	0° 0′	*64° 45′	*16° 43′	67° 52′	298° 39′
ρ	90° 0′	90° 0′	*22° 48′	47° 15′	40° 28′

There is a poor cleavage in the plane (100). $d^{18°}$ 1·486. The extinction appears to be straight on (010). The position of the optic axes was not observed.

p-*Nitrophenyl* β-*bromoethyl sulphide* crystallises in the monoclinic system with *a* : *b* : *c* = 1·8113 : 1 : 1·1187; β = 96° 18′, the habit being as in Fig. 5. The following are the mean angular values (4 crystals):

	a (100).	*c* (001).	*m* (110).	*q* (011).	*s* (201).	*r* (101).
φ	0° 0′	0° 0′	*60° 57′	84° 54′	0° 0′	0° 0′
ρ	90° 0′	*6° 18′	90° 0′	*48° 18′	36° 19′	53° 45′

No marked cleavage was found. $d^{16°}$ 1·742. The extinction was straight on (100), but the position of the optic axes was not observed.

p-*Nitrophenyl* β-*iodoethyl sulphide* crystallises in the monoclinic system with *a* : *b* : *c* = 0·5081 : 1 : 0·5160; β = 104° 45′, the habit

being as in Fig. 6. The following are the mean angular values (3 perfect crystals):

	b (010).	*i* (021).	*q* (011).	*m* (110).	*o* (111).
ϕ	0° 0′	45° 11′	*63° 29′	*27° 24′	68° 21′
ρ	90° 0′	90° 0′	90° 0′	*29° 47′	54° 5′

CCXIV.—*The Influence of the Sulphur Atom on the Reactivity of Adjacent Atoms or Groups. Part II. Comparative Reactivities of Chlorine in some β- and γ-Chloro-sulphides.*

By GEORGE MACDONALD BENNETT and WILLIAM AMBLER BERRY.

IN Part I of this series (this vol., p. 477), a qualitative comparison was made of the reactivities of the chlorine atoms in the β-, γ-, and δ-positions relative to a sulphur atom. In the present communication, we describe quantitative measurements of the reactivities of the chlorine atoms in some β- and γ-chloro-sulphides, namely, in the *o*-, *m*-, and *p*-nitrophenyl β-chloroethyl sulphides, *p*-nitrobenzyl β-chloroethyl sulphide, and *p*-nitrophenyl γ-chloropropyl sulphide, described in the preceding paper, together with the unsubstituted phenyl β-chloroethyl- and γ-chloropropyl-sulphides.

Comparative measurements were first made of the extent of their interaction with aqueous alcoholic sodium hydroxide solution during a short interval of time at 55°. With respect to this test, the substances arrange themselves in order of diminishing reactivity as follows: *o*- and *p*-nitrophenyl β-chloroethyl sulphide>*m*-isomeride≫phenyl β-chloroethyl sulphide>phenyl γ-chloropropyl sulphide and its *p*-nitro-derivative.

The nitrobenzyl sulphide suffered some profound decomposition in presence of alkali, doubtless owing to the activation of the methylene group situated between the sulphur atom and the nucleus. No attempt was made to calculate a velocity coefficient for this reaction, since from analogy with the behaviour of other chloro-sulphides (compare Bales and Nickelson, J., 1922, **121**, 2137) it is probable that two reactions are involved, namely, a true hydrolysis

to the corresponding hydroxy-compound and the formation of an unsaturated sulphide by removal of one molecular proportion of hydrogen chloride. The result does, however, show that, in agreement with the conclusions previously reached concerning β- and γ-chloro-sulphides (Bennett and Hock, J., 1925, **127**, 2671; this vol., p. 477), the γ-chloropropyl sulphide is in each case less reactive than the closely related β-chloroethyl compound.

In order to obtain a more accurate comparison of the reactivities of these substances we examined their hydrolysis by 50% aqueous alcohol at 75°, a reaction similar to that used by Olivier for a similar purpose (*Rec. trav. chim.*, 1922, **41**, 646) and likely to be free from the defect of subsidiary reactions. We have therefore made a comparison of the initial velocities of hydrolysis; the results are in column 4 of Table I.

The reaction of the chloro-sulphides with piperidine was also examined with a view to quantitative measurement, but it was discarded when the product of the reaction was found to be a mixture. Finally, we also examined the reaction of these substances with potassium iodide, since this had been found to be quantitative and free from subsidiary reactions in the preparation of the β-iodo-sulphides (see preceding paper). Similar reactions have, moreover, been studied by Conant and his colleagues (Conant, Kirner, and Hussey, *J. Amer. Chem. Soc.*, 1925, **47**, 488) and found suitable for accurate measurement. The velocities of reaction of these chloro-sulphides have been measured in acetone solution at 55°. The method of determining ionic iodine described by these authors was found to be unsuitable and a modified procedure was worked out. The reaction was in all cases bimolecular and the coefficients are given in Table I.

TABLE I.

	Reaction with potassium iodide at 55°.		Hydrolysis at 75°.
Substance.	k.	Relative values.	Relative values.
$Ph{\cdot}S{\cdot}C_2H_4Cl$	0·091	1·00	1·00
$o\text{-}NO_2{\cdot}C_6H_4{\cdot}S{\cdot}C_2H_4Cl$	0·180	1·98	0·023
$m\text{-}NO_2{\cdot}C_6H_4{\cdot}S{\cdot}C_2H_4Cl$	0·189	2·09	0·083
$p\text{-}NO_2{\cdot}C_6H_4{\cdot}S{\cdot}C_2H_4Cl$	0·257	2·62	0·052
$p\text{-}NO_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}S{\cdot}C_2H_4Cl$	0·215	2·36	—
$Ph{\cdot}S{\cdot}C_3H_6Cl$	0·330	3·52	0·0031
$p\text{-}NO_2{\cdot}C_6H_4{\cdot}S{\cdot}C_3H_6Cl$	0·836	9·19	0·0010

Interpretation of the Results.

The substances are arranged with respect to the hydrolysis in an order which is the opposite of that shown in the reaction with potassium iodide. This contrast must depend on the nature and

mechanism of the two reactions used. It may be explained if the reactions involved are of opposite polar type. A similar contradiction was pointed out by Conant, Kirner, and Hussey (*loc. cit.*), who remark with reference to certain chloro-compounds that the increased reactivity with potassium iodide " appears to be just the reverse of what would be predicted from a consideration of polarity." A consideration of the influence of certain activating groups "would," they point out, " lead to the conclusion that the chlorine atom of $Ph{\cdot}CO{\cdot}CH_2Cl$ was more *positive* than the chlorine atom of benzyl chloride: yet it is 500 times more reactive in a reaction in which the chlorine is *eliminated as a negative ion* and is *replaced by a negative ion*. . . . It seems evident that no adequate interpretation of the facts can be stated solely in terms of polarity." This difficulty is in reality the same as that presented by our own opposed sets of reaction velocities. A further clear case of the same kind is shown in Table II, which gives the results of the comparison of benzyl chloride and its nitro-compounds as determined by hydrolysis (Olivier, *loc. cit.*) and by the potassium iodide reaction (Conant and others).

TABLE II.

Substance.	Relative reactivity with KI at 50°.	Relative reactivity with water at 30°.
$Ph{\cdot}CH_2Cl$	1	1
o-$NO_2{\cdot}C_6H_4{\cdot}CH_2Cl$	9·15	0·047
m-$NO_2{\cdot}C_6H_4{\cdot}CH_2Cl$	3·96	0·057
p-$NO_2{\cdot}C_6H_4{\cdot}CH_2Cl$	6·95	0·044

All these anomalies disappear if it be admitted that, whilst a negative charge on the chlorine atom accelerates the hydrolysis (compare Oxford and Robinson, J., 1926, 384), it is a positive charge on the chlorine atom that makes it react more rapidly with potassium iodide. This will be the case if, as we suggest, the latter reaction involves two stages, the first of which is the formation of a complex between the organic chloro-compound and the iodide ion. In the second stage, the neutral organic iodo-compound is formed by the ejection of a chlorine ion from the complex. The first stage of the reaction will proceed at a higher velocity the greater the *positive* charge on the chlorine atom, since this will favour combination with the negative iodine ion. On this assumption, our two sets of data become consistent among themselves, and with the electron distribution deduced for β- and γ-chloro-sulphides in Part I of the series. The reaction velocities observed for $Ph{\cdot}S{\cdot}C_2H_4Cl$ and $Ph{\cdot}S{\cdot}C_3H_6Cl$ lie respectively below and above that found by Conant and his colleagues for $Ph(CH_2)_4Cl$, namely, 0·211.* This confirms

* This value has been obtained from their figure by use of their interpolation formula and multiplication by 2·302.

the suggestion made in Part I that actually the chlorine atom in the β-position is negatively, and in the γ-position positively, charged as compared with the normal.

Kirner (*J. Amer. Chem. Soc.*, 1926, **48**, 2745) has recently found three ethers to have reactivities in the order $PhO{\cdot}C_2H_4Cl < PhO{\cdot}C_3H_6Cl > PhO{\cdot}C_4H_8Cl$, with respect to the potassium iodide reaction. The influence of an atom of oxygen and one of sulphur in a molecule should be similar, if similarly situated, so that this result is in qualitative agreement with the conclusion arrived at in Part I that chlorine varies in reactivity (to hydrolysis) with position relative to sulphur in the order : $\beta > \gamma < \delta$.

The introduction of a nitro-group into the nucleus of any of these compounds—chloro-sulphides or benzyl chlorides—gives a positive charge to the chlorine atom and so alters the velocities of the two reactions discussed in the directions observed. No large difference of effect was found with orientation of the nitro-group in the *o*-, *m*-, and *p*-positions in the sulphides, which is consistent with the conclusion of Oxford and Robinson (*loc. cit.*) that " the alternating effect of a nitro-group cannot be discerned beyond the limits of the conjugated system of which it forms a part." In the case of the reaction with aqueous alcoholic sodium hydroxide, the introduction of the nitro-group actually increases the reactivity in the β-chloro-sulphides. Since in the true hydrolysis the converse effect is observed, the increase must be due to the subsidiary reaction involving the elimination of hydrogen chloride.

Experimental.

Preparation of β-Hydroxyethyl and γ-Hydroxypropyl Phenyl Sulphides.—These compounds were obtained by the condensation of sodium thiophenoxide and the respective chlorohydrins : The thiophenol (15 g.), a solution of sodium hydroxide (6 g. in 100 c.c. of water), and ethylene chlorohydrin (12 c.c., or 15 c.c. of trimethylene chlorohydrin in the case of the propyl compound) were mixed and heated to about 60°. When the solution had become neutral to litmus, 20 c.c. of *N*-sodium hydroxide and 4 c.c. of the chlorohydrin were added and the mixture was heated for a further 15 minutes. The precipitated oil was removed in ether.

An attempt to distil phenyl β-hydroxyethyl sulphide under diminished pressure gave an unsaturated compound, probably due to the splitting out of water from the side chain giving rise to phenyl vinyl sulphide. The preparation of the chloroethyl sulphide was therefore carried out with the crude hydroxy-compound by means of the Darzens reaction (preceding paper, p. 1671). The products were removed by ether extraction.

Phenyl β-chloroethyl sulphide is a colourless liquid with a rather pungent smell and a very slight vesicant action; b. p. 117°/12 mm. (Found: Cl, 20·4. Calc.: Cl, 20·55%). *Phenyl γ-chloropropyl sulphide* is a colourless liquid and is not appreciably vesicant; b. p. 137°/13 mm. (Found: Cl, 18·8. $C_9H_{11}ClS$ requires Cl, 19·0%).

Reaction of the Chloro-sulphides with Piperidine.—This reaction was investigated with a view to employ it as a means of determining the relative reactivities of the chloro-compounds.

o-Nitrophenyl β-chloroethyl sulphide (1 g.) was boiled under reflux for 8 hours with piperidine (1·2 g.) and alcohol (10 c.c.). The mixture was then made slightly alkaline and distilled in steam to remove the alcohol and excess of piperidine. The remaining oil was dissolved in ether, and the solution dried. On passing dry hydrogen chloride into the ethereal solution, a precipitate was formed (0·7 g.), m. p. 231°. This compound was soluble in water and the addition of sodium hydroxide caused the precipitation of an oil, which solidified to give pale yellow crystals, m. p. 45°, of *o-nitrophenyl β-piperidinoethyl sulphide* (Found: N, 10·7. $C_{13}H_{18}O_2N_2S$ requires N, 10·5%). The compound precipitated from the ethereal solution was therefore the hydrochloride of this base.

Evaporation of the remaining ethereal solution gave a dark oil which did not crystallise. It gave a negative result with a test for chlorine, but its reaction with potassium permanganate as compared with that of the original chloro-sulphide indicated the presence of an unsaturated group. It was therefore probably *o*-nitrophenyl vinyl sulphide.

Further experiments with only one equivalent of piperidine did not give improved yields of the hydrochloride.

p-Nitrophenyl β-chloroethyl sulphide, when subjected to the same reaction, also gave similar products, namely, a base and an unsaturated compound. The hydrochloride had m. p. 217° and the free base, *p-nitrophenyl β-piperidinoethyl sulphide*, melted at 52°.

Reaction of the Chloro-sulphides with Alcoholic Sodium Hydroxide.—A comparison of the reactivities of the chloro-sulphides with alcoholic sodium hydroxide was made in the following way: The chloro-sulphide (0·001 mol.) was weighed into a test-tube, 5 c.c. of absolute alcohol were pipetted on to it, and the mixture was gently warmed to bring the organic matter into solution. *N*/5-Sodium hydroxide (5 c.c.) was added, and the tube was stoppered and immediately immersed in a thermostat. After a definite period of time, the contents of the tube were washed out and titrated with standard hydrochloric acid.

The following table summarises the results :

Compound.	Temp.	Time (hrs.).	Titration of reaction mixture (c.c. of 0·1*N*-HCl).	Amount of NaOH (expressed as c.c. of acid).
o-$NO_2 \cdot C_6H_4 \cdot S \cdot C_2H_4Cl$	55°	0·5	1·87	8·13
m-$NO_2 \cdot C_6H_4 \cdot S \cdot C_2H_4Cl$	55	0·5	2·87	7·13
p-$NO_2 \cdot C_6H_4 \cdot S \cdot C_2H_4Cl$	55	0·5	1·75	8·25
$Ph \cdot S \cdot C_2H_4Cl$	55	2·0	7·16	2·84
$Ph \cdot S \cdot C_3H_6Cl$	55	2·0	9·24	0·76
p-$NO_2 \cdot C_6H_4 \cdot S \cdot C_3H_6Cl$	55	2·0	9·22	0·78

Some experiments were also conducted at 42° :

p-$NO_2 \cdot C_6H_4 \cdot S \cdot C_2H_4Cl$	42°	0·5	4·00	6·00
$Ph \cdot S \cdot C_2H_4Cl$	,,	,,	9·55	0·45
p-$NO_2 \cdot C_6H_4 \cdot S \cdot C_3H_6Cl$	,,	,,	9·80	0·20
$Ph \cdot S \cdot C_3H_6Cl$	,,	,,	9·75	0·25

When *p*-nitrobenzyl β-chloroethyl sulphide was subjected to this reaction, some other reaction than replacement of chlorine by hydroxyl took place, for a brown compound was produced along with a peculiar odour which was always present when an attempt to condense the sodium salt of *p*-nitrobenzyl mercaptan with ethylene chlorohydrin did not give the desired thioether. The hydroxy-compound is also decomposed by sodium hydroxide in a manner similar to that of the chloro-compound.

It follows that with respect to the reaction with sodium hydroxide in alcoholic solution, these compounds may be arranged as follows in descending order of reactivity: *p*-$NO_2 \cdot C_6H_4 \cdot S \cdot C_2H_4Cl$ > *o*-$NO_2 \cdot C_6H_4 \cdot S \cdot C_2H_4Cl$ > *m*-$NO_2 \cdot C_6H_4 \cdot S \cdot C_2H_4Cl$ > $Ph \cdot S \cdot C_2H_4Cl$ > $Ph \cdot S \cdot C_3H_6Cl$ and *p*-$NO_2 \cdot C_6H_4 \cdot S \cdot C_3H_6Cl$. The method used is not sufficiently accurate to enable a statement to be made as to which of the last two compounds is the more reactive.

Hydrolysis of the Chloro-sulphides.—The chloro-sulphide (0·001 g.-mol.) was dissolved in alcohol (25 c.c.), and the solution placed in a thermostat at 75° for several minutes. Water (25 c.c.) which had been immersed in the thermostat was then added, the time noted, and the reaction flask stoppered. After a definite time interval, the contents of the flask were cooled, diluted with water, and titrated with standard sodium hydroxide solution.

From this titration value, the proportion of hydrolysis (x) was calculated, and values for the relative reactivities were obtained from the expression

$$\text{Relative reactivity} = t_1 \log \{1/(1 - x_2)\}/t_2 \log \{1/(1 - x_1)\},$$

t_1 and x_1 being the values found for $Ph \cdot S \cdot C_2H_4Cl$.

The following table summarises the results :—

Substance.	x.	Time (mins.).	Rel. reactivity.
$Ph{\cdot}S{\cdot}C_2H_4Cl$	0·748	15	1·0
$o\text{-}NO_2{\cdot}C_6H_4{\cdot}S{\cdot}C_2H_4Cl$	0·243	130	0·023
$m\text{-}NO_2{\cdot}C_6H_4{\cdot}S{\cdot}C_2H_4Cl$	0·628	130	0·083
$p\text{-}NO_2{\cdot}C_6H_4{\cdot}S{\cdot}C_2H_4Cl$	0·460	130	0·052
$Ph{\cdot}S{\cdot}C_3H_6Cl$	0·081	300	0·003
$p\text{-}NO_2{\cdot}C_6H_4{\cdot}S{\cdot}C_3H_6Cl$	0·027	300	0·0010

This order of relative reactivities was confirmed in two further sets of experiments.

p-Nitrobenzyl β-chloroethyl sulphide is omitted from the above list, since the product of its hydrolysis was undoubtedly a mixture. After the hydrolysis of *p*-nitrophenyl β-chloroethyl sulphide, the corresponding hydroxy-compound crystallised from the reaction mixture. *p*-Nitrobenzyl β-chloroethyl sulphide, however, yielded an oily product which did not crystallise even on inoculation with a crystal of the pure hydroxy-compound. An unsaturated impurity was found to be present.

Reaction of the Chloro-sulphides with Potassium Iodide.—This reaction was applied under conditions similar to those used by Conant and others (*loc. cit.*), namely, the initial concentrations of the organic chloro-compound and the potassium iodide were in the ratio 5 : 1, the iodide concentration being approximately 0·04*N*. Absolute acetone, purified as described by Conant and Kirner (*J. Amer. Chem. Soc.*, 1924, **46**, 233), was used as solvent.

Andrews's method for estimation of iodide in presence of chloride (*J. Amer. Chem. Soc.*, 1903, **25**, 756), as used by Conant and others, was found to be unsatisfactory in the present investigation, owing to reaction between the iodic acid and the organic sulphide in the chloroform used for indicator. Even after removal of the organic compound, the end-point with chloroform as indicator was not well defined, and starch could not be used owing to the great acidity of the solution.

A convenient method in which starch can be used as indicator was found in that described by Lang (*Z. anorg. Chem.*, 1922, **122**, 332), depending on the addition of an oxidising agent (*e.g.*, potassium iodate) to an acid solution of an iodide in presence of hydrogen cyanide. The iodine is converted quantitatively into iodine cyanide, which does not colour starch. As the acidity of the solution is approximately normal (when hydrochloric acid is used), starch can be used as indicator. Acetone in the titration flask causes a temporary fading of the blue starch–iodide colour when near the end-point, *e.g.*, a further drop of iodate solution regenerates the blue colour, which then fades again on standing: this occurs until the true end-point is reached, after which addition of iodate no longer causes an evanescent blue colour. Thus, although the

acetone does not affect the value for the end-point, its presence makes the determination difficult. The acetone was therefore removed by passing a current of steam through the solution before titrating it.

The experimental procedure adopted in these measurements was as follows: 50 C.c. of 0·04*N*-potassium iodide (in the pure acetone) were added to 0·01 g.-mol. of the organic halide contained in a conical flask. The organic compound dissolved rapidly and as soon as it was thoroughly mixed, 5 c.c. of the mixture were pipetted into a separating funnel containing 20 c.c. of water. This precipitated the organic halide and prevented any reaction: in the estimation as subsequently described, this reading gave the blank for calculating the concentration of the potassium iodide in the reaction and also the value for A_0 in the formula (below). 5 C.c. lots of the mixture were pipetted into each of a series of nine tubes (made of stout glass tubing, about 6 in. long and 0·5 in. inside diameter) which were then sealed up in the blow-pipe flame. These tubes were placed in a thermostat at 55·0°.

After about 30 minutes, one of the tubes was removed and opened and the contents were washed into water (10 c.c.). The time was noted and this was counted as the zero time of the readings. The whole was then extracted with chloroform (four portions of 5 c.c.), the chloroform extracts being washed with water (10 c.c.) to recover any potassium iodide solution which may have been removed mechanically in the chloroform. This aqueous washing of the chloroform was finally extracted with 5 c.c. of chloroform. The aqueous solution was then distilled in steam for 3 minutes to remove the chloroform and acetone, a splash-bulb being used to prevent any loss. The mixture, which then had a bulk of about 70 c.c., was cooled and concentrated hydrochloric acid (15 c.c.) and potassium cyanide solution (8 c.c. of $N/2$) were added. It was titrated against 0·003*M*-potassium iodate solution, starch being used as indicator.

At definite time intervals, tubes were removed from the thermostat and worked up as indicated above. The velocity coefficient was calculated from the bimolecular formula

$$k = \frac{2{\cdot}302}{4b(t_2 - t_1)} \log_{10} \frac{(4A_0 + A_2)A_1}{(4A_0 + A_1)A_2},$$

where A_0 = blank titration value at the commencement of reaction, A_1 = titration value at time t_1, A_2 = titration value at time t_2, and b = the concentration of potassium iodide in the reaction (calc. from A_0), time being measured in hours and the concentrations in g.-mol. per litre.

Except in one instance, the greatest percentage variation among the values for k in a series of measurements is less than 10%, which

is satisfactory in view of the necessarily complicated experimental procedure.

o-*Nitrophenyl* β-*Chloroethyl Sulphide.*—0·01 G.-mol. mixed with 50 c.c. of 0·04*N*-potassium iodide in pure acetone. Temperature of thermostat 55·0°. The titrations (*A*) are expressed as c.c. of 0·003*M*-potassium iodate.

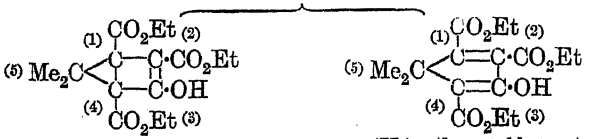
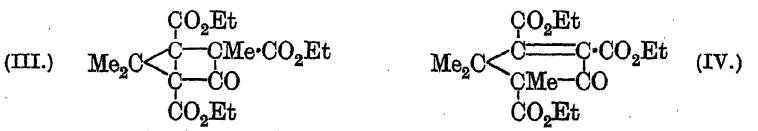
We wish to thank the Chemical Society for assistance in the purchase of materials, and the Department of Industrial and Scientific Research for a maintenance grant which has enabled one of us (W. A. B.) to take part in the work described in this and the preceding paper.



THE UNIVERSITY, SHEFFIELD. [*Received, April 8th*, 1927.]

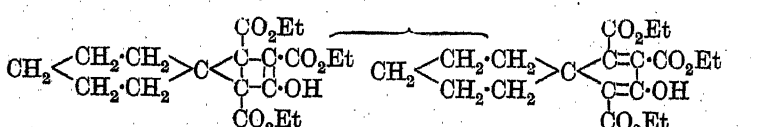
CCXV.—*The Chemistry of Polycyclic Structures in Relation to their Homocyclic Unsaturated Isomerides. Part VIII. The Differing Effects of the* gem-*Dimethyl and* spirocyclo*Hexane Groupings on the Direction of Blocking of an Intra-annular Tautomeric System by Substitution.*

By CHRISTOPHER KELK INGOLD and ERNEST ARTHUR SEELEY.



IN Parts I and II (Farmer and Ingold, J., 1920, **117**, 1362; Farmer, Ingold, and Thorpe, J., 1922, **121**, 128) proof was adduced that the bridged-ring ester (I), first prepared by Perkin and Thorpe (J.,

1901, **79**, 729), behaved as though it also had the structure (II), and that its derivatives and hydrolysis products exhibited similar evidence of tautomeric behaviour.

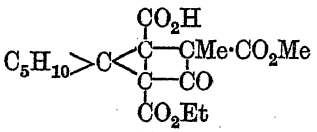


(I.) (*more stable type*) (II.) (*less stable type*)

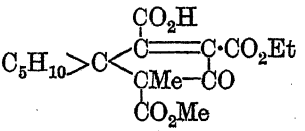
It then became of interest to ascertain which of the two types of structure would be perpetuated when substitution converted the tautomeric parent into a static derivative. Thus the sodio-derivative of the above hydroxy-ester might methylate on carbon in position 2 through form (I) or in position 4 through form (II), giving, in the first case, a stable bridged ring, and, in the second, a stable monocyclic derivative. This question was answered in Part V (J., 1923, **123**, 3303) where it was shown that the static methyl derivative possessed the bridged constitution (III) and not the monocyclic structure (IV):

(*static*; *formed*)

Part IV (J., 1923, **123**, 853) recorded an investigation of the derivatives of a hydroxy-ester (V, VI) analogous to (I, II) but containing a *spirocyclo*hexane ring in place of the *gem*-dialkyl group. Ingold and Thorpe (J., 1919, **115**, 320) had adduced theoretical reasons for believing that the bridged structure in type (V) would be less stable than that in type (I); and it was subsequently found (Part IV, *loc. cit.*) that the reactions indicating the *cyclo*pentene phase are actually more pronounced, and those indicating the bridged phase less pronounced, in the *cyclo*hexane than in the *gem*-dimethyl series.



(V.) (*less stable form*) (VI.) (*more stable form*)

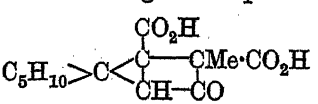


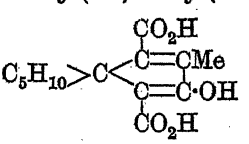
It therefore seemed possible that the blocking of the mobile intra-annular system by methylation might occur through the unbridged form in the *cyclo*hexane series, the methyl group entering

in position 4, in contrast to the established course of the reaction in the *gem*-dimethyl series.

When the methylation product obtained from the sodio-derivative of the *spirocyclo*hexane ester (V, VI) is boiled with hydrochloric acid, a solid acid ester is obtained which may be formulated either as (VII) or as (VIII) according as the methyl group occupies position 2 or 4.

(VII.)

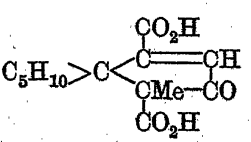




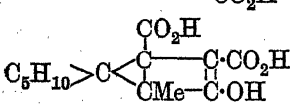
(VIII.) (*static*; *formed*)

These formulæ assume that one of the carbethoxyl groups has been converted into a carbomethoxyl group during methylation; a partial conversion of this nature was established by Ingold and Thorpe (*loc. cit.*) and similar interchanges have frequently been recorded. The position given to the free carboxyl group is tentatively assigned on the grounds that the acid ester does not evolve carbon dioxide at its melting point. Any doubt which might be entertained on these points does not affect the substance of this argument. Either type of formula necessarily represents the acid ester as a substance in which intra-annular tautomerism has been suspended by substitution.

Hydrolysis of the acid ester with alcoholic potassium hydroxide leads to the production of a dibasic acid, $C_{13}H_{16}O_5$, the properties of which determine the position of the methyl group. The possible constitutions of an acid of this composition derived from an acid ester having formula (VII) are given by formulæ (IX) and (X); on the other hand, if the acid ester possessed the structure (VIII), the dibasic acid might be represented either by (XI) or by (XII).

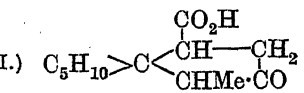


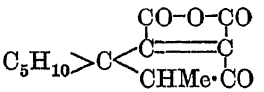
(IX.)



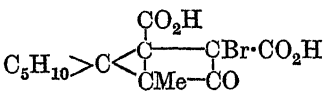
(X.)

(XI.)





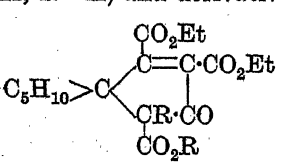
(XII.)



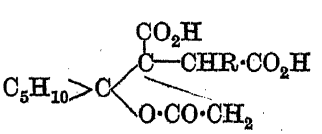
Of these four formulæ, (XII) alone is consistent with the following properties of the isolated acid: (*a*) It gives a deep violet colour with ferric chloride, and is therefore a β-hydroxyacrylic acid. (*b*) It readily yields a stable cyclic anhydride, from which the original acid can be recovered after fission of the anhydride ring

with hot alkali. (*c*) On treatment with a cold dilute solution of bromine in acetic acid, the dibasic acid undergoes nuclear substitution, one atom of hydrogen being replaced (compare Part IV, *loc. cit.*, pp. 857—862).

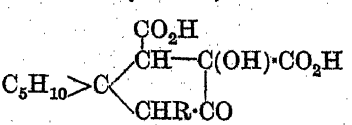
Formula (XII) connotes, of course, only one of the possible intra-annular tautomeric forms possessed by the dibasic acid $C_{13}H_{16}O_5$, and we regard formulæ (XIV) and (XV) as representing the most probable constitutions of its anhydride and bromo-derivative, respectively.



(XIII.) 



(XIV.)



(XV.)

These observations show that the static methylation product (VIII) has a formula of the type assigned to it, the tautomerism of the *spirocyclo*hexane five-carbon nucleus having been suppressed by methylation in a direction conforming to the general chemical differences between this series and the corresponding *gem*-dimethyl series of intra-annular tautomeric compounds.

These experiments necessitate a revision of the structures which Ingold and Thorpe (*loc. cit.*) assigned to certain derivatives of the mobile ester (V, VI) before the intra-annular tautomerism of the five-carbon nucleus was discovered. Thus the ester was assumed to methylate in position 2 by analogy with the methylation of the *gem*-dimethyl ester (I, II). The formula now suggested for the methylated product is XVI (R=Me), the probable structures of the fission products, m. p.'s 172° and 185°, being represented by XVII and XVIII (R=Me). Corresponding changes are necessary in the structures of the homologues (XVI, R=Et; XVII, R=Et; XVIII, R=H) and derivatives:

(XVI.) {R = Me, oil. R = Et, oil.

(XVII.) {R = Me, m. p. 172°. R = Et, m. p. 149°.

(XVIII.) {R = Me, m. p. 185°. R = H, m. p. 206°.

EXPERIMENTAL.

Methyl Ethyl Hydrogen 4-*Methyl*-5-cyclo*hexane*spiro-Δ^1-cyclo*pentan*-3-*one*-1 : 2 : 4-*tricarboxylate* (VIII).—The yellow sodio-derivative (20 g.) of ethyl 5-*cyclo*hexane*spirodicyclo*penten-3-ol-1 : 2 : 4-tricarboxylate was heated with a large excess of methyl iodide as described by Ingold and Thorpe (*loc. cit.*), and the crude methylation product (19 g.) was boiled for 12 hours with 20% hydrochloric acid. On extraction with ether a stiff gum was obtained which solidified after 2 months; the *acid ester* was then crystallised from ether–ligroin. It separated in prisms, m. p. 92—93° (Found: C, 60·9, 61·0; H, 6·7, 6·8; *M*, by titration, 339. $C_{17}H_{22}O_7$ requires C, 60·4; H, 6·6%; *M*, monobasic, 338).

4-*Methyl*-5-cyclo*hexane*spiro-(0 : 1 : 2)-dicyclo*penten*-3-*ol*-1 : 2-*dicarboxylic Acid* [4-*Methyl*-5-cyclo*hexane*spiro-(0 : 1 : 2)-dicyclo*pentan*-3-*one*-1 : 2-*dicarboxylic Acid*] (XII).—The above acid ester was boiled with 2·2 parts of potassium hydroxide in 4*N*-solution in absolute methyl alcohol, and after 6 hours the precipitate was collected, dissolved in water, and decomposed by dilute hydrochloric acid (carbon dioxide was evolved). The aqueous solution was extracted thoroughly with ether, and the *acid* thus recovered was crystallised first from ether–ligroin and then from ether (Found: C, 61·8; H, 6·4; *M*, by titration, 126·3. $C_{13}H_{16}O_5$ requires C, 61·8; H, 6·4%; *M*, dibasic, 126·1).

The acid has m. p. 214—216°, and with an aqueous alcoholic solution of ferric chloride gives an intense violet coloration which after several minutes is replaced by a yellowish-brown precipitate. A dilute solution of permanganate was decolorised in about 1 minute. Oxidations with permanganate and with ferricyanide were tried on a larger scale under various conditions, but the products could not be crystallised.

The Anhydride (XIV).—The acid (0·4 g.) was heated for 20 minutes with 6 c.c. of acetyl chloride at 100°, and the residue obtained on evaporation was rubbed with aqueous sodium hydrogen carbonate and dried on porous porcelain. Subsequent treatment indicated the presence of a small amount of unchanged acid, which was difficult to remove by crystallisation, and the product was therefore again treated with acetyl chloride and the residue crystallised twice from ether–ligroin; large, pale green prisms, m. p. 95°, were then obtained (Found by microanalysis: C, 65·9, 66·3; H, 6·0, 6·6. $C_{13}H_{14}O_4$ requires C, 66·6; H, 6·0%). The green colour of this substance, which is absent from the acid, is similar to that of ketomalonic ester, which also contains a cross-conjugated system. The anhydride is affected only very slowly by boiling water, but is

hydrolysed by hot aqueous sodium hydroxide, yielding the sodium salt of the original acid, m. p. 214—216° (mixed m. p. the same). A solution of the anhydride in ether–ligroin gives precipitates with *p*-toluidine and *p*-chloroaniline which are soluble with effervescence in sodium hydrogen carbonate and are therefore presumably the substituted amic acids. The anhydride does not give a colour with ferric chloride, but rapidly decolorises permanganate.

The methyl-alcoholic filtrate from the potassium salt of the dibasic acid, on being worked up for organic acids, yielded a considerable amount of gum together with a small amount of a solid acid, which, after several crystallisations from benzene, had m. p. 102—105°, but still did not appear quite pure. The investigation of this had to be discontinued for lack of material.

2-*Bromo*-4-*methyl*-5-cyclo*hexane*spiro-(0 : 1 : 2)-dicyclo*pentan*-3-*one*-1 : 2-*dicarboxylic Acid* (XV).—The above dibasic acid (0·37 g.), dissolved in 10 c.c. of glacial acetic acid, was treated with 3 c.c. of a 10% solution of bromine in acetic acid (theory, 2·4 c.c.). After 4 hours, the bromine was nearly decolorised. On concentration of the acetic acid solution at the ordinary temperature, the *bromo-acid* readily crystallised. It separated from ether–benzene in small prisms, m. p. 197—198° (Found: Br, 23·6. $C_{13}H_{15}O_5Br$ requires Br, 24·1%).

4-*Methyl*-5-cyclo*hexane*spirocyclo*pentan*-3-*one*-1-*carboxylic Acid* (XIII).—The acid ester (VIII) was heated for 3 hours at 135—150° with constant-boiling hydriodic acid. The liquid was extracted with ether, and the iodine removed from the extract with aqueous sodium hydrogen sulphite. The product obtained on evaporation of the ether contained sulphur, but this was readily eliminated by crystallisation from ether–ligroin, which yielded the pure monobasic acid, m. p. 114—116° (Found: C, 68·4; H, 8·6. $C_{12}H_{18}O_3$ requires C, 68·5; H, 8·6%).

The *semicarbazone*, prepared from the acid, semicarbazide hydrochloride, and aqueous sodium acetate, has m. p. 223° (Found: C, 58·6; H, 8·2. $C_{13}H_{21}O_3N_3$ requires C, 58·8; H, 7·9%).

Gums which cannot be crystallised were obtained on attempting to oxidise this ketonic acid with permanganate and ferricyanide at 20—60°.

We desire to thank the Chemical Society for defraying part of the cost of this investigation.

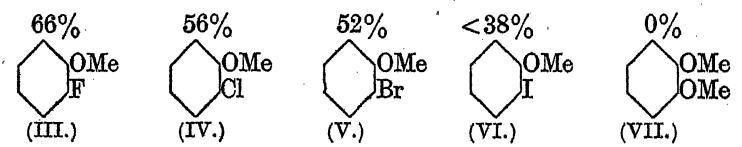
[*Received, May 11th,* 1927.]

CCXVI.—*The Nature of the Alternating Effect in Carbon Chains. Part XX. The Conditions underlying Vicinal Substitution in* o-*Substituted Benzenes containing* op-*Orienting Groups.*

By CHRISTOPHER KELK INGOLD and ERNEST WALTER SMITH.

IN Part V it was shown (Ingold and Ingold, J., 1926, 1310) that whilst acet-*o*-anisidine (I) and aceto-*N*-methyl-*o*-anisidine are nitrated mainly in the 4- and 5-positions, *ON*-diacetyl-*o*-aminophenol (II), in which the disparity between the *op*-orienting powers of the groups is much greater, yields a large proportion of a vicinal nitro-derivative:



The nitration of *o*-fluoroanisole which was recorded in Part VI (*ibid.*, p. 1328) provided a still more striking example (III) of vicinal substitution in a nucleus *o*-disubstituted with *op*-orienting groups, and in Part VII (*ibid.*, p. 1685) the hypothesis was advanced that, in general, the proportion of *v*-substitution is a function of the disparity between the polar activities of the groups. It was suggested, as a possible explanation, that in an unbalanced system in which the reaction phases are determined almost wholly by one group, the second group may regulate the relative importance of these by controlling the displacement of valency-electrons past the points more directly under its influence.

An opportunity for testing this matter appeared to be provided by the recorded observations on the substitution of the halogen derivatives of benzene. Thus the experiments of Holleman (*Rec. trav. chim.*, 1915, **34**, 204) and Swarts (*ibid.*, **35**, 131) on the nitration of *o*- and *p*-dihalogenobenzenes indicate the sequence F<Cl,Br<I for the *op*-directive powers of the halogens; and although (owing to the mutual interference of the groups) caution is necessary in generalising from such observations when the directive powers of the groups are close together (as with Cl and Br), the complete sequence F<Cl<Br<I is indirectly confirmed by the regular gradation of the nuclear reactivity of the monohalogenobenzenes (Olivier, *ibid.*, 1914, **33**, 244; and unpublished observations by Miss F. R. Shaw), and of the dipole moment of comparable mono- and di-halogeno-derivatives (Höjendahl, *Nature*, 1926, **117**, 896; Errera, *Compt. rend.*, 1926, **182**, 1623).

The methoxyl group is more strongly *op*-orienting even than iodine (see below), and hence the above sequence can be expanded to F<Cl<Br<I<OMe. Therefore, if the circumstances regulating vicinal substitution have been correctly conceived, the successive introduction of these groups into the *o*-position of anisole should produce a series of substances which, taken in order, should show diminishing *v*-substitution. Since the proportion of *v*-nitration of *o*-fluoroanisole has been shown to be 66% (Part VI),* whilst that of veratrole (VII) is 0%, the other *o*-halogenoanisoles should fall into their places between these limits.

No support for this deduction was forthcoming from the literature. The nitration of *o*-chloroanisole has been investigated successively by Fischli (*Ber.*, 1878, **11**, 1463), Reverdin (*Ber.*, 1896, **29**, 2598), and Reverdin and Eckhard (*Ber.*, 1899, **32**, 2622), all of whom describe the 4-nitro-derivative, but none mentions the formation of any by-product. Reverdin also nitrated *o*-bromoanisole (*loc. cit.*) and *o*-iodoanisole (*ibid.*, p. 997), but in neither case observed the formation of any isomeride of the 4-nitro-compound. We therefore re-investigated the nitration of all these substances, and are able to show that the 6-nitro-compounds also are formed, and that the proportions of vicinal substitution fit into the series as is shown in the following formulæ (IV, V, VI):

(III.) (IV.) (V.) (VI.) (VII.)

Since the total proportions of the 3- and 5-isomerides oriented by the halogen atoms are only of the order of 2—3% (see experimental portion), the diminishing vicinal substitution in the above series is accompanied by a closely corresponding increase in substitution para to the methoxyl group.

Experimental.

Nitration of o-*Chloroanisole.*—A cooled solution of 3·1 g. of nitric acid (*d* 1·5) in acetic anhydride (12 c.c.) was very slowly added to a solution of *o*-chloroanisole (10 g.) in acetic anhydride (40 c.c.), which was cooled in ice and mechanically stirred. When the addition was complete, the solution was allowed to warm to the laboratory temperature and to remain thereat for several hours,

* A still more extreme case of *v*-substitution can be foreseen in *o*-fluoroacetanilide, which has not yet been investigated, but should yield slightly more than 66% of the 6-nitro-derivative under the conditions used in this investigation and in Part VI.

after which the solvent was removed by distillation under reduced pressure. Distillation of the product yielded 0·8 g. of unchanged *o*-chloroanisole, b. p. about 100°/13 mm. (Found: C, 56·5; H, 4·8. Calc.: C, 56·2; H, 4·9%), and 0·5 g. of undistillable residue, probably dinitro-derivatives, the whole of the remainder being a mixture of mononitro-derivatives (Found: C, 44·9; H, 3·2; N, 7·7. Calc.: C, 44·8; H, 3·2; N, 7·5%) having b. p. 125—165°, which is the b. p. range of an artificial mixture of 4- and 6-nitro-2-chloroanisoles (see below).

The mononitro-derivatives were boiled under reflux with 5% sodium hydroxide for 1 hour, preliminary experiments having shown that the labile isomerides (3- and 5-) are completely decomposed under these conditions and that the reagent is without action on the 4- and 6-nitro-compounds. The latter were extracted with ether, the aqueous solution was acidified with dilute nitric acid, and the nitroguaiacols were extracted with the same solvent. The chloride ion was then estimated either gravimetrically or volumetrically. The values in three separate nitrations were 1·64%, 1·61%, and 1·50%. The yield of mixed nitroguaiacols isolated by extraction with ether from the combined aqueous solutions obtained in the three experiments was equivalent to 1·4% of converted chloronitroanisoles, that is, the yield was 89% on the basis of the chloride estimations. Distillation in steam yielded a yellow solid which when crystallised from water gave a small amount of 3-nitroguaiacol, m. p. 61°, identified by direct comparison; and crystallisation of the original mixture yielded 5-nitroguaiacol, which was similarly identified.

The mixture of 4- and 6-nitro-compounds contained in the ethereal extract from the alkaline solution was analysed by the freezing-point method either directly or after distillation (b. p. as before), preliminary experiments having shown that operations corresponding with those described above do not affect the results obtained.

For the construction of the f. p. diagram, 2-chloro-4-nitroanisole (m. p. 95°) was prepared and purified as described by Reverdin. 2-Chloro-6-nitroanisole was obtained by Holleman (*Rec. trav. chim.*, 1915, **35**, 14) from 2 : 3-dichloronitrobenzene and sodium methoxide, but this method being unsuitable for the preparation of quantities sufficient for our purpose, the following process was evolved. *o*-Chlorophenol was added slowly to mechanically stirred, dilute nitric acid (1 : 3), and the mixture kept over-night at the ordinary temperature. The solid product was then collected, washed with water, and distilled in steam; from the distillate, bright yellow needles of 2-chloro-6-nitrophenol, m. p. 70° (softening at 65°),

separated. This was methylated with a large excess of methyl sulphate and dilute alkali by prolonged mechanical shaking at 40°. The product was collected, washed with sodium or ammonium hydroxide until colourless, and crystallised several times from aqueous alcohol; m. p. 56° (Found: C, 44·9; H, 3·4. Calc.: C, 44·8; H, 3·2%).

The freezing points were taken by the usual method in a double-jacketed tube, provided with arrangements for stirring and seeding, and surrounded by a water-bath, which was also stirred and kept at an approximately constant level well above the substance under examination. The rate at which the temperature was allowed to fall was always close to 0·3° per minute, and the maximal temperatures attained during freezing were accepted as valid readings provided that (*a*) the rise from the preceding minimum was close to 0·5°, (*b*) separation of solid with falling temperature but without total solidification did not take place. Temperatures were not corrected, but all were taken under the conditions mentioned on the same thermometer, which was graduated in fifths of a degree and could be read to tenths or less. The following values were obtained for mixtures of 2-chloro-4-nitroanisole and 2-chloro-6-nitroanisole:

2-Chloro-4-nitroanisole.	F. p.	2-Chloro-4-nitroanisole.	F. p.	2-Chloro-4-nitroanisole.	F. p.
100·0%	94·0°	66·3%	72·9°	30·1%	34·8°
91·7	89·3	61·0	71·0	28·9	37·9
86·5	86·6	56·9	67·5	26·2	39·9
82·5	84·0	53·2	64·7	24·0	41·1
78·9	81·9	47·1	58·0	20·0	43·0
76·6	80·0	42·8	52·6	16·5	44·6
73·9	79·0	38·1	47·0	13·0	47·0
72·1	77·5	34·3	42·0	8·3	48·8
68·4	76·0	31·8	38·5	0·0	53·3

These figures lie on a two-branch curve showing a eutectic, f. p. 34·8°, containing 30·1% of the 4-nitro-isomeride.

The f. p.'s of samples of mixed 4- and 6-nitro-compounds obtained in independent nitrations were 53·9° and 51·2°, which correspond with 43·2 and 41·3%, respectively, of the 4-nitro-derivative, since in each case the addition of small amounts of this compound raised the f. p. Another sample, f. p. 54·2°, corresponding with 43·8% of the 4-nitro-compound, on treatment with 22, 34, and 49% of its weight of the 6-nitro-derivative, had f. p.'s 44·7°, 40·8°, and 36·8°, respectively, which agree closely with the curve.

The most probable values of the proportions of the isomerides to the nearest unit % are therefore: 4-nitro, 42%; 6-nitro, 56%; 3- plus 5-nitro-, 2%.

The value for the 4-nitro-compound was confirmed by separation after the destruction of the 3- and 5-nitro-derivatives. The mixture

of the 4- and 6-nitro-compounds (10·00 g.) was fractionally crystallised from dilute alcohol, 32% of the pure 4-derivative being obtained. The combined residues had f. p. 46° on the branch of the f. p. curve in which the solid phase is the 6-nitro-isomeride. It follows that both isomerides can be qualitatively separated by crystallisation from dilute alcohol, followed by partial solidification of the fused residues. The above f. p. corresponds with 15% of the 4-nitro-compound, so that the quantity originally present was $32 + (0{\cdot}15 \times 68) = 42{\cdot}2\%$ of the binary mixture, that is, 41·6% of the original nitration product.

Nitration of o-*Bromoanisole.*—These experiments were so similar to the preceding series that only the more important differences need be mentioned.

Boiling with alkali for 4 hours was carried out to ensure complete destruction of the 3- and 5-nitro-compounds.

2-Bromo-6-nitrophenol, m. p. 65°, which was prepared in the same way as its chloro-analogue, could not be methylated conveniently with methyl sulphate, and was therefore converted into its silver salt, which was heated under reflux with a large excess of methyl iodide dissolved in benzene. Final purification was effected as in the case of the chloro-compound. M. p. 66°.

The whole of the f. p. curve of the 4- and 6-nitro-compounds was not plotted, but only a portion containing the f. p. of the nitration mixture on each branch and the eutectic. It was found convenient to allow a slightly higher rise of temperature on freezing, and 1·0° was the standard taken.

The results were as follows: The products from two independent nitrations yielded bromide ion corresponding with 2·70 and 2·67%, respectively, of the 3- plus 5-isomerides, and the yield of mixed nitroguaiacols was 85% calculated on this basis. The f. p. curve used for analysis of the mixture of the 4- and 6-nitro-compounds was based on the following f. p. observations:

2-Bromo-4-nitroanisole.	F. p.	2-Bromo-4-nitroanisole.	F. p.	2-Bromo-4-nitroanisole.	F. p.
0·0%	64·3°	23·7%	49·4°	36·9%	52·0°
7·1	59·6	25·2	47·1	42·2	56·2
13·3	55·7	27·3	46·8	43·4	57·5
17·7	52·8	29·7	46·8	45·8	60·0
20·2	50·9	32·2	48·3	50·5	65·0

The curve contains two rectilinear branches intersecting at 29% of the 4-nitro-compound, the corresponding f. p. being 45·5°. The binary mixtures obtained from two nitration experiments had f. p.'s 60·0° and 61·8°, indicating, respectively, 46·0 and 47·5% of the 4-nitro-derivative, since additions of small amounts of this isomeride to the first sample showed the f. p. to be on the corresponding

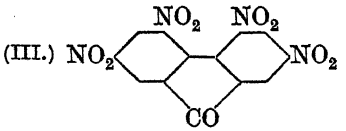
branch of the curve. The second sample was mixed with the exact quantity of the 6-nitro-isomeride calculated to change the composition to that of the eutectic. The f. p. was then 45·0° and the addition of further small quantities of the 6-nitro-compound raised this.

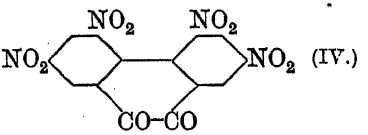
The most probable values of the proportions of the isomerides to the nearest unit % are therefore: 4-nitro-, 45%; 6-nitro-, 52%; 3- plus 5-nitro-, 3%.

Nitration of o-Iodoanisole.—*o*-Iodoanisole was nitrated in acetic anhydride solution (*a*) under the conditions used for the analogous chloro- and bromo-compounds, (*b*) at greater dilutions, (*c*) at a lower temperature, — 10° to — 5°. In each case, a small amount of iodine was liberated which afterwards became reabsorbed. For this reason, and also because it was not found possible selectively to destroy the 3- and 5-nitro-compounds by alkalis or bases (despite numerous exploratory experiments with *o*-iodonitrobenzene), we were unable to study the nitration product quantitatively. Reverdin (*loc. cit.*) isolated 60% of the 4-nitro-compound from his nitration product, and we therefore endeavoured to isolate as much as possible of this isomeride by his method. From the products of two independent nitrations we obtained 62% and 58%, respectively, of this isomeride, but the residues could not be separated.

THE UNIVERSITY, LEEDS. [*Received, May 11th*, 1927.]

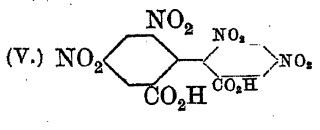
CCXVII.—*Investigations in the Diphenyl Series. Part VI. The Configuration of Diphenyl Derivatives.*

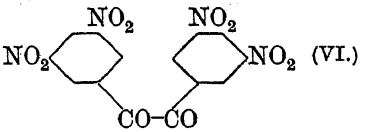




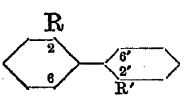
By FRANK BELL and PERCY HARRY ROBINSON.

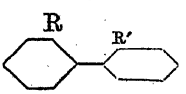
THE normal and the acid quinine salt of 4-nitrodiphenic acid can be crystallised without showing any sign of resolution. 6-Nitrodiphenic acid is readily resolvable, and the optical activity is apparently of a normal degree of permanence. This striking difference in behaviour of two such similarly constituted acids can be accounted for only by the assumption that the presence of the nitro-group in position 6 is essential to prevent the interchange





of the enantiomorphs (I) and (II). The fact that it has so far proved impossible to prepare tetranitrofluorenone (III) or tetra-





nitrophenanthraquinone (IV), whilst diphenic acid and benzil readily yield tetranitro-derivatives (V and VI), could be anticipated

(III.)  (IV.) 

from this "obstacle" theory. Moreover, it would be expected that diphenic acids unsubstituted in the 6 : 6′-positions should

(V.)  (VI.) 

form anhydrides, in spite of many statements to the contrary (*e.g.*, Adkins, Steinbring, and Pickering, *J. Amer. Chem. Soc.*, 1924, **46**, 1918; Underwood and Kochmann, *ibid.*, p. 2069). It is now found that 4-nitro- and 4 : 4′-dinitro-diphenic acids yield anhydrides under suitable conditions; an attempt to prepare the anhydride of 6-nitrodiphenic acid was, however, unsuccessful. According to the present hypothesis, a diphenyl derivative with two sufficiently large groups in the 2- and 2′-positions, that is, groups which, owing to size or electrical character, are unable to pass the 6′- and 6-positions, respectively, should be capable of resolution

(VII.)   (VIII.)

(VII and VIII). Suitable derivatives for testing this point have not yet been obtained. The dicamphorsulphonyl derivative of 2 : 2′-diaminodiphenyl was a viscous mass, and the camphor(and bromocamphor)-sulphonates of several 2 : 2′-derivatives of tetramethylbenzidine proved unsuitable for crystallisation. Menthyl hydrogen and di-*d*-β-octyl diphenates were not obtained in a solid condition, but dimenthyl and *d*-β-octyl hydrogen diphenates were crystallised from several solvents without showing any indication of resolution. The resolvability of such compounds is therefore still an open question.

EXPERIMENTAL.

Optically Active 6-Nitrodiphenic Acid.—Morphine hydrate (7·7 g.) was added to a boiling solution of 6-nitrodiphenic acid (7·2 g.) in alcohol (500 c.c.). The precipitated salt (7·8 g.; m. p. 224°) (Found: C, 63·6, 63·7; H, 5·4, 5·3%. $[\alpha]_{5461}$ −87·5° in pyridine,

$c = 4{\cdot}99$; $l = 2{\cdot}0$) was extracted repeatedly with boiling alcohol, and the product ($[\alpha]_{5461}$ $-91{\cdot}5°$ in pyridine; $c = 4{\cdot}81$; $l = 1{\cdot}0$) was dissolved in a large bulk of boiling water and decomposed with a slight excess of hydrochloric acid. The solution was extracted with ether, and the extract was repeatedly washed with dilute hydrochloric acid, dried with sodium sulphate, and then evaporated to dryness. The residue was further purified by reprecipitation from solution in ammonia by hydrochloric acid. The *d* + *dl*-6-nitrodiphenic acid melted indefinitely at 240—245°, and had $[\alpha]_{5461}$ $+56{\cdot}2°$ ($c = 5{\cdot}91$; $l = 1{\cdot}0$) in absolute ethyl alcohol.

The alcoholic mother-liquor containing the more soluble salt ($[\alpha]_{5461}$ $-84{\cdot}6°$ in pyridine solution; $c = 5{\cdot}0$, $l = 1{\cdot}0$) was concentrated and poured into dilute hydrochloric acid, and the precipitated *l* + *dl*-acid recovered as described above. The *l* + *dl*-acid melted at 239—245° and had $[\alpha]_{5461}$ $-66{\cdot}7°$ in ethyl alcohol ($c = 5{\cdot}07$; $l = 1{\cdot}0$). Quinine hydrogen 6-nitrodiphenate was equally suitable and after one crystallisation gave on decomposition the *d* + *dl*-acid with $[\alpha]_{5461}$ $+62°$.

The acid ($[\alpha]_{5461}$ $-66{\cdot}7°$) was dissolved in boiling acetic acid and allowed to crystallise slowly. The acid which crystallised had $[\alpha]_{5461}$ $-57{\cdot}6°$, whilst the mother-liquor, on evaporation to dryness, gave an acid with $[\alpha]_{5461}$ $-60{\cdot}3°$. Solutions of four different samples of acid having $\alpha_{5461} = -1{\cdot}12°$, $-2{\cdot}90°$, $-3{\cdot}38°$, and $+3{\cdot}32°$ respectively in absolute ethyl alcohol were left in corked flasks at laboratory temperature for 6 months; they then had the values $\alpha_{5461} = -1{\cdot}11°$, $-2{\cdot}92°$, $-3{\cdot}24°$, and $+3{\cdot}24°$, respectively.

Dichloride of 4-Nitrodiphenic Acid.—The acid was added slowly to warm thionyl chloride, and the resultant solution evaporated to dryness in a vacuum. The residual solid crystallised from benzene–light petroleum as a pale yellow powder, m. p. 90—92° (Found: C, 52·6; H, 2·1. $C_{14}H_7O_4NCl_2$ requires C, 51·8; H, 2·2%).

4-Nitrodiphenic Anhydride.—Thionyl chloride was added drop by drop to 4-nitrodiphenic acid, and the resultant solution evaporated to dryness in a vacuum. The residual solid crystallised from acetic anhydride in small needles, m. p. 205—207° (Found: C, 62·8; H, 2·4. $C_{14}H_7O_5N$ requires C, 62·4; H, 2·6%).

4 : 4′-Dinitrodiphenic Anhydride.—4 : 4′-Dinitrodiphenic acid (1·9 g.) and its acid chloride (2·1 g.) were heated under reflux with acetic anhydride for several hours. On cooling, the liquid filled with small prisms, which sintered at 125° and melted at 232—234° (Found: C, 51·9; H, 3·0; loss on drying to constant weight at 130°, 24·3. $C_{14}H_6O_7N_2,C_4H_6O_3$ requires C, 51·9; H, 2·9; loss, 24·5%). After crystallisation from benzene, the anhydride formed

a powder, m. p. 233—235° (Found: C, 54·1; H, 2·1. $C_{14}H_6O_7N_2$ requires C, 53·5; H, 1·9%).

Dichloride of 6-Nitrodiphenic Acid (compare 4-nitrodiphenic acid).—This was a pale yellow powder, m. p. 87° (Found: C, 51·8; H, 2·2. $C_{14}H_7O_4NCl_2$ requires C, 51·8; H, 2·2%). Attempts to prepare the anhydride of this acid resulted in viscous products only.

2 : 2′-*Dibenzamidotetramethylbenzidine*, prepared by interaction of the components in pyridine, separated from benzene as a crystalline powder, m. p. 201° (Found: C, 75·9; H, 6·1. $C_{30}H_{30}O_2N_4$ requires C, 75·3; H, 6·3%), and 2 : 2′-*di*-p-*toluenesulphonylamidotetramethylbenzidine*, similarly prepared, crystallised from alcohol in leaflets, m. p. 203° (Found: C, 62·8; H, 5·8. $C_{30}H_{34}O_4N_4S_2$ requires C, 62·3; H, 5·9%).

2-*Aminotetramethylbenzidine*, prepared by the same method as 2 : 2′-diaminotetramethylbenzidine, crystallised from alcohol in plates, m. p. 138° (Found: C, 74·8; H, 7·8. $C_{16}H_{21}N_3$ requires C, 75·3; H, 8·2%).

d-β-*Octyl hydrogen diphenate*, prepared from diphenic anhydride and *d*-β-octanol in the usual way, formed large needles, m. p. 70—73°, when crystallised from light petroleum (Found: equiv., 349. $C_{22}H_{26}O_4$ requires equiv., 354). It was unchanged in rotatory power ($[\alpha]_D$ +51°; $c = 5·0$; $l = 1·0$ in absolute ethyl alcohol) by recrystallisation from light petroleum or aqueous ethyl alcohol.

Dichloride of Diphenic Acid.—Diphenic acid (20 g.) was dissolved in warm thionyl chloride (100 c.c.), and the excess of thionyl chloride then removed in a vacuum. The residue was boiled with benzene, and the solution was filtered from diphenic anhydride (2—3 g.) and diluted with light petroleum. A yield of 80% of the dichloride, m. p. 97°, was obtained.

Dimenthyl Diphenate.—(*a*) A solution of equivalent quantities of menthol and diphenic acid dichloride in ether was boiled for 15 hours in the presence of potassium carbonate. Water was then added and the ethereal layer was separated, dried, and evaporated. The oily residue was dissolved in light petroleum, from which it separated in plates (yield 30%), m. p. 123—126°, $[\alpha]_{5461}$ −118·6°, which, after recrystallisation from light petroleum, had m. p. 126° and $[\alpha]_{5461}$ −120·4° in chloroform solution ($c = 4·88$, $l = 2·0$) (Found: C, 78·5; H, 8·3. $C_{34}H_{46}O_4$ requires C, 78·7; H, 8·9%). (*b*) A solution of equivalent quantities of menthol and diphenic acid dichloride in pyridine, after standing for 12 hours, was poured into water, and the resulting precipitate crystallised from light petroleum. Successive crops had $[\alpha]_{5461}$ −119·6°, −119·2°, −119·0° (yield 60%),

and after recrystallisation from light petroleum or acetic acid the ester had $[\alpha]_{5461}$ −120·3° ($c = 4{\cdot}94$, $l = 2{\cdot}0$).

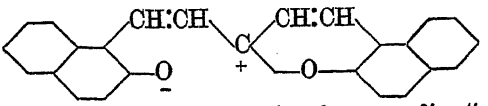
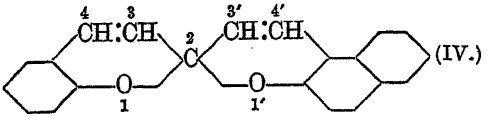
CCXVIII.—*Styrylpyrylium Salts. Part IX. Colour Phenomena associated with Benzonaphtha- and Dinaphtha-*spiro*pyrans.*

By ROBERT DICKINSON and ISIDOR MORRIS HEILBRON.

IN a previous communication (this vol., p. 14) a preliminary account was given of the remarkable property exhibited by di-β-naphtha-*spiro*pyran of forming in cold inert solvents colourless solutions which develop an intense violet-blue colour on heating; on cooling, the colour disappears and the substance may be recovered unchanged. This phenomenon, which may be repeated any number of times, we tentatively suggested might be accounted for by intramolecular change from the *spiro*-type (I) to the ortho-quinonoid system (II), a view which has been advanced by Löwenbein and



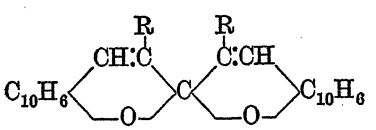


(I.) (II.)

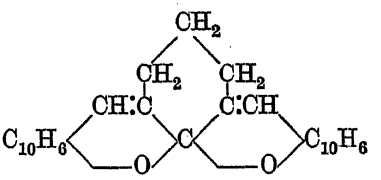
Katz also (*Ber.*, 1926, **59**, 1377), who almost simultaneously observed the same effects in the case of the 3-methyl, phenyl, and benzyl derivatives of the above compound.

On the other hand, Dilthey, Berres, Hölterhoff, and Wübken (*J. pr. Chem.*, 1926, **114**, 179), who have also examined this phenomenon, reject the quinonoid hypothesis on the grounds that (i) whereas true quinones mostly show a bathochromic effect in piperidine solution and never a hypsochromic action, di-β-naphtha-*spiro*pyran gives only a yellow solution which is unaffected by heat (compare Dilthey and Wizinger, *Ber.*, 1926, **59**, 1856), and (ii) neither dibenzo*spiro*pyrans nor mixed benzo-β-naphtha*spiro*pyrans show any alteration in colour either on melting or in solvents, although quinone formation is equally possible in both cases. They conclude that the appearance of colour is due to ionic dissociation, the

coloured form being represented as a heteropolar molecule of the type (III):



(III.) 

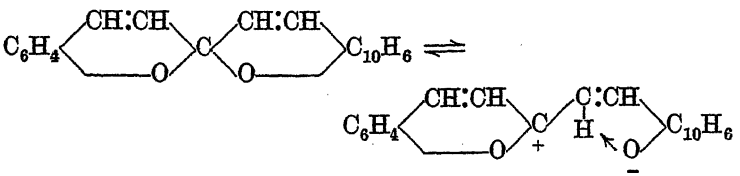


The possibility of the phenomenon being due to free radical formation has been considered by Löwenbein and by Dilthey, both concluding that such a view is incorrect. Dilthey treated a hot solution of di-β-naphtha*spiro*pyran in chlorobenzene with a stream of oxygen for an hour, and was unable to detect any change; a similar result was obtained with hydrogen. These two experiments show the absence of tervalent carbon and univalent oxygen, respectively. We have repeated the former, and also, on passing oxygen through a solution of the compound in toluene at 100°, could not detect any change, even after 15 hours' treatment. Further, we find that the colour is unchanged by the addition of quinol, a reagent which almost instantaneously reduces all the known types of radicals, with disappearance of the colour (compare Ingold, *Ann. Rep.*, 1924, **21**, 115—121). In addition, both Löwenbein and Dilthey have definitely shown that the molecular weights of these compounds are normal, whether the solution is coloured or not.

We have now made a very extensive examination of various *spiro*pyrans, and whereas we are in agreement with Dilthey that the colour effect is ionic in character, it will be shown that other factors enter into the case. In the first place, we have prepared *benzo*-β-*naphtha*spiro*pyran* (IV) by the acid condensation of 2-naphthol-1-aldehyde with *o*-hydroxystyryl methyl ketone, followed by hydrolysis of the resulting styrylpyrylium salt, and find that it exhibits, contrary to Dilthey's generalisation, the characteristic colour changes in solution, a wine-red colour being developed in hot solvents. We have also prepared the 3- and 3′-*methyl* derivatives of (IV). The former was obtained by condensing 2 : 3-dimethylbenzopyrylium chloride (Decker and Fellenberg, *Annalen*, 1909, **364**, 26) with 2-naphthol-1-aldehyde and resembles the parent benzo-β-naphtha*spiro*pyran in all respects, giving a deep red solution in boiling xylene and melting to a reddish-purple liquid. On the other hand, the isomeric 3′-*methylbenzo*-β-*naphtha*spiro*pyran*, the preparation of which from the condensation of 2-naphthol-1-

aldehyde with *o*-hydroxystyryl ethyl ketone definitely fixes its structure, gives no coloured solutions in boiling solvents, nor does it melt to a coloured liquid. This compound is undoubtedly identical with that obtained by Dilthey and his co-workers (*loc. cit.*), who, however, from their method of preparation were unable definitely to fix its constitution. We have also prepared 3 : 3′-*dimethyldi*-β-*naphtha*spiro*pyran* (V), *ethyl di*-β-*naphtha*spiro*pyran*-3 : 3′-*dicarboxylate* (VI), and 3 : 3′-*trimethylenedi*-β-*naphtha*spiro*pyran* (VII), none of which gives rise to highly coloured solutions.

(V, R = CH_3; VI, R = CO_2Et.)



(VII.)

These experiments taken in conjunction with the work of Löwenbein and Katz (*loc. cit.*) lead to the conclusion that the conditions necessary for colour development are not wholly governed, as stated by Dilthey and his co-workers (*loc. cit.*), by the loading of the *spiro*pyran with two naphthalene nuclei, but that the determining factors are (a) *at least one naphthalene nucleus must be present* and (b) *the* 3′-*carbon atom in the naphthapyran ring must be unsubstituted.*

The obvious deduction to be drawn from (a) is that the ionised molecule arises through scission of the naphthapyran ring. Furthermore, when it is considered that the system thus produced contains a strongly polar, conjugated group, $\bar{O}—C=C—\overset{4'}{C}H=\overset{3'}{C}H—\overset{+}{R}$ (in which R represents the positively charged pyran residue), it will be seen that conditions peculiarly conducive to co-ordinated ring formation exist. In this connexion, factor (b) becomes operative. In the first place, it definitely proves that the quinonoid formulation fails to account for the observed facts. Secondly, it follows that, so long as the 3′-carbon atom in the benzo-β-naphtha*spiro*pyrans is unsubstituted, "chelate" formation can readily occur, but that this process is absolutely precluded when any other group is substituted for the free hydrogen atom. The same condition holds for the di-β-naphtha*spiro*pyrans: here the positions 3 and 3′ are identical, but at least one of them must be unsubstituted. The cumulative experimental evidence has consequently forced us to the conclusion that the colour development is the result of a series of changes in which equilibrium is established between the neutral

*spiro*pyran and an ionised " chelate " compound, as represented by the following formulæ:

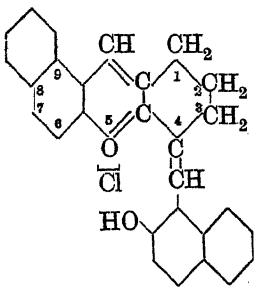
We are extending this investigation to include the influence of substitution in the 4- and 4′-positions of the *spiro*pyran nucleus. It remains to be mentioned that we have so far failed to obtain a pyrylium salt or *spiro*pyran by the condensation of 2-naphthol-1-aldehyde with dibenzyl ketone; two compounds have been isolated, the constitutions of which are under investigation.

Experimental.

*Benzo-β-naphtha*spiro*pyran* (IV).—A solution of 2-naphthol-1-aldehyde (5 g.) and 2-hydroxystyryl methyl ketone (5 g.) in alcohol (40 c.c.) was treated with 60% perchloric acid solution (9 c.c.), saturated with dry hydrogen chloride, and kept for 3 days at 0°. The separated crystalline solid was then washed with ether, and shaken with concentrated ammonia in presence of excess of ether until it had dissolved. After being washed and dried, the dark ethereal solution was concentrated. The crystalline crust which separated was recrystallised first from ether, then twice from acetone with charcoal, and finally from aqueous acetone. The spiro*pyran* was obtained in small, colourless, glistening plates; these darkened at about 160° and melted at 168—169° to a deep purple liquid which very slowly resolidified, on cooling, with gradual fading of the colour.

The *spiro*pyran is soluble in concentrated sulphuric acid, giving a ruby-red solution, and develops with boiling alcoholic sodium hydroxide a purplish-red colour. Its colourless solutions in acetone, benzene, and xylene become wine-red on heating, the colour disappearing again on cooling. On warming with alcohol, a similar colour develops, but it is more purple, and is still more so when water is added to the solution (Found: C, 84·4; H, 4·4. $C_{21}H_{14}O_2$ requires C, 84·6; H, 4·7%).

3′-*Methylbenzo-β-naphtha*spiro*pyran*.—Perchloric acid (8 c.c. of 60%) was added to a solution of 2-naphthol-1-aldehyde (5 g.) and 2-hydroxystyryl ethyl ketone (5 g.) in alcohol (40 c.c.), and the whole saturated with hydrogen chloride. The separated microcrystalline perchlorate was washed with ether, suspended in benzene,



and treated with a few drops of concentrated ammonia. Water was then added and the benzene solution was separated, dried, and, after concentration, treated with light petroleum, whereupon crystals slowly separated (yield, about 2·5 g.). These were twice recrystallised from absolute alcohol (charcoal), finally being obtained in clusters of colourless, silky needles, m. p. 177—178° (Dilthey, *loc. cit.*, describes pale yellowish needles, m. p. 174°). This *spiro*pyran shows no colour change when heated with inert solvents, such as xylene. In concentrated sulphuric acid, the solution is orange-red (Found: C, 84·2; H, 5·3. $C_{22}H_{16}O_2$ requires C, 84·6; H, 5·1%).

3-*Methylbenzo*-β-*naphtha*spiro*pyran*.—A solution of salicylaldehyde (2 g.) and methyl ethyl ketone (1·2 g.) in glacial acetic acid (6 c.c.) was saturated with hydrogen chloride and kept for a few hours to enable the primary condensation to become complete; 2-naphthol-1-aldehyde (2·9 g.), dissolved in acetic acid (9 c.c.), was then added, the colour changing from red to purple. After 12 hours, ether was gradually added, the pyrylium chloride slowly crystallising. This was collected, washed with ether, and shaken in ethereal suspension with an aqueous solution of sodium acetate until the colour was discharged. The ethereal solution, after being washed, dried, and concentrated, deposited pale greenish-yellow prisms, which were recrystallised first from ether and then from acetone, giving faintly greenish-yellow prisms. These darkened at 145° and melted at 149° to a purple liquid; on cooling, the colour faded but did not disappear completely until the substance had solidified, after several days. Colourless solutions of the *spiro*pyran in acetone, xylene, etc., become wine-red on heating, the colour disappearing again on cooling. Its ruby-red solution in concentrated sulphuric acid is faintly fluorescent (Found: C, 84·5; H, 5·3. $C_{22}H_{16}O_2$ requires C, 84·6; H, 5·1%).

3 : 3′-*Dimethyldi*-β-*naphtha*spiro*pyran* (V).—A hot solution of 2-naphthol-1-aldehyde (2·1 g.) and diethyl ketone (1 c.c.) in glacial acetic acid (10 c.c.) was saturated with hydrogen chloride. After the mixture had been kept at 0° for several days, a small amount of the pyrylium chloride separated in green needles. These were removed, and the mother-liquor was treated with excess of perchloric acid; chocolate-brown needles of the salt slowly separated. Both products were dissolved in acetone (the chloride giving a violet and the perchlorate a dark red solution) and, while hot, treated with dilute ammonia, drop by drop, until the colour was discharged. The spiro*pyran* crystallised from the yellow acetone solutions, either on evaporation or on the addition of water. Recrystallised from benzene, the compound separated in pale lemon-

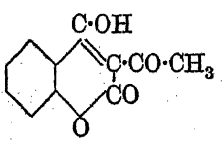
yellow rhombs, m. p. 238° to an olive-green liquid. It does not exhibit any colour changes when heated with solvents (Found: C, 85·9; H, 5·1. $C_{27}H_{20}O_2$ requires C, 86·2; H, 5·3%).

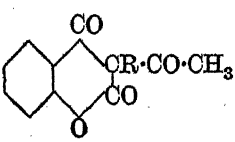
4-2′-*Hydroxy*-1′-*naphthylidene*-1 : 2 : 3 : 4-*tetrahydro*-8 : 9-*benzoxanthylium Chloride* (annexed formula).—A solution of 2-naphthol-1-aldehyde (5 g.) and *cyclo*hexanone (2 c.c.) in alcohol (50 c.c.) was saturated with hydrogen chloride and kept for 12 hours at 0°. The separated crystalline solid (yield, 95%) was washed with ether and recrystallised from absolute formic acid previously saturated with hydrogen chloride. The salt separated in dark brown, glistening needles, insoluble in water and sparingly soluble in alcohol to a reddish-purple solution. In concentrated sulphuric acid its colour is orange-red (Found: C, 74·1; H, 5·2; Cl, 7·4. $C_{28}H_{21}O_2Cl,HCO_2H$ requires C, 74·0; H, 4·9; Cl, 7·5%).

3 : 3′-*Trimethylenedi*-β-*naphtha*spiro*pyran* (VII).—The above-mentioned salt (2 g.), suspended in boiling alcohol (50 c.c.), was treated with sodium acetate, the heating being continued until the colour of the pyrylium salt was discharged, a curdy, greenish-yellow solid separating. After drying, this was twice crystallised from benzene, separating in minute, sulphur-yellow rhombs, m. p. 233—234° (decomp.). The yellow benzene solution exhibits a fine green fluorescence. The spiro*pyran* is not appreciably soluble in alcohol, and does not fluoresce in concentrated sulphuric acid. A cherry-red colour slowly develops on prolonged boiling with alcoholic potash. This *spiro*pyran does not exhibit any colour changes on heating in solvents (Found: C, 86·5; H, 5·4. $C_{28}H_{20}O_2$ requires C, 86·6; H, 5·2%).

Ethyl Di-β-*naphtha*spiro*pyran*-3 : 3′-*dicarboxylate* (VI).—A solution of 2-naphthol-1-aldehyde (2 g.) and ethyl acetonedicarboxylate (1·2 g.) in hot alcohol (12 c.c.) was saturated with hydrogen chloride, and the passage of the gas was maintained until the solution was cold. After 2 days, the dark, crystalline deposit was washed with ether, suspended in hot acetone (which became bright red), and treated with dilute ammonia drop by drop until the colour was discharged. Alternatively, the pyrylium salt may be suspended in ether and hydrolysed by shaking it with aqueous sodium acetate, but the former method is preferred. The acetone solution, after being filtered, was treated with water until crystallisation ensued. Recrystallised from acetone, or benzene and light petroleum, the spiro*pyran* formed pale sulphur-yellow rhombs, m. p. 205—207°. It is very stable to hydrolysing agents, resisting the action of

alcoholic potash, but with acids it readily reverts to the pyrylium salt (Found: C, 75·5; H, 4·9. $C_{31}H_{24}O_6$ requires C, 75·6; H, 4·9%).



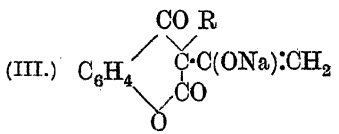


We desire to express our thanks to the Council of the Department of Scientific and Industrial Research for a grant to one of us (R. D.) which enabled this research to be carried out.

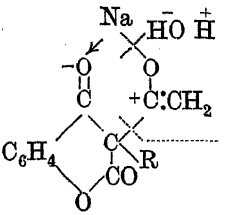
THE UNIVERSITY, LIVERPOOL. [*Received, May 27th*, 1927.]

CCXIX.—*The Preparation of 4-Hydroxycoumarin Derivatives.*

By ISIDOR MORRIS HEILBRON and DOUGLAS WILLIAM HILL.



THE hydroxycoumarins here described were prepared as a preliminary to the study of their action on aryl magnesium compounds, details of which will be furnished in subsequent papers. 4-Hydroxycoumarin (benzotetronic acid) was first described by Anschütz (*Annalen*, 1909, **367**, 169), who prepared it by condensing sodioacetoacetic ester with *o*-acetoxybenzoyl chloride in ethereal solution, followed by hydrolysis of the primarily isolated 3-acetyl-4-hydroxycoumarin (I). We have now obtained the substituted 3-methyl-, 3-benzoyl-, and 3-benzyl-4-hydroxycoumarins in good yield by this method. The 3-phenyl derivative has not been examined, as it has already been obtained by Pauly and Lockemann (*Ber.*, 1915, **48**, 28) by the intramolecular condensation of methyl *o*-phenylacetoxybenzoate in presence of sodium at 160°. Employing the α-substituted acetoacetic esters, we expected to obtain the acetyl derivatives (II) on removal of solvent from the condensation mixture; the products, however, were sodium salts, from which the acetyl-free hydroxycoumarins were obtained when their respective aqueous solutions were acidified.



(I.)  (II.) 

(R = CH_3, COPh, or CH_2Ph)

The extraordinarily ready elimination of acetyl is at first sight somewhat anomalous. It has been shown, however, by Widmann (*Ber.*, 1902, **35**, 1153) that 3-acetylcoumarin possesses strongly acidic properties, behaving as a typical pseudo-acid, and thus by analogy the sodium compounds now obtained may be similarly represented as still containing the acetyl intact in the molecule (III).

Although offering an explanation of the formation of sodium salts, this view in itself does not explain the subsequent ease with which the acetyl group is eliminated, for obviously precisely the same effect could occur with 3-acetyl-4-hydroxycoumarin, from which, however, the acetyl radical is by no means readily eliminated, requiring indeed several hours' heating with moderately concentrated potassium hydroxide solution for its removal.

(III.) 

 (IV.)

We submit, however, that a satisfactory interpretation of the observed facts can be arrived at by assuming that in the acetyl 3-substituted benzotetronic acids the simple enol does not exist as such, but that the sodium derivatives are present as co-ordinated salts (IV) only stable in non-aqueous media. Owing to the great tendency of the negatively charged oxygen of the carbonyl group to pass into the enolic state, as evidenced by the fact that benzotetronic acid itself is a strong acid, the chelated acetyl sodium compound is disrupted by water with formation of the free hydroxycoumarin. These changes obviously do not occur with the unsubstituted 3-acetylbenzotetronic acid, for here a free hydrogen atom is available for immediate formation of the isomeric coumarin form, and consequently this compound closely resembles 3-acetylcoumarin itself in stability.

Considerable difficulty was encountered in the methylation of these 4-hydroxycoumarins. This appears to be a general characteristic of this class of compounds, as similar difficulties were met with by Sonn (*Ber.*, 1917, **50**, 1292), who obtained only very small yields of 4 : 7-dimethoxycoumarin by the action of methyl sulphate upon the 4 : 7-dihydroxy-compound, the main product being 4-hydroxy-7-methoxycoumarin. We have now, however, prepared the dimethoxy-derivative in good yield by employing diazomethane.

EXPERIMENTAL.

4-Hydroxy-3-methylcoumarin.—Ethyl methylsodioacetoacetate (from 100 g. of the ester) in ether (600 c.c.) was treated with *o*-acetoxybenzoyl chloride (46 g.), prepared by the action of thionyl chloride upon *o*-acetoxybenzoic acid, and the mixture was heated under reflux on the water-bath for 18 hours. The resultant yellow

solid was filtered off, well washed with ether, and dissolved in water, the solution was carefully neutralised with dilute sulphuric acid, and the semi-solid precipitate was crystallised repeatedly from dilute alcohol in presence of animal charcoal and finally from methyl alcohol, the *coumarin* being obtained in colourless needles, m. p. 230°, readily soluble in alcohol and somewhat sparingly soluble in ether and benzene (yield, 60%) (Found : C, 68·3; H, 4·8. $C_{10}H_8O_3$ requires C, 68·1; H, 4·6%).

4-*Methoxy*-3-*methylcoumarin* was prepared by heating the dry silver salt of the coumarin under reflux with a slight excess of methyl iodide. Silver iodide and the excess of methyl iodide were removed; the residual colourless oil slowly solidified and was then crystallised first from ether and finally from alcohol, the *methyl ether* separating in colourless needles, m. p. 89·5° (Found : C, 69·0; H, 5·4. $C_{11}H_{10}O_3$ requires C, 69·4; H, 5·3%).

4-*Hydroxy*-3-*benzylcoumarin*.—Ethyl benzylsodioacetoacetate, prepared by adding the ester (90 g.) to granulated sodium (9 g.) in xylene (90 c.c.), was boiled under reflux with *o*-acetoxybenzoyl chloride (50 g.) in ether (300 c.c.) for 24 hours. The resultant thick precipitate was filtered off and dissolved in water, and the solution rendered acid. The semi-solid mass was extracted with ether, the solution dried, and after removal of the ether the residue was crystallised from aqueous alcohol, from which the *coumarin* separated in colourless needles, m. p. 205° (Found : C, 76·1; H, 4·9. $C_{16}H_{12}O_3$ requires C, 76·2; H, 4·7%).

4-*Hydroxy*-3-*benzoylcoumarin* was prepared in a similar manner from ethyl α-benzoylsodioacetoacetate. The *coumarin* crystallised from 96% alcohol in colourless needles, m. p. 144°, readily soluble in alcohol, less soluble in benzene and ether. It is also readily soluble in sodium carbonate solution (Found : C, 71·8; H, 3·8. $C_{16}H_{10}O_4$ requires C, 72·1; H, 3·8%).

4-*Methoxycoumarin*.—(1) A solution containing 4-hydroxycoumarin (2 g.), acetone (200 c.c.), and aqueous potassium hydroxide (16 c.c. of 20%) was gently warmed and treated with methyl sulphate (2·5 g.), added in small quantities at a time. The mixture was boiled for an hour and the 4-*methoxy*-derivative was precipitated by dilution with water and separated from a small quantity of unchanged 4-hydroxycoumarin by addition of sodium carbonate in slight excess. It crystallised from water in colourless flakes, m. p. 124° (yield, 25%).

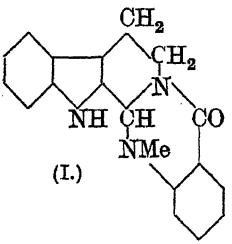
(2) Freshly prepared nitrosomethylurea (Werner, J., 1919, **115**, 1098) (25 g.), suspended in a solution of 4-hydroxycoumarin (10 g.) in acetone (100 c.c.), was very slowly treated with concentrated potassium hydroxide solution (17 g. in 12 c.c. of water), care being

taken to prevent the reaction becoming too violent. The *methoxycoumarin* was precipitated with water and crystallised as above (yield, 40%) (Found: C, 67·9; H, 4·5. $C_{10}H_8O_3$ requires C, 68·1; H, 4·6%).

4 : 7-Dihydroxycoumarin was prepared by a slight modification of Sonn's method (*loc. cit.*), ethyl cyanoacetate being employed in place of the free acid. A better yield of the coumarin was obtained by heating the ketimine under reflux with concentrated sulphuric acid (20 c.c.) and water (40 c.c.) for 3 hours. The ketimine gradually dissolved and after some time the ketone separated; it was recrystallised from hot water; m. p. 265° (yield, 80%).

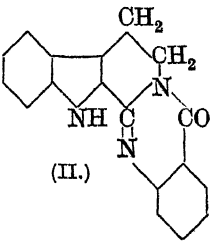
4 : 7-*Dimethoxycoumarin.*—Sonn (*loc. cit.*) obtained this compound together with a large amount of 7-methoxy-4-hydroxycoumarin by the action of methyl sulphate upon 4 : 7-dihydroxycoumarin at 0°. On repeating this work it was found that the yield of alkali-insoluble product was almost negligible. Attempts to methylate the 4-hydroxy-group with methyl iodide and sodium ethoxide or silver oxide also failed. The dimethyl ether was finally obtained in good yield by passing diazomethane into a solution of 7-methoxy-4-hydroxycoumarin (7 g.) in absolute alcohol (150 c.c.); after remaining for 3 hours at room temperature, the solution was concentrated and the dimethoxycoumarin was precipitated by dilution with water, washed with dilute alkali solution to remove unchanged 7-methoxy-4-hydroxycoumarin, and recrystallised from boiling water. It formed colourless needles, m. p. 155—156°, identical with Sonn's product (yield, 85%).

Our thanks are due to Mr. J. Kirwan, M.Sc., for help in some of the preparative work and to the Council of the Department of Scientific and Industrial Research for a grant to one of us (D. W. H.).



THE UNIVERSITY, LIVERPOOL. [*Received, May 27th*, 1927.]

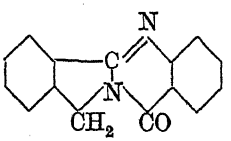
CCXX.—*A Synthesis of Rutæcarpine.*



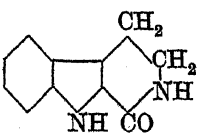
By YASUHIKO ASAHINA, RICHARD HELMUTH FRED MANSKE, and ROBERT ROBINSON.

FOLLOWING the analytical investigations (Asahina and Mayeda, *J. Pharm. Soc. Japan*, 1916, No. 416; Asahina and Fujita, *ibid.*, 1921, 863; Asahina, *ibid.*, 1924, No. 503, 1) which clearly proved that evodiamine and rutæcarpine, the alkaloids of *Evodia rutæcarpa*, Benth. and Hook., have the constitutions (I) and (II), respectively,

synthetical experiments were instituted by one of us in Japan,* whilst, on the other hand, the natural development of some work in progress at Manchester led in the same direction; the outcome is the present joint memoir, in which we describe an unexpectedly simple synthesis of rutæcarpine (II).



(I.)



(II.)

As a preliminary we studied the preparation of a quinazolone derivative from an available cyclic amide and anthranilic acid and found that phthalimidine and methyl anthranilate readily condense in the presence of phosphorus trichloride (compare Sen and Rây, J., 1926, 646) with formation of an *iso*quinazindolone (III). The

(III.)

(IV.)

application of this process to 3-keto-3 : 4 : 5 : 6-tetrahydro-4-carboline (IV) (Manske and Robinson, this vol., p. 240) resulted in the production of rutæcarpine. The identity of the synthetical specimen with one of natural origin was proved by careful direct comparison.

Experimental.

iso*Quinazindol-2-one* (III).—A mixture of phthalimidine (6·7 g.), methyl anthranilate (8 g.), and phosphorus trichloride (30 g.) was heated under reflux for 3 hours, the product was decomposed by ice and hydrochloric acid, and the *base*, precipitated by addition of alkali to the solution, filtered after treatment with charcoal, was purified to some extent by redissolution in hydrochloric acid and recovery. It crystallised from ethyl alcohol in slender, colourless needles (yield, 4 g.), m. p. 205—206° (Found: C, 76·9; H, 4·5; N, 11·9. $C_{15}H_{10}ON_2$ requires C, 76·9; H, 4·3; N, 12·0%). This

* The degradative fission of rutæcarpine yields 3-β-aminoethylindole-2-carboxylic acid, and recently this acid has been reconverted into rutæcarpine. Its *o*-nitrobenzoyl derivative was reduced and then dehydrated. A brief account of the experiment will be found in the May (1927) issue of the *Journal of the Pharmaceutical Society of Japan*. Y. A.

weak base is soluble in moderately concentrated hydrochloric acid and is sparingly soluble in most neutral organic solvents.

Rutœcarpine (II).—A mixture of the ketotetrahydrocarboline (4 g.), methyl anthranilate (5 g.), and phosphorus trichloride (20 g.) was heated under reflux for 4 hours and the excess of the trichloride was then removed by distillation under diminished pressure. The residue was decomposed with ice, the solid collected and boiled with concentrated hydrochloric acid (200 c.c.), and the solution filtered hot. Unchanged lactam was recovered from the solution; the insoluble, pale brown residue crystallised from boiling ethyl alcohol in colourless needles (yield about 1·5 g.), m. p. 257—258° (Found: C, 75·3; H, 4·7; N, 14·7. Calc. for $C_{18}H_{13}ON_3$: C, 75·2; H, 4·5; N, 14·6%), which also melted at 257—258° when mixed with a specimen of rutæcarpine from *Evodia rutœcarpa*. The experiments involved in the following observations were carried out side by side with both specimens and with identical results in every case. The substance is sparingly soluble in most organic solvents and crystallises from ethyl acetate in characteristic, very slender needles; it is very stable and may be distilled in small quantities in a high vacuum without decomposition. The bright yellow solution in sulphuric acid becomes deep brown on the addition of Mandelin's reagent or colourless on dilution with water. On boiling with dilute hydrochloric acid, the substance does not dissolve but is coloured yellow. The colourless solution in acetic acid exhibits a bluish-green fluorescence after the introduction of a few drops of sulphuric acid. The hot alcoholic solution becomes yellow on the addition of solid potassium hydroxide, but after dilution with water the colour is discharged and the unchanged substance separates in needles, m. p. 257°.

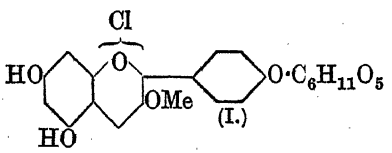
CCXXI.—*Experiments on the Synthesis of Anthocyanins. Part III.*

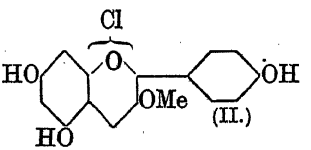
By ALEXANDER ROBERTSON and ROBERT ROBINSON.

THE fact that we have investigated 4'-, 3-, and 7-glucosidoxyflavylium salts (Parts I and II), which, unlike the anthocyanins, are not derivatives of phloroglucinol, is partly due to our having attacked the problem of the synthesis of the naturally occurring pigments in stages, but partly also to the circumstance that the methods employed in the anthocyanidin syntheses have been found in some details to be inapplicable to related glucosides.



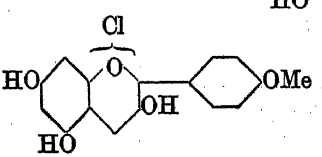
In the preparation of the latter, the condensation has hitherto been effected in dry ethereal solution and under these conditions *O*-triacetylphloroglucinaldehyde does not react satisfactorily with the appropriate ketones. In order to overcome this difficulty, it was necessary to obtain mono- or di-acetylated phloroglucinaldehydes, but all efforts to prepare the monoacetyl or monocarbomethoxy-derivatives failed. On the other hand, O-*diacetylphloroglucinaldehyde* was found to be the product when a solution of phloroglucinaldehyde in aqueous sodium hydroxide was agitated with an ethereal solution of acetic anhydride. No clear proof of the constitution of this substance can be adduced, but it must be either diacetoxysalicylaldehyde or diacetoxy-*p*-hydroxybenzaldehyde and the reaction with ferric chloride is in agreement with the former hypothesis.

This view is supported by the observation that the substance condenses readily with ω-methoxyacetoveratrone in ethereal solution in presence of hydrogen chloride, with ultimate production of cyanidin trimethyl ether, whereas *O*-triacetylphloroglucinaldehyde cannot be employed in flavylium salt syntheses in ethereal solution. This aldehyde exhibits some tendency to condense with suitable components under the requisite conditions to glucosidoxyflavylium salts, but the yields are very unsatisfactory. It was then found that O-*monobenzoylphloroglucinaldehyde* could be prepared by the Schotten–Baumann method, and this substance not only answered our immediate purpose, but also proved to be by far the best form in which to introduce phloroglucinaldehyde in all syntheses leading to pyrylium salts of anthocyanidin type.



The results of anthocyanidin syntheses which depend in the final stages on demethylation by means of hydriodic acid are subject to unexplained variations and uniformity cannot be relied upon. Partial demethylation is a frequent occurrence, and is not only capricious in its incidence, but is also difficult to detect by analysis; in other cases, Zeisel and Herzig–Meyer determinations of the product may prove the absence of methoxyl and yet the experiment has gone awry, since the material, usually quite crystalline, does not exhibit the normal reactions. We suspect the influence of inorganic catalysts in promoting nuclear methylation by a process analogous to Claisen's transformation of phenyl allyl ether to allylphenol. In view of this uncertainty, we are engaged in the repetition of the anthocyanidin syntheses by processes not involving demethylation. Employing *O*-benzoylphloroglucinaldehyde, we have already obtained benzoylpelargonidin and cyanidin chlorides. We do not wish to imply that demethylation of methoxylated flavylium salts by means of hydriodic acid is always an unsatisfactory

process, since in many cases it gives excellent results, and we are often compelled to rely upon this effective but clumsy method.



Experiments bearing on the constitution of *O*-benzoylphloroglucinaldehyde are in progress; it is either 2-benzoyloxy-4 : 6-dihydroxybenzaldehyde or 4-benzoyloxy-2 : 6-dihydroxybenzaldehyde. The benzoyloxyflavylium salts obtained with the aid of this aldehyde are stable towards acids, but are hydrolysed by alkalis, and the hydroxyflavylium salts are then recoverable by the action of acids on the product. The condensation of *O*-benzoylphloroglucinaldehyde with *p-O*-tetra-acetyl-β-glucosidoxy-ω-methoxyacetophenone (Part I, J., 1926, 1717) in ethereal solution with the aid of hydrogen chloride yielded an intermediate which was hydrolysed by means of methyl-alcoholic ammonia and subsequent treatment with hydrochloric acid with formation of a *pelargonidin methyl ether glucoside chloride* (I). This substance closely resembles a natural monoglucosidic anthocyanin in general character.

(I.)

(II.)

(III.)

The related sugar-free flavylium salt (II) derived on hydrolysis with 15% hydrochloric acid was synthesised independently, and furthermore the isomeride (III) has been obtained for comparison. The colour reactions of these pelargonidin chloride methyl ethers with sodium carbonate differ in a characteristic manner and a consideration of them shows (*a*) that callistephin and other anthocyanins derived from pelargonidin are certainly not 4′-glucosides, callistephin being probably a 3-glucoside (the position 5 is excluded on account of the fact that alcoholic solutions of callistephin, unlike those of pelargonenin, do not exhibit fluorescence. It is probable, although not yet quite certain, that position 7 can be excluded for the same reason), and (*b*) that partial demethylation of pelargonidin chloride 3 : 4′-dimethyl ether with hydriodic acid yields the 4′-monomethyl ether (III).

EXPERIMENTAL.

O-Diacetylphloroglucinaldehyde.—A mixture of pure phloroglucinaldehyde (6 g.), dissolved in *N*-sodium hydroxide (54 c.c.), and

ether (150 c.c.) was cooled to — 5°, and acetic anhydride (12 c.c.) gradually added with vigorous shaking. The reaction proceeded rapidly. The ethereal layer was separated, and the aqueous solution twice extracted with fresh ether. The combined ethereal solutions were mixed with water (10—15 c.c.), the ether was distilled, and the residue washed repeatedly with cold water. The oil gradually crystallised in contact with water and after a few days was ground, allowed to remain under water for 2 days longer, and then collected (5·5 g.). The solution of this product in 80% alcohol, after treatment with charcoal, deposited crystals on slow evaporation; these recrystallised from 60% alcohol (charcoal) in almost colourless, prismatic needles, m. p. 102—103°, presenting a homogeneous appearance under the microscope (Found: C, 55·4; H, 4·3. $C_{11}H_{10}O_6$ requires C, 55·5; H, 4·2%). The substance is readily soluble in ether and moderately readily soluble in cold methyl or ethyl alcohol. An alcoholic solution develops a wine-red coloration on the addition of ferric chloride. On further acetylation by means of acetic anhydride and potassium carbonate, an almost theoretical yield of *O*-triacetylphloroglucinaldehyde was obtained. The product had m. p. 156—157°, whereas Pratt and Robinson (J., 1925, **127**, 1182) give m. p. 151°. A specimen prepared from phloroglucinaldehyde, however, after repeated crystallisation from ethyl alcohol and then from methyl alcohol, sintered at 151° and had m. p. 156—157°. A mixture of the two specimens had m. p. 156—157°. Attempts to prepare monoacetylphloroglucinaldehyde by limiting the amount of acetic anhydride employed gave mixtures of the above diacetyl derivative and unchanged phloroglucinaldehyde. No definite carbomethoxy-derivatives could be obtained. Treatment of alkaline solutions of phloroglucinaldehyde at 0° with methyl chloroformate resulted in the immediate deposition of a brick-red product.

O-*Benzoylphloroglucinaldehyde.*—The phloroglucinaldehyde employed in the preparation of this substance should be obtained by the use of freshly distilled anhydrous hydrogen cyanide, since the material resulting from the modification described by Pratt and Robinson (J., 1925, **127**, 1132) is difficult to free from a colouring matter which has a deleterious effect on the yield. Phloroglucinaldehyde (5·2 g.) was added to a solution (cooled to 10°) of potassium hydroxide (1·7 g.) in water (150 c.c.). The mixture was cooled to — 5°; part of the potassium derivative then separated in glistening plates. Benzoyl chloride (2·35 g.) was then introduced in three portions with very vigorous shaking, which was continued until the odour of the chloride had almost disappeared. The mixture was stirred for ½ hour with an excess of aqueous sodium bicarbonate,

and the solid was then collected, washed, again triturated with aqueous sodium bicarbonate, isolated, and dried in the air (yield, 7·5 g.). The crude product was dissolved in hot alcohol (100 c.c., charcoal), and the filtered solution poured into water (400 c.c.). The emulsion quickly resolved itself into a suspension of hair-fine needles, which were isolated (5 g.) and found to be sufficiently pure for many purposes. The substance crystallises from chloroform (charcoal) in colourless, elongated prisms which become pink at 155°, darken at 185°, turn brick-red at 195°, and melt at 198—200° to a dark red liquid (Found: C, 64·8; H, 3·8. $C_{14}H_{10}O_5$ requires C, 65·1; H, 3·9%). The substance is easily soluble in ether and the simple alcohols, moderately readily soluble in hot chloroform, and very sparingly soluble in carbon tetrachloride. It gives a wine-red coloration with ferric chloride in alcoholic solution.

4′-β-*Glucosidoxy*-5 : 7-*dihydroxy*-3-*methoxyflavylium Chloride* (I).—A cold solution of *O*-benzoylphloroglucinaldehyde (0·6 g.) and *p*-*O*-tetra-acetyl-β-glucosidoxy-ω-methoxyacetophenone (0·5 g.) in dry ether (100 c.c.) was slowly saturated with hydrogen chloride; it gradually assumed a deep orange-red colour and then exhibited a strong yellowish-green fluorescence. A part of the product crystallised, and after 4 days the remainder was precipitated by the addition of ether (100 c.c.). The isolated salt (0·5—0·7 g.) dissolved in alcohol to an intensely fluorescent solution, but it could not be recrystallised, because pseudo-base formation occurred in solutions containing less than 5—6% of hydrochloric acid, and the use of more concentrated acid solutions caused hydrolysis. A solution of the crude product (2·7 g.), from several experiments, in methyl alcohol (200 c.c.) was saturated at 0° with ammonia and allowed to remain at 0° for 24 hours. The ammonia and methyl alcohol having been removed in a vacuum in the cold, the residue crystallised from 75% methyl alcohol containing 3% of hydrogen chloride in masses of microscopic, prismatic needles (1·2 g.) (deposition slow). The salt was then dissolved in 4% aqueous hydrochloric acid at 60—70° and separated on cooling in red, prismatic needles which showed a weak golden reflex only after being dried in a vacuum (Found in air-dried material: C, 47·7; H, 5·7. Found in material dried over soda-lime in a vacuum for 24 hours: C, 53·1; H, 5·3. $C_{22}H_{23}O_{10}Cl,4H_2O$ requires C, 47·6; H, 5·7%. $C_{22}H_{23}O_{10}Cl,H_2O$ requires C, 52·8; H, 5·0%. The monohydrate is very hygroscopic). When heated in a capillary tube, the salt evolves steam above 100°, sinters at 125°, and darkens and melts at 130—131°. The glucoside is easily soluble in cold 0·5—2% hydrochloric acid and in cold 50% methyl alcohol containing 4% of hydrogen chloride; it is easily soluble in hot aqueous hydrochloric acid (up to 20%).

The aqueous acid solutions are not completely extracted on being shaken with *iso*amyl alcohol. The alcoholic hydrochloric acid solutions are deep red, dilute aqueous solutions are orange-red, and in all cases the solutions are not fluorescent. The sodium carbonate reaction is dark wine-red, becoming dirty brown, whilst the addition of sodium acetate to an acid solution produces a more stable, intense dark red coloration. The *picrate* separated from a hot 80% alcoholic solution of the salt containing an excess of picric acid in compact, deep red, spherical masses of microscopic crystals. It darkens at 125°, is almost black at 170°, and melts with further decomposition at 186—188°.

5 : 7 : 4′-*Trihydroxy*-3-*methoxyflavylium Chloride* (II).—(A). A slow stream of hydrogen chloride was passed through a solution of *p*-hydroxy-ω-methoxyacetophenone (Part I, *loc. cit.*) (1·6 g.) and *O*-triacetylphloroglucinaldehyde (2·8 g.) in anhydrous formic acid (10 c.c.) for 4 hours, and the mixture kept for 36 hours. The salt precipitated by ether was collected (3 g.) and hydrolysed by boiling aqueous alcoholic hydrochloric acid during 5 minutes; on cooling, a red, amorphous material was deposited. This was extracted by boiling water, and 20% hydrochloric acid was added to the filtrate until a faint turbidity appeared. On cooling, the salt separated in stellate aggregates of dark red, prismatic needles. Recrystallisation from 3—4% hydrochloric acid gave freely twinning, elongated, nearly rectangular, microscopic prisms which were dark red in mass and crimson by transmitted light under the microscope (Found in material dried over soda–lime for 12 hours: C, 56·6; H, 4·6. $C_{10}H_{15}O_5Cl,H_2O$ requires C, 56·7; H, 4·4%). When crystallised from a mixture of hydrochloric acid and ethyl alcohol, highly characteristic, boat-shaped, microscopic plates are obtained. These have a reddish-brown colour and a greenish reflex, but this is lost on exposure to air. This salt is sparingly soluble in cold dilute hydrochloric acid (down to 0·5%) and is only moderately readily soluble in hot hydrochloric acid; very dilute solutions have a brownish orange-red colour, hot concentrated aqueous solutions and alcoholic solutions are crimson, and all solutions are non-fluorescent. Aqueous sodium carbonate dissolves the salt, giving a stable, intense, reddish-violet solution, more bluish-violet in thin layers. Willstätter and Burdick (*Annalen*, 1916, **412**, 162) state that "Die säure Losung des Callistephins schlägt mit Soda und sogar mit Alkalilauge nur in Rotviolett bis Violettrot um, während Pelargonenin schon mit Soda violett blau wird." In this connexion, it is interesting to note that 3 : 7 : 4′-trihydroxyflavylium chloride gives a definitely bluer alkali colour-reaction than the 3 : 5 : 7-trihydroxymethoxyflavylium chloride. In alcoholic solution, for

example, the former, like pelargonenin, gives a pure blue coloration (compare Willstätter and Bolton, *Annalen*, 1916, **412**, 136; Pratt and Robinson, J., 1923, **123**, 193). *iso*Amyl alcohol extracts the salt completely from an aqueous acid solution. Pseudo-base formation was observed.

(B). Characteristic, twinning, rectangular prisms separated in the course of 2 minutes when the above-described glucosidoxydihydroxymethoxyflavylium chloride was boiled in 15% aqueous hydrochloric acid solution. The substance was recrystallised and identified by its reactions, solubility relations, and crystalline form with the pelargonidin chloride 3-methyl ether prepared as in (A) above. The filtrate from this hydrolysis was extracted with *iso*amyl alcohol in order to remove the last traces of flavylium chloride and with ether to remove the *iso*amyl alcohol; it was then found to reduce Fehling's solution.

3 : 5 : 7-*Trihydroxy*-4'-*methoxyflavylium Chloride* (III).—A solution of anisoylcarbinol (0·6 g.) (Tiffeneau, *Compt. rend.*, 1910, **150**, 1182) and *O*-triacetylphloroglucinaldehyde (1 g.) in formic acid (15 c.c.) was saturated with hydrogen chloride and after 36 hours the product was precipitated by ether and collected. It was dissolved in alcohol (200 c.c.) and concentrated hydrochloric acid (20 c.c.), the solution boiled for 5 minutes, the greater part of the alcohol removed by distillation, and the salt precipitated by the addition of concentrated hydrochloric acid. Separation from accompanying red impurities was effected by extraction with boiling 0·5% hydrochloric acid, the acid concentration of the filtrates was increased to 8—10%, and finally the substance was crystallised from 2% hydrochloric acid, separating in crimson, microscopic, rhombic prisms (Found in material dried over soda-lime for 12 hours: C, 56·4; H, 4·6. $C_{16}H_{13}O_5Cl,H_2O$ requires C, 56·7; H, 4·4%). The yield, as in the similar synthesis of peonidin, was poor and we have since found that *O*-benzoylphloroglucinaldehyde gives much better results than the triacetate in condensations with benzoylcarbinol derivatives. In mass this salt has a dark brown colour and exhibits a weak bluish-green reflex. When it is crystallised from aqueous-alcoholic hydrochloric acid (about 5%), highly characteristic, regular, diamond-shaped plates are obtained. The salt is very sparingly soluble in cold aqueous hydrochloric acid and not readily soluble even in boiling 2% hydrochloric acid. Concentrated aqueous solutions are crimson, very dilute solutions are brownish orange-red; alcoholic solutions are bluish eosin-red. The reaction with sodium carbonate is characteristic, the solutions, both alcoholic and aqueous, being strongly dichroic, red in thick layers and bluish-purple in thin layers. Under

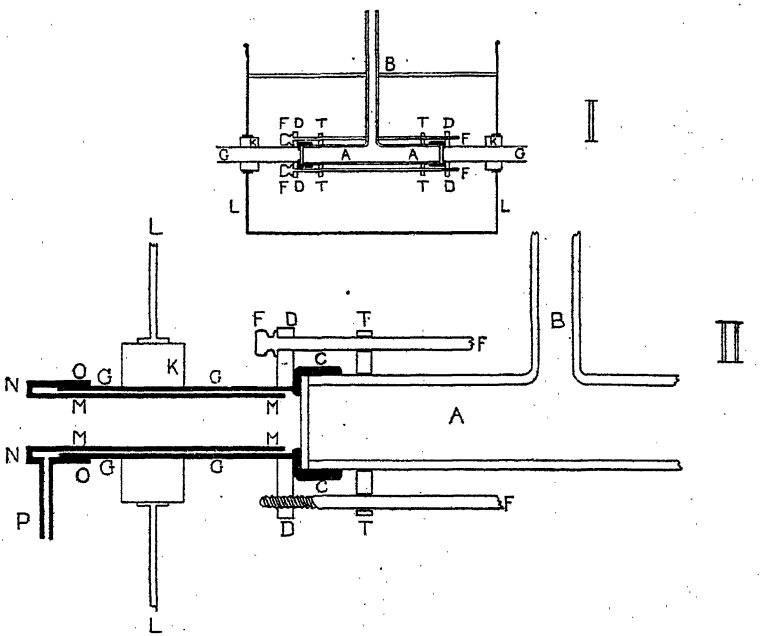
some conditions of illumination, the liquid appears green and violet. The specimen of incompletely demethylated pelargonidin chloride dimethyl ether described as crystallising in diamond-shaped plates (Pratt and Robinson, J., 1925, **127**, 1188) has been re-examined and undoubtedly contains a large proportion of the monomethyl ether now described. The crystal forms are identical and the colour reactions with sodium carbonate are closely similar. The dichroism observed in both cases was identical, but the specimen from the demethylation gave a slightly more bluish-purple colour in thin layers and probably contains a little pelargonidin chloride.

The authors wish to thank the Royal Society and the Chemical Society for grants which have defrayed a part of the cost of the investigation.

THE UNIVERSITY OF MANCHESTER. [*Received, June 7th*, 1927.]

CCXXII.—*A New Form of Thermostat and Observation Tubes for Polarimetric Work.*

By THOMAS STEWART PATTERSON.



IN polarimetric investigation, it is of very great importance to maintain a steady known temperature while the rotation of the active substance is being observed. The author in the course of his work has tried various forms of apparatus designed for this purpose, and some fifteen years ago adopted one which, since it has been found to give accurate results and to be easy to manipulate, may be of use to others engaged in similar work.

The polarimeter tube is so placed as to be in direct contact with the water in the thermostat. The upper part, I, of the accompanying figure gives a general idea of the whole apparatus. The polarimeter tube, A, has attached to it a side tube, B, reaching above the level of the liquid in the thermostat. The glass end discs may be cemented to the polarimeter tube or may be fixed in position by means of pieces of rubber tubing marked C in the lower, more detailed part of the figure. These act partly to prevent ingress of water into the tube or exit of material from it, and serve also, by being turned over the end of the cover glass, as washers to take up the pressure exerted by the brass end pieces, DD, of which there is one at each end. These are fastened together by means of the brass rods, FF, which have a small knob at one end and a screw at the other; the latter fits into a corresponding screw in one of the discs. These are really arranged as in the upper sketch, but the lower sketch shows the

details of each end. These rods just pass easily through holes in two collars, T T, which thus serve to keep the end plates, D D, in position. To the flanges, D D, are brazed brass tubes, G G. When the apparatus is in use, these brass tubes are passed through rubber bungs which fit into collars in the wall, L, of the bath, as shown at K K.

In carrying out an observation, the thermostat is emptied of liquid, and the polarimeter tube in its support of flanges and rods, either filled with the active liquid or empty, is introduced through the rubber bungs to appear as shown in I, an operation easily

FIG. 1.

performed. The active liquid may now be introduced into the tube, if this has not already been done, and the thermostat filled with water, upon which, preferably, there should float a layer of oil.

The temperature of the thermostat may be controlled by any suitable form of adjustable thermo-regulator, that used in this laboratory being one designed by the author (*J. Soc. Chem. Ind.*, 1902, **21**, 456). The liquid in the thermostat is also, in most cases, mechanically stirred, but this is not necessary for temperatures of 0°, 100°, and that of the atmosphere. By means of suitable screws on the legs of a quadrupod or tripod stand, the thermostat is adjusted so that the axis of the tube coincides accurately with the axis of the polarimeter.

Owing to the fact that there is direct contact between the glass of the polarimeter tube and the water in the thermostat, the temperature in the polarimeter tube becomes constant very rapidly; and since, between observations, the water in the thermostat may be replaced by water which, previously, has been heated very near the desired temperature, the time which must be allowed to elapse before a new temperature is established is reduced to a minimum. The variation of the temperature during the time required for the observations is very small indeed and the temperature may be maintained within about one-tenth of a degree of any desired value for long periods.

The temperature of boiling water is very easy to adjust too, especially when a layer of oil is used. A very small flame is sufficient to keep the water in the thermostat in ebullition and the temperature in the polarimeter tube is then exceedingly steady.

This is the upper limit of temperature at which we have used the apparatus, but it would not be difficult to adapt it for higher temperatures, by using concentrated potassium carbonate solution, for example, instead of water. For temperatures above 100°, we use an oil thermostat with an air chamber in which the tube is heated.

The apparatus described, however, may be used for temperatures *below* that of the atmosphere and it is possible to obtain very constant readings at a temperature of zero, which again is, of course, a very simple one to obtain; the thermostat is filled with a slush of ground ice and water. The difficulty then arises, however, that moisture is apt to condense on the end plates of the polarimeter tubes. To get over this difficulty, various methods were tried, but ultimately one which is exceedingly effective and also very simple has been adopted. This is illustrated in II. A piece of brass tubing, M M M M, which fits into the tube G G with a clearance of, perhaps, half a millimetre, and of a length sufficient to reach to about a millimetre or two from the end plate of the polarimeter tube, is soldered by an annulus, N, to another short piece of brass tube, O O, which just slips on to the outside of the tube G G. To this tube, O, is soldered a short narrow brass tube, P. The whole part M N O P can thus easily be removed when not wanted and equally easily replaced in position when required; one such part is fitted at each end of the polarimeter tube. The little tubes P are then connected to two of the arms of a Y piece, the third arm of which, in turn, connects with a drying tower containing sulphuric acid and pumice stone, this again being connected to a gas holder containing air. When observations are to be made at a temperature below that of the atmosphere, a quite slow current of dry air is

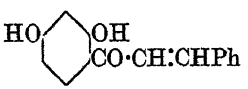
duced through the tubes P passes through the narrow space between the tubes M M and G G to near the end plate of the polarimeter tube, and out through the tube M M M M. The air close to the polarimeter end plate is thus kept thoroughly dry and no moisture is deposited upon the end plate. This arrangement is surprisingly efficient and even when a freezing mixture of carbon dioxide and alcohol is used as cooling agent, which causes the whole of the apparatus quickly to be covered with ice, a perfectly clear view through the polarimeter tube may be obtained, so long as the current of air is passing.

This little piece of apparatus will be found of very considerable value, since by its means it is easy to determine rotation values at zero, which is probably the most suitable standard temperature for the expression of polarimetric results, inasmuch as it can always be easily obtained, but which hitherto has been avoided, doubtless owing to the difficulty occasioned by the condensation of moisture on the end discs.

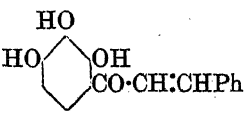
The bath which we use is 25 cm. long by 5 broad by 17 deep and accommodates comfortably tubes 160 mm. in length.

UNIVERSITY OF GLASGOW. [*Received, June 2nd,* 1927.]

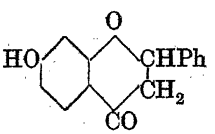
CCXXIII.—*Some Substituted Phenyl Styryl Ketones, with Remarks on the Condensation of Cinnamic Acid with Resorcinol and Pyrogallol.*



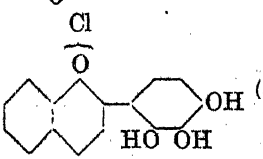
By THOMAS ERIC ELLISON.



THE condensation of benzoic acid with resorcinol in presence of zinc chloride takes place in two stages; 2 : 4-dihydroxybenzophenone is formed first and then, by further heating and participation of a second molecule of resorcinol in the reaction, 3-hydroxy-9-phenylfluorone. Pyrogallol behaves in an analogous fashion to resorcinol.



The behaviour of other simple carboxylic acids with these two phenols depends essentially on the relative velocity of the second stage of the reaction. When this is slow, as, *e.g.*, with acetic acid, the hydroxy-ketone can readily be isolated: when it is rapid, the only products that can be obtained are fluorones or more complex colouring matters. In the case of cinnamic acid, the primary condensation products would be hydroxyphenyl styryl ketones (hydroxychalkones); and the formation of chalkones in this way has actually been reported, that of 2 : 4-dihydroxyphenyl styryl ketone (I) from cinnamic acid and resorcinol by Bargellini



and Marantonio (*Atti R. Accad. Lincei*, 1908, **17**, ii, 119) and that of 2 : 3 : 4-trihydroxyphenyl styryl ketone (II) from cinnamic acid and pyrogallol by Dutta and Watson (J., 1912, **101**, 1238).

In the hope of being able to extend this method to the synthesis of some of the less accessible chalkones, their work has now been repeated, but the compounds in question were obtained neither by following the details given by the authors nor by any variations of the method, the only substances isolated being more complex colouring matters. To throw more light on the question, the chalkones (I) and (II) have been synthesised by more orthodox methods, and it is found that they are not identical with the substances held to be chalkones by the authors cited. It seems, therefore, that if, in the condensation of cinnamic acid with resorcinol and pyrogallol by means of zinc chloride, chalkones are formed at all, which is very probable, they are so rapidly transformed into more complex products that it is impossible to isolate them.

(I.) 

(II.)

(III.) 

(IV.)

Resacetophenone and benzaldehyde condense together in alkaline-alcoholic solution to give a mixture of 2 : 4-dihydroxyphenyl styryl ketone (I) and the isomeric 7-hydroxyflavanone (III). It is not uncommon to find chalkone and flavanone being simultaneously formed by this method, and the possibility of the two products being, in this particular case, geometrical isomerides is excluded by the colourless nature of the second substance and the fact that it yields only a monoacetyl derivative. Gallacetophenone and benzaldehyde condense together readily both in acid and in alkaline solution. By boiling with alcoholic hydrochloric acid, they yield benzylidenebisgallacetophenone, $C_6H_5\cdot CH[CH_2\cdot CO\cdot C_6H_2(OH)_3]_2$ (Kostanecki and Blumstein, *Ber.*, 1900, **33**, 1478). The same compound is obtained by saturating a solution of the reagents in glacial acetic acid with dry hydrogen chloride.

Despite the quantitative nature of this reaction, similar compounds cannot be obtained when benzaldehyde is replaced by anisaldehyde, salicylaldehyde, piperonal, or *m*-nitrobenzaldehyde. By the use of alcoholic potash, the required chalkone (II) is obtained

in good yield. In order to establish the generality of the last-mentioned method, which does not appear to have been applied hitherto to gallacetophenone, the benzaldehyde was replaced in turn by salicylaldehyde, *m*-hydroxybenzaldehyde, vanillin, and resorcylaldehyde. The last two were found not to condense appreciably with gallacetophenone under the action of alcoholic potash, whereas salicylaldehyde gave a moderate yield of 2 : 3 : 4-trihydroxyphenyl 2-hydroxystyryl ketone,

$$C_6H_2(HO)_3{\cdot}CO{\cdot}CH{:}CH{\cdot}C_6H_4{\cdot}OH,$$

and *m*-hydroxybenzaldehyde a small amount of 2 : 3 : 4-trihydroxyphenyl 3-hydroxystyryl ketone. Salicylidenegallacetophenone is very slowly converted into 2′ : 3′ : 4′-trihydroxy-2-phenylbenzopyrylium chloride (IV) by the action of anhydrous hydrogen chloride on the suspension in ether; but owing to the small amount of this substance which has so far been isolated, the investigation of it is not yet completed.

EXPERIMENTAL.

2 : 4-*Dihydroxyphenyl Styryl Ketone* (I) and 7-*Hydroxyflavanone* (III).—To a solution of resacetophenone (20 g.) and benzaldehyde (13·3 g.) in methyl alcohol (120 c.c.), potassium hydroxide (40 g. in 40 c.c. of water) was added and the mixture was kept at 65° for 3½ hours and then poured into water. Unchanged benzaldehyde having been extracted with ether, an excess of hydrochloric acid was added, which precipitated a yellow oil (about 12 g.). After 12 hours, the partly solidified oil was carefully treated with glacial acetic acid, and the undissolved solid, consisting of almost pure 7-hydroxyflavanone, was crystallised from toluene. Addition of water to the acetic acid solution precipitated a mixture of the chalkone and flavanone, which were ultimately separated by a tedious fractional crystallisation from toluene, in which the chalkone is the more soluble. 7-*Hydroxyflavanone* crystallises from toluene in colourless needles, m. p. 189° (Found: C, 74·8; H, 5·3. $C_{15}H_{12}O_3$ requires C, 75·0; H, 5·0%). It is insoluble in water and moderately easily soluble in alcohol or glacial acetic acid. In cold sodium carbonate solution, it gives a colourless solution which turns yellow on boiling. In sodium hydroxide, it at once forms a yellow solution which goes darker on heating owing to the conversion of the flavanone into the chalkone, but the change is never complete.

The flavanone (1 g.) was heated on the water-bath for 3 hours with acetic anhydride (10 c.c.) and anhydrous sodium acetate (5 g.). The *acetyl* derivative thus produced crystallised from 50% alcohol

in colourless needles, m. p. 98° (Found: C, 72·0; H, 5·0. $C_{17}H_{14}O_4$ requires C, 72·3; H, 5·0%).

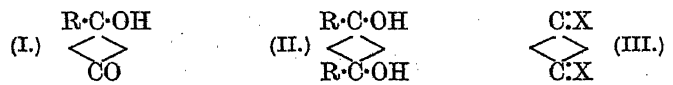
2 : 4-*Dihydroxyphenyl styryl ketone* crystallises from toluene in bright yellow, rectangular prisms, m. p. 133—134° (Found: C, 74·9; H, 5·3. $C_{15}H_{12}O_3$ requires C, 75·0; H, 5·0%). It is very slightly soluble in boiling water and very soluble in alcohol, glacial acetic acid, and acetone. It forms a deep yellow solution in concentrated sulphuric acid.

2 : 3 : 4-*Trihydroxyphenyl Styryl Ketone* (II).—Gallacetophenone (4·2 g.) and benzaldehyde (2·7 g.) were dissolved in alcohol (4·5 c.c.), and potassium hydroxide (9 g. in 10 c.c. of water) was added. The mixture was kept at 60° for 3 hours and then poured into dilute hydrochloric acid, on which the *chalkone* separated as a brown oil (about 4 g.) which slowly solidified. It was repeatedly crystallised from 75% methyl alcohol, animal charcoal being used to remove a slightly fluorescent, dark impurity, and was thus obtained in orange-yellow prisms containing methyl alcohol of crystallisation. After drying at 110°, it had m. p. 165—166° (Found: C, 70·2; H, 4·9. $C_{15}H_{12}O_4$ requires C, 70·3; H, 4·7%). It forms deep brown solutions in alkali and in concentrated sulphuric acid. It is practically insoluble in water, slightly soluble in benzene and toluene, and very soluble in acetic acid and alcohol.

2 : 3 : 4-*Trihydroxyphenyl* 2-*Hydroxystyryl Ketone*.—Gallacetophenone (4·2 g.) and salicylaldehyde (3·1 g.), dissolved in alcohol, were treated with potassium hydroxide (10 g. in 10 c.c. of water), and the solution kept at 65° for 3½ hours. Dilute hydrochloric acid was then added which precipitated the *chalkone* (3·3 g.) as a brown oil, which soon solidified. It crystallised from 75% methyl alcohol in long, yellow needles having a light brown colour in bulk. It became almost black at 205° and melted with complete decomposition at 224—225° (Found: C, 65·8; H, 4·4. $C_{15}H_{12}O_5$ requires C, 66·2; H, 4·4%). The chalkone is insoluble in water, benzene, and chloroform, slightly soluble in boiling xylene, and very soluble in acetone and alcohol. It gives dark brown solutions in alkali and in concentrated sulphuric acid, and on heating with concentrated hydrochloric acid it is slowly converted into the pyrylium chloride, but with much decomposition.

2 : 3 : 4-*Trihydroxyphenyl* 3-*Hydroxystyryl Ketone*.—Gallacetophenone (2·5 g.), *m*-hydroxybenzaldehyde (1·8 g.), potassium hydroxide (5 g. in 5 c.c. of water), and alcohol (40 c.c.) were heated together at 75° for 8 hours. Addition of dilute hydrochloric acid precipitated the *chalkone* (1 g.), which crystallised from 80% methyl alcohol (charcoal) in bright yellow needles, melting at 219—220° to a dark red liquid (Found: C, 66·0; H, 4·7. $C_{15}H_{12}O_5$ requires

C, 66·2; H, 4·4%). It forms a deep brown solution in alkali and a deep orange solution in concentrated sulphuric acid.



The author is indebted to Mr. A. Russell, B.Sc., for his valuable assistance with the experimental work.

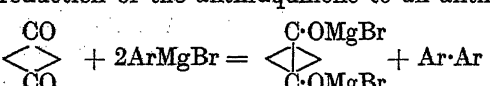
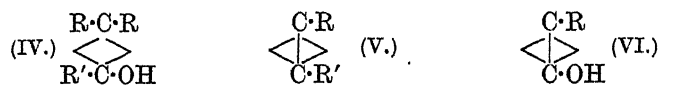
QUEEN'S UNIVERSITY, BELFAST. [*Received, May 23rd*, 1927.]



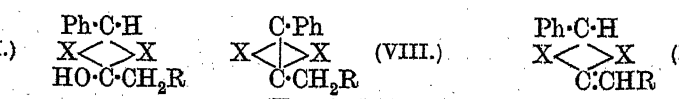
CCXXIV.—*The Synthesis of* meso-*Alkyl and* meso-*Aryl Anthracene Derivatives. Part II.*

By EDWARD DE BARRY BARNETT, JAMES WILFRED COOK, and JOHN LAURENCE WILTSHIRE.

THE action of Grignard solutions upon anthraquinone, 2-methylanthraquinone, and alizarin dimethyl ether has been studied by Haller and Guyot (*Bull. Soc. chim.*, 1904, **31**, 797), Guyot and Staehling (*ibid.*, 1905, **33**, 1104), Haller and Comptesse (*Compt. rend.*, 1910, **150**, 1290), Guyot and Vallette (*Ann. Chim.*, 1911, **23**, 363), Padova (*ibid.*, 1910, **19**, 353), Kovaché (*ibid.*, 1918, **10**, 226), Sirker (J., 1915, **107**, 1242), Clarke and Carleton (*Ber.*, 1908, **41**, 935; *J. Amer. Chem. Soc.*, 1911, **33**, 1966), and Ingold and Marshall (J., 1926, 3080) and has been found to lead to the alkyl- or aryl-hydroxyanthrone (I) or the dialkyl- or diaryl-dihydroanthraquinol (II), the last class of compound being by far the most readily accessible.

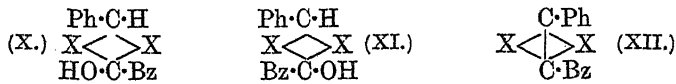


These last are stable towards alkaline reducing agents, although very easily reduced to the anthracene derivatives in acid solution, but when R is an alkyl group there is usually a marked tendency for loss of water to take place with the production of an alkylideneanthracene (III) or a polymerisation product of this. The yields of diol (II) recorded in different experiments are very varied. For example, by the action of magnesium phenyl bromide on anthraquinone, Haller and Guyot obtained only a 10% yield of the diol, Ingold and Marshall a 34% yield, and Kovaché an 80% yield. It has now been found that one of the chief reasons for the poor yields frequently obtained lies in the reducing action of the Grignard solution, which leads to the partial reduction of the anthraquinone to an anthraquinol:



a reaction which is somewhat analogous to a pinacol condensation, but which takes place in the complete absence of metallic magnesium (compare Boyd and Hatt, this vol., p. 898). Occasionally the reduction proceeds further and a considerable quantity of the diarylanthracene may be formed.

The action of Grignard solutions on anthrones has been studied by Haller and Guyot (*Bull. Soc. chim.*, 1904, **31**, 797), Guyot and Staehling (*ibid.*, 1905, **33**, 1104, 1144), Jüngermann (*Ber.*, 1905, **38**, 2868), Krollpfeiffer and Branscheid (*ibid.*, 1923, **56**, 1617), Sieglitz and Marx (*ibid.*, 1923, **56**, 1619), Kehrmann, Monnier, and Ramm (*ibid.*, 1923, **56**, 169), Barnett and Matthews (*ibid.*, 1926, **59**, 1429), and Barnett, Cook, and Matthews (*ibid.*, 1926, **59**, 2863) and has been found to lead to a dihydroanthranol (IV), from which (when R = H) loss of water takes place extremely easily (for example, by treatment with an acid) with the formation of an alkyl- or aryl-anthracene (V).



When neither R group represents a hydrogen atom the yields of the dihydroanthranol are excellent, although in this case the subsequent loss of water is impossible, but when one of these groups is a hydrogen atom the Grignard solution brings about considerable conversion of the anthrone into the enolic anthranol (VI) and poorer yields of the dihydroanthranol are obtained. The reaction is also complicated in some cases by reduction taking place which is probably due, at least in part, to loss of an alcohol from the dihydroanthranol first formed (compare Branscheid, *Dissert.*, Marburg, 1923). The method is, nevertheless, an extremely valuable one for the synthesis of both *meso*-alkyl- and *meso*-aryl-anthracenes, although of less general application than might be expected.

The action of magnesium alkyl halides on 1 : 5-dichloro-9-phenyl-anthrone gave oily products (probably VII) from which in some cases yellow and fluorescent (VIII) and/or colourless and non-fluorescent (IX) isomeric substances were obtained.

The action of magnesium benzyl chloride on 1 : 5-dichloro-9-phenylanthrone yielded a dihydroanthranol to which the *trans*-configuration is assigned (X), since it could not be converted into phenylbenzyldichloroanthracene (XII), all attempts at dehydration

leading either to the isolation of the unchanged material or to the production of indefinite substances from which no pure product could be isolated. A less amount of the *cis*-dihydroanthranol (XI) must have been formed simultaneously, as the liquors from the *trans*-isomeride gave, on evaporation, an oil from which phenylbenzyldichloroanthracene (XII) was easily obtained as a yellow, fluorescent substance by treatment with acids:

The fact that phenyldichloroanthrone can yield alkylidene compounds whereas phenylanthrone yields only the anthracene derivatives is in harmony with previous observations on the stabilising influence of α-chlorine atoms on the derivatives of 9 : 10-dihydroanthracene, and the inter-conversion of the alkylidene compounds (IX) and the anthracene derivatives (VIII) would supply definite proof of the theory of transannular tautomerism (Barnett, Cook, and Matthews, *loc. cit.*). To this end a detailed examination of the products described in the present communication is now in progress.

Ingold and Marshall (*loc. cit.*) have shown that the 9 : 10-diarylanthracenes undergo a reversible deepening in colour when heated with an inert solvent of high boiling point and have attributed this to dissociation of the " bridge " bond leaving the *meso*-carbon atoms in the tervalent state. Liebermann, Glawe, and Lindenbaum (*Ber.*, 1904, **37**, 3337) and Schlenk (*Annalen*, 1912, **394**, 191) have previously brought forward evidence of the existence of anthracene derivatives in which one of the *meso*-carbon atoms is tervalent, although the latter observer was unable to detect dissociation of 9 : 10-diphenylanthracene. The present authors have confirmed qualitatively Ingold and Marshall's statements as regards the reversible deepening in colour of the diarylanthracenes in mesitylene solution, and have found that not only the diarylanthracenes mentioned in the sequel, but also the 9-phenyl-10-alkylanthracenes exhibit the same phenomenon. A similar remark applies to 9-phenylanthracene, although in this case the effect is so slight as to be barely perceptible. The colourless products to which the alkylidene formula (IX) has been attributed in the foregoing do not become coloured when their solutions in mesitylene are boiled, and this is regarded as additional evidence in favour of the structure assigned to them.

Ingold and Marshall assume, by analogy with the hexa-arylethanes, that the formation of disodio- and dipotassio-compounds of the diarylanthracenes indicates the existence of a dissociable " bridge " bond. This argument is inadmissible, as anthracene

itself gives similar compounds (Schlenk, Appenrodt, Michael, and Thal, *Ber.*, 1914, **47**, 473) and, indeed, the formation of these compounds is merely a further example of the resemblance of the " bridge " to an ethylenic bond.

In any case, the dissociation of the diaryl- and arylalkyl-anthracenes is just as much in harmony with the orthoquinonoid formula as with the " bridge " formula and there appears to be no method of differentiating between these two structures. Arguments based on physical properties such as refractivity (compare Auwers, *Ber.*, 1920, **53**, 941) are fictitious, since the " bridge," if it does exist, does not behave like an ordinary single bond, although represented as such. In all its chemical properties it exactly resembles an ethylenic bond and in calculating a physical constant it should be treated as a double bond. If this is done, the " bridge " and the orthoquinonoid structures represent each a system containing seven double bonds and are therefore indistinguishable. The chief advantages of the " bridge " formula are that it represents reactions of transannular addition and loss somewhat more clearly than the orthoquinonoid formula does, and it does not predict the existence of two α- or two β-monosubstitution products which would be expected from the orthoquinoid structure in the absence of a conception of dynamic equilibrium. For these reasons, it is used in this communication and is regarded as the best symbolical representation of the anthracene molecule whether the " bridge " bond has any real existence or not.

EXPERIMENTAL.

9 : 10-*Diphenyl*-9 : 10-*dihydroanthraquinol* was prepared from anthraquinone and magnesium phenyl bromide in 50% yield without using the special precautions recommended by Kovaché. The pure product melted at 260—263° (Haller and Guyot give 247° and Ingold and Marshall 252—254°). To prove the formation of anthraquinol, the crude Grignard product was poured on ice and ammonium chloride, the ether removed by distillation in steam, and the resulting solid extracted with boiling dilute sodium hydroxide solution, all these operations being performed in an inert atmosphere. When air was blown through the deep red alkaline extract, anthraquinone was deposited, and after recrystallisation it was identified by the method of mixed melting points.

In another experiment in which the crude diol was recrystallised from xylene, 9 : 10-diphenylanthracene was isolated from the liquors and identified by direct comparison with an authentic sample.

9 : 10-Di-*p*-anisyl-9 : 10-dihydroanthraquinol * was prepared by

* This compound was previously prepared by Haller and Comptesse (*loc. cit.*), who also reduced it to dianisylanthracene.

Ingold and Marshall's method (*loc. cit.*) from anthraquinone and magnesium *p*-anisyl bromide.* The inherent improbability of their statement that octahydrodiphenylanthracene is obtained when this diol is heated with hydriodic acid and phosphorus at 150° led us to repeat the experiment and we have identified their product as 9 : 10-dihydroanthracene by direct comparison with an authentic sample. A previous example of facile loss of a *meso*-group on heating with hydriodic acid has been given by one of us (J., 1926, 1684).

1-*Chloro*-9 :10-*diphenylanthracene*.—By boiling 1-chloroanthraquinone for 4 hours with 4 mols. of an ethereal solution of magnesium phenyl bromide a crude product was obtained from which 1-chloro-9 : 10-diphenylanthracene was isolated by recrystallisation first from toluene and then from acetic acid. It then formed a yellow, crystalline powder, m. p. 185° (Found: Cl, 9·7. $C_{26}H_{17}Cl$ requires Cl, 9·7%). In addition to the above, the crude product also contained 1-chloroanthraquinone (due to atmospheric oxidation of the anthraquinol) and as it gave an indigo-blue colour with concentrated sulphuric acid the diol also was doubtless present. For the preparation of 1-chloro-9 : 10-diphenylanthracene, it was found best to remove the anthraquinone by extraction with alkaline hydrosulphite solution and then to reduce by boiling with zinc dust and acetic acid.

2-Chloro-9 : 10-diphenylanthracene was obtained as a yellow, crystalline powder, m. p. 194°, by reduction of the crude diol obtained from 2-chloroanthraquinone and magnesium phenyl bromide (Found: Cl, 9·7. Calc.: Cl, 9·7%). Subsequent to our preparation of this compound, it was described by Ingold and Marshall (*loc. cit.*).

1 : 5-*Dichloro*-9 : 10-*diphenyl*-9 : 10-*dihydroanthraquinol*.—A vigorous reaction took place when 12 g. of 1 : 5-dichloroanthraquinone were added to a cold ethereal solution of magnesium phenyl bromide (4 mols.). After boiling for 6 hours, the whole was poured on ice and solid ammonium chloride, and volatile substances were removed by distillation with steam. The crude product contained much dichloroanthraquinone (due to atmospheric oxidation of the anthraquinol) and this was removed by repeated extraction with large volumes of boiling alkaline hydrosulphite solution. The residue, recrystallised from nitrobenzene and from xylene, formed a colourless, crystalline powder which melted to a red liquid at

* 49 G. of pure *p*-bromoanisole were obtained when a solution of 52 g. of *p*-bromophenol in 200 c.c. of 10% potassium hydroxide solution was heated on the water-bath until neutral (about 2 hours) with 70 g. of methyl *p*-toluenesulphonate, the whole being shaken from time to time. After addition of a large excess of alkali and heating for an hour to destroy the excess of the ester, the bromoanisole was removed by distillation with steam, dried in ethereal solution with calcium chloride, and distilled.

320° and gave an indigo-blue solution in concentrated sulphuric acid. The yield was 5 g. and numerous attempts under various conditions failed to improve it (Found: C, 71·9; H, 4·45. $C_{26}H_{18}O_2Cl_2$ requires C, 72·0; H, 4·2%). Unlike all other dihydroanthraquinols which have been studied up to the present, the above diol is extremely stable to reduction, and prolonged boiling with zinc dust and acetic acid, with or without the addition of hydrochloric acid, failed to convert it into diphenyldichloroanthracene.

1 : 5 : 9 : 10-*Tetrachloro*-9 : 10-*diphenyl*-9 : 10-*dihydroanthracene* was obtained when dry hydrogen chloride was passed through a solution of the above diol in boiling tetralin, and also when 1 : 5-dichloro-9 : 10-diphenylanthracene was treated with a solution of chlorine in carbon tetrachloride. It formed colourless crystals which melted to a red liquid at 250° and liberated iodine from potassium iodide in acetic acid solution (Found: Cl, 30·3. $C_{26}H_{16}Cl_4$ requires Cl, 30·2%).

9-*Benzylanthracene*.—By the action of a well-cooled solution of magnesium benzyl chloride (3 mols.) on anthrone (1 mol.) there was obtained a colourless, crystalline compound, m. p. 50°. This dihydroanthranol (IV. R = H; R′ = C_7H_7) is less stable than its isomeride (Cook, J., 1926, 2160) and passes into 9-benzylanthracene on keeping over-night in a vacuum desiccator.

Neither *o*-tolyl- nor *p*-anisyl-anthracene could be obtained from anthrone by the action of magnesium tolyl or anisyl bromide, most of the anthrone being recovered unchanged.

Action of Grignard Solutions on 9-Phenylanthrone.—In all cases, 9 g. of finely powdered 9-phenylanthrone were added to an ethereal solution of the Grignard reagent (3 mols.), the whole being cooled in a freezing mixture. After remaining over-night at the ordinary temperature, the mixture was poured on ice and solid ammonium chloride, the ethereal layer washed, and the ether removed by distillation. The residual crude dihydroanthranol passed very easily into the alkylanthracene by heating with acetic acid alone or with the addition of acetic anhydride or a few drops of hydrochloric or dilute sulphuric acid. In order to establish the reaction, the dihydroanthranol was purified and analysed in three cases. Attempts to effect dehydration in such a way that an alkylidene derivative was formed were not successful. When the reaction was carried out with magnesium *iso*butyl bromide, only 9-phenylanthracene was obtained, a result which may be due to the reducing properties of the Grignard solution but is more probably to be attributed to loss of butyl alcohol from the crude dihydroanthranol. The same result was obtained when the Grignard solution was carefully freed from metallic magnesium.

9-Phenyl-10-α-naphthyldihydroanthranol was found to be more stable than the other dihydroanthranols, but it was converted into 9-phenyl-10-α-naphthylanthracene by boiling for 3 hours with acetic anhydride.

Phenyl-*n*-butylanthracene, phenylbenzylanthracene, and phenyl-α-naphthylanthracene are yellow in colour, but all the other hydrocarbons are colourless. They are all strongly fluorescent. The dihydroanthranols are all colourless and non-fluorescent.

The following table gives the m. p. and analytical figures for carbon and hydrogen, the calculated values being in brackets. The solvent from which final crystallisation was effected is given after the m. p.

Group.	Phenylalkyl (or aryl)-dihydroanthranol.	Phenylalkyl (or aryl)-anthracene.
Et	—	M. p. 110° (alcohol). 93·4, 6·5 ($C_{22}H_{18}$: 93·6, 6·4%).
Pr$^{\alpha}$	M. p. 148—150° (much lower in a preheated bath) (benzene–light petroleum). 87·6, 7·2 ($C_{23}H_{22}O$: 87·9, 7·0%).	M. p. 115—116° (alcohol). 93·1, 6·7 ($C_{23}H_{20}$: 93·2, 6·75%).
Pr$^{\beta}$	—	M. p. 166—167° (methyl ethyl ketone–alcohol). 93·2, 6·9 ($C_{23}H_{20}$: 93·25, 6·75%).
Bu$^{\alpha}$	—	M. p. 156° (ethyl acetate). 92·6, 7·1 ($C_{24}H_{22}$: 92·9, 7·1%).
*iso*Amyl	—	M. p. 203—204° (benzene–alcohol). 92·3, 7·45 ($C_{25}H_{24}$: 92·6, 7·4%).
Bz	M. p. 177° (benzene). 89·3, 6·2 ($C_{27}H_{22}O$: 89·5, 6·1%).	M. p. 155° (acetic acid). 94·0, 6·0 ($C_{27}H_{20}$: 94·2, 5·8%).
α-$C_{10}H_7$	M. p. 260—262° (toluene). 90·2, 5·65 ($C_{30}H_{22}O$: 90·4, 5·5%).	M. p. 244—245°* (benzene–alcohol). 94·5, 5·4 (Calc.: 94·7, 5·3%).

* Previously made by a different method by Guyot and Staehling (*Bull. Soc. chim.*, 1905, **33**, 1120), who gave the m. p. as 229°.

Action of Grignard Solutions on 1 : 5-*Dichloro*-9-*phenylanthrone.*—In all cases the reaction was carried out by adding finely powdered 1 : 5-dichloro-9-phenylanthrone (m. p. 254° and not 245° as erroneously given previously; Barnett and Matthews, *Ber.*, 1926, **59**, 670) to an ethereal solution of 3—4 mols. of the Grignard reagent, the whole being cooled in a freezing mixture. After remaining over-night at the ordinary temperature, the mixture was poured on ice and solid ammonium chloride. The washed and filtered ethereal solution was then evaporated to dryness. Under these conditions viscous oils which could not be made to crystallise were obtained with all the magnesium alkyl halides, and these were

therefore dissolved in acetic acid and heated on the water-bath with the addition of a little sulphuric or hydrochloric acid.

1 : 5-*Dichloro*-9-*phenyl*-10-*methylene*-9 : 10-*dihydroanthracene* (IX; R = H), after recrystallisation from ethyl acetate, formed a snow-white, crystalline powder which showed no fluorescence; m. p. 150° (Found : C, 74·6; H, 4·5; Cl, 20·8. $C_{21}H_{14}Cl_2$ requires C, 74·8; H, 4·2; Cl, 21·1%).

1 : 5-*Dichloro*-9-*phenyl*-10-*ethylidene*-9 : 10-*dihydroanthracene* (IX; R = Me). The crude dihydroanthranol, when boiled with acetic acid and a mineral acid, gave chiefly a red, resinous product, but by dissolving this in ethyl acetate, adding alcohol, and then allowing the solution to evaporate slowly at the ordinary temperature, a colourless product (about 0·5 g. from 7 g. of phenyldichloroanthrone) was obtained which, after recrystallisation from alcohol and then from ethyl acetate, melted at 159° (Found : C, 75·3; H, 4·9. $C_{22}H_{16}Cl_2$ requires C, 75·2; H, 4·6%).

n-*Propyl derivatives.* By treating the red resin obtained by heating the crude dihydroanthranol with acetic and hydrochloric acids as described above, a small amount of a colourless, non-fluorescent product was isolated which, after recrystallisation from methyl alcohol, melted at 135°. This was undoubtedly 1 : 5-*dichloro*-9-*phenyl*-10-*propylidene*-9 : 10-*dihydroanthracene* (IX; R = Et) (Found : C, 75·3; H, 5·1. $C_{23}H_{18}Cl_2$ requires C, 75·6; H, 4·9%).

In another experiment, in which the crude dihydroanthranol was treated with acetic and sulphuric acids, the red resin, when treated as described above, yielded a small amount of a yellow, strongly fluorescent substance which, after being washed with boiling methyl alcohol and recrystallised from ethyl acetate, melted at 196°. This product was almost certainly 1 : 5-*dichloro*-9-*phenyl*-10-n-*propyl-anthracene* (VIII; R = Et), but the yield was less than 0·1 g. from 7 g. of phenyldichloroanthrone (Found : C, 75·8; H, 5·6. $C_{23}H_{18}Cl_2$ requires C, 75·6; H, 4·9%).

iso*Propyl derivative.* Treatment of the crude dihydroanthranol with acetic and either sulphuric or hydrochloric acids yielded a red resin from which, by treatment with ethyl acetate as described above, about 0·2 g. of a yellow, strongly fluorescent, crystalline powder, m. p. 195° (to a red liquid), was isolated which analysis indicated to be 1 : 5-*dichloro*-9-*phenyl*-10-iso*propylanthracene* (Found : C, 75·0; H, 5·1. $C_{23}H_{18}Cl_2$ requires C, 75·6; H, 4·9%).

n- *and* iso-*Butyl derivatives.* In neither case was it found possible to isolate sufficient pure material from the red resin for analysis, but from the *n*-butyl product a minute amount of a yellow, fluorescent, crystalline powder, m. p. 186° (to a red liquid), was obtained.

1 : 5-*Dichloro*-9-*phenyl*-10-*benzyl*-9 : 10-*dihydroanthranol* (X).—The reaction between phenyldichloroanthrone and magnesium benzyl chloride was carried out as with other magnesium alkyl halides. After the mixture had been poured on ice and ammonium chloride, the colourless solid which was insoluble in ether was collected, washed with ether, and recrystallised from alcohol; m. p. 173° (yield, 3·5 g. from 7 g. of phenyldichloroanthrone) (Found: Cl, 16·5. $C_{27}H_{20}OCl_2$ requires Cl, 16·5%). This product was much more stable to acids than most dihydroanthranols; when boiled under reflux with glacial acetic acid and either hydrochloric or sulphuric acid, or with acetic anhydride, or when heated alone to 300°, it underwent some change, but repeated crystallisation of the product from various solvents failed to yield any substance of constant melting point.

1 : 5-*Dichloro*-9-*phenyl*-10-*benzylanthracene* (XII).—When the ethereal solution from the above preparation was evaporated to dryness, an oil was left which rapidly passed into a crystalline solid when heated on the water-bath with glacial acetic acid containing a little hydrochloric acid. After boiling with animal charcoal in acetone–aqueous alcohol solution and recrystallisation from benzene, this was obtained as a yellow, crystalline powder, m. p. 209°. The solution showed a strong blue fluorescence (Found: C, 78·4; H, 4·8. $C_{27}H_{18}Cl_2$ requires C, 78·4; H, 4·6%).

1 : 5-*Dichloro*-9 : 10-*diphenyl*-9 : 10-*dihydroanthranol* was obtained in good yield from phenyldichloroanthrone and magnesium phenyl bromide and after recrystallisation from alcohol melted and evolved gas at 201° (Found: Cl, 17·2. $C_{26}H_{18}OCl_2$ requires Cl, 17·0%).

Attempts to prepare the corresponding α-naphthyl compound led only to the isolation of unchanged phenyldichloroanthrone.

1 : 5-*Dichloro*-9 : 10-*diphenylanthracene*.—The above dihydroanthranol was boiled with glacial acetic acid containing a little hydrochloric acid, and the product recrystallised several times from amyl alcohol and from benzene–light petroleum. It then formed a yellow, crystalline powder, m. p. 236° after previous sintering (Found: Cl, 17·9. $C_{26}H_{16}Cl_2$ requires Cl, 17·8%). On oxidation with sodium dichromate in boiling glacial acetic acid, it passed into the same dihydroanthraquinol that was obtained by the action of magnesium phenyl bromide on 1 : 5-dichloroanthraquinone.

The authors desire to express their thanks to the Research Fund Committee of the Chemical Society for a grant which has defrayed some of the cost of this research.

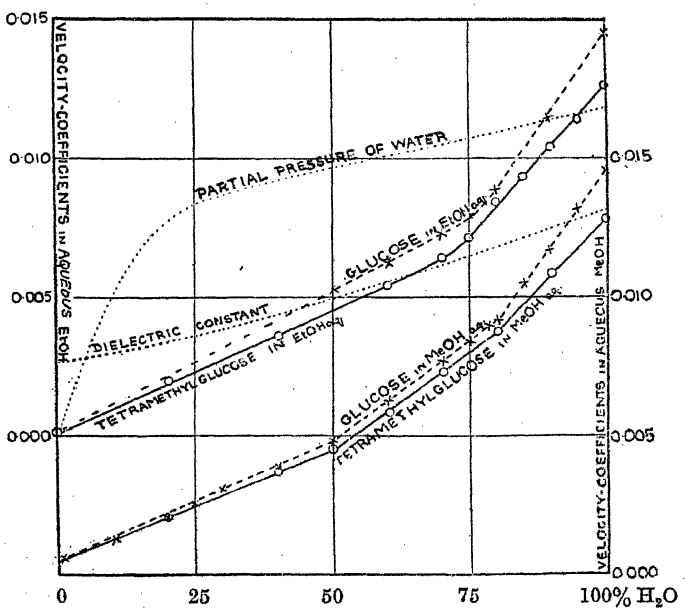
[*Received, March 30th*, 1927.]

CCXXV.—*Studies of Dynamic Isomerism. Part XXIII. Mutarotation in Aqueous Alcohols.*



By Evan Matthew Richards, Irvine John Faulkner, and Thomas Martin Lowry.

The present paper summarises the mutarotation data for some 80 solutions of glucose and of tetramethyl glucose in aqueous methyl and ethyl alcohols. These measurements formed part of a research on the influence of water concentration on velocity of mutarotation, and may therefore be regarded as a sequel to a recent investigation of the velocity of mutarotation of tetramethyl glucose and tetra-acetyl glucose in aqueous acetone (Part XXI; J., 1926, 720). The results, however, were of an entirely different character from those recorded in the preceding papers of this series. Thus, whereas solutions in aqueous pyridine gave a curve with a strongly developed maximum (J., 1925, **127**, 2883), and those in aqueous acetone gave a drooping curve approaching asymptotically to the axis of concentration (J., 1926, 721), the curves for solutions in aqueous alcohols show an approximate proportionality between water concentratation and velocity, which persists up to 50% and up to about 70% of water in the case of methyl and ethyl alcohol, respectively.

It is not easy to give a precise interpretation of these facts. The direct proportionality between water content and velocity of mutarotation, which has been established by these present experiments, was regarded by Baker, Ingold, and Thorpe as a logical deduction from the hydrate theory of mutarotation, a conclusion that was illustrated by a diagram on which a line passing through the origin was labelled "Theoretical for Lowry and Armstrong's Mechanism" (J., 1924, **125**, 281). Since, however, the lines which represent the influence of water concentration on the velocity of mutarotation in the two aqueous alcohols do not point towards the value for pure water, but to a velocity which is only about two-thirds as great, we cannot adopt the elementary view that mutarotation depends on a simple mass action, in which the catalytic activity of the water is proportional to its volume concentration and independent of all other factors. Moreover, we have already shown in the case of aqueous acetone that the velocity of mutarotation is not proportional to the "fugacity" of the water, since the partial vapour pressure of this component rises steeply in the region of small concentrations, whereas the velocity curves rise only very slowly from a horizontal asymptote. A similar conclusion can now be drawn in reference to aqueous ethyl alcohol, since the steep rise in the partial vapour pressure of the water, recently recorded by

Dobson (J., 1925, **127**, 2872), is again in complete contrast with the slow progressive increase of velocity indicated by the straight lines of Fig. 1; nor does it appear likely that these unrelated curves could be brought into agreement by means of a correction based upon a hypothetical variation in the "fugacity" of the sugar. The new experimental evidence therefore provides ample confirmation of the view, which was already adopted in 1904 (J., **85**, 1567), that the velocity of mutarotation of the sugars in aqueous solutions is not controlled by the initial hydration of the anhydrous sugar (which

FIG. 1.

Mutarotation of glucose and tetramethyl glucose in aqueous methyl and ethyl alcohols.

can be regarded for this purpose as an instantaneous action) but by a much slower, and more fundamental, molecular rearrangement of the hydrate.

The factors which determine the velocity of this fundamental change of structure have not yet been fully disclosed. On general grounds it might be supposed that the velocity of the change would be proportional to the dielectric constant of the solution. The data for the dielectric constant of aqueous ethyl alcohol, which are plotted in Fig. 1, show that this property is related to the water content of the solutions according to a nearly linear law, which

extends (with a " sag " of 3 or 4 units in the centre of the curve) over the whole range of concentrations from 0 to 100%. Whilst, however, the dielectric constants for water and for ethyl alcohol are in the ratio 80 : 26 = 3 : 1, the velocities of mutarotation in the two solvents are in a ratio which cannot be less than 80 : 1, since the velocity coefficient for tetramethyl glucose falls from 0·0128 in water to a figure which is certainly less than 0·00016 in alcohol. The velocity of mutarotation in pure alcohol is indeed so small as to be almost negligible, whereas the dielectric constant of the medium is quite high enough to give to it the normal properties of an ionising solvent. Again, the curve showing the variation of the dielectric constant with the water content of the solution (like that which expresses the partial vapour pressure of the water) gives no indication whatever of the abrupt change of direction in the velocity curve, which is more than twice as steep for solutions containing from 75 to 100% H_2O as for solutions containing 0 to 70% H_2O.

Since none of these suggested relationships can be verified, the theory which links the velocity of mutarotation with the acid and basic properties of the medium (J., 1925, **127**, 1382) is at the present time the only one for which any experimental justification can be found. In the case of aqueous solutions, detailed evidence of this relationship is given by Euler's precise quantitative determination of the influence of hydrogen-ion concentration on the velocity of mutarotation of α- and β-glucose (*Z. anorg. Chem.*, 1925, **146**, 45; compare Hudson, *J. Amer. Chem. Soc.*, 1907, **29**, 1572, and Kuhn and Jacob, *Z. physikal. Chem.*, 1924, **113**, 389). In the case of solvents which are either wholly or partly non-aqueous, the hydrogen-ion concentrations are not known; but, since mutarotation can be arrested in media which possess only acid or only basic properties (as well as in media which possess neither), there can be little doubt that in these cases also the velocity of mutarotation must be a fairly simple function of these two properties.

Experimental.

The first experiments were made with samples of purified glucose and glucose hydrate supplied by Messrs. British Drug Houses, Limited. The suitability of these two samples for experiments on mutarotation was established by the fact that they gave normal values for the velocity coefficient in aqueous solutions, namely, $k_e = 0{\cdot}0146$ for the anhydrous sample and $k_e = 0{\cdot}0147$ for the hydrated sample at 20°.* We are indebted to Mr. G. F. Smith

* The values recorded here and in the preceding papers (Parts XIX to XXII) are for $k_e = 1/t\{\log_e(a_0 - a_\infty) - \log_e(a_t - a_\infty)\}$ and not for $k_{10} = 1/t\{\log_{10}(a_0 - a_\infty) - \log_{10}(a_t - a_\infty)\}$.

for a detailed investigation of this point. His observations showed that a commercial sample of glucose, which gave $k_e = [0{\cdot}0160]$, 0·0142, 0·0145, 0·0144 and 0·0144, after precipitation with alcohol gave $k_e = 0{\cdot}0153$, 0·0146. After crystallisation of the original sample from alcohol the product gave $k_e = 0{\cdot}0146$, 0·0146, whilst after a second crystallisation from alcohol it gave $k_e = 0{\cdot}0145$. The average, $k_e = \mathbf{0{\cdot}0146}$, of these very concordant data may be taken as a standard velocity coefficient in future tests of the purity of glucose. Values recorded by other workers are set out below for comparison.

	0·0095	0·0219	Worley and Andrews (*J. Physical Chem.*, 1927, **31**, 744).

When dissolved in methyl alcohol (purified as described in Part XIX and containing about 99·5% MeOH), the anhydrous glucose gave a velocity coefficient $k_e = 0{\cdot}0006$. The corresponding value for tetramethyl glucose in a sample of methyl alcohol containing 99·1% MeOH was 0·0004, but this was subsequently reduced to 0·0002 by further purification of the alcohol, and even lower values have since been recorded by Worley and Andrews (*J. Physical Chem.*, 1927, **31**, 742) for the velocity coefficient of glucose in anhydrous methyl alcohol. The minimum velocity, however, represents a standard of purity which cannot be maintained in practice, since it corresponds with the conditions required to produce a complete arrest of mutarotation in a hydrocarbon solvent; Worley's velocities, as well as our own, are therefore a little too high at the alcohol end, but not to such an extent as to affect the general form of the velocity curves.

On account of the limited solubility of glucose in ethyl alcohol, suitable solutions could not be prepared in the higher ranges of concentration, and, even when methyl alcohol was used, it was

found convenient to prepare many of the solutions by filtering off an excess of the sugar, instead of by weighing out an exact percentage. Since identical velocity coefficients were obtained for these filtered solutions of glucose in 40% alcohol, and for solutions containing 4% of sugar, it appears that the velocity is not affected by the corresponding changes of sugar concentration; but, since filtration introduces an additional risk of contamination by catalytically active impurities, the difficulty of securing concordant velocities was increased considerably by the sparing solubility of the sugar, and in several cases the experiment had to be repeated more than once before a trustworthy minimum velocity could be recorded. It was therefore decided to regard all the data for glucose as preliminary determinations only, and to confirm the whole of the observations by duplicate experiments with tetramethyl glucose. This procedure had the double advantage that the sugar was of undoubted purity (compare J., 1925, **127**, 1387, footnote; 1926, 721), and that solutions of any desired strength could be prepared in an aqueous alcohol of any desired concentration and examined under comparable conditions. Moreover, it was found in practice that much less difficulty was experienced in securing consistent values for the velocity coefficients. Nevertheless, the complete concordance of the velocity curves for tetramethyl glucose with those already plotted for the parent sugar shows that the velocity coefficients finally recorded for glucose must have been substantially correct.

Results.—In order to economise space, all the direct readings of rotatory power have been omitted, but the unimolecular velocity coefficients deduced from them are set out in Tables I to IV below, and are represented graphically in Fig. 1. In general there is no great difference between the velocity of mutarotation in methyl and ethyl alcohols of a given water content, as is seen in the following summary of the data for glucose:

Water (%)	90	80	70	60	50	40	30	20	10
10,000 k_e (EtOH)	114	89	73	61	52	38	—	16	—
10,000 k_e (MeOH)	117	91	76	62	48	39	31	20	13

The two curves must cross, however, on either side of the 50% point, since the velocities at this concentration are slightly less in methyl than in ethyl alcohol, whereas they are slightly greater in the ranges outside 40 to 60% H_2O.

In Fig. 1, the full lines are for tetramethyl glucose, whilst the dotted lines refer to the less trustworthy experiments with glucose. Curves have also been added to show the dielectric constant, and the partial pressure of water vapour, in mixtures of ethyl alcohol and water. The experimental points have been represented as lying

on or near two straight lines for each of the series of observations in aqueous ethyl alcohol, and three straight lines in the case of methyl alcohol. It is probable that the points might be represented equally well as lying on a continuous curve, like Worley's data for

aqueous methyl alcohol at 25°; but for this purpose it would be essential that the curve should be indistinguishable from a straight line at concentrations up to 50% MeOH or 70% EtOH. Whilst, therefore, we do not suggest that there are any real " kinks " in the velocity curves, we have plotted the data on a linear framework, on the ground that they probably belong to the type, of which the real existence was demonstrated many years ago by Pickering (see especially *Phil. Mag.*, 1892, **33**, 134), which can be represented more closely by a pair of intersecting lines than by a single parabolic curve. Discontinuities of an even more striking character than those discovered by Pickering have been recorded by McCombie and his colleagues (J., 1921, **119**, 970; 1923, **123**, 2688) in the data for the velocity of saponification of esters in aqueous alcohols, where " breaks " were observed at 79, 64, 48, and 37% MeOH, and at 80, 62·5 or 59, 46, and 30% EtOH. Since their observations did not include the most dilute alcohols, it is not possible to make a direct comparison of these " breaks " with the rapid changes of curvature which are shown by our data at about 20% MeOH and 25% EtOH; but the change of curvature at 48 to 50% MeOH which is indicated by our data occurs at a concentration agreeing closely with that of their " break " at 48% MeOH. A " break " at this concentration has also been recorded in the viscosity, dielectric constant, and heat of dilution of this series of aqueous alcohols (McCombie, *loc. cit.*, p. 2690).

Summary.

(*a*) Data are given for the velocity of mutarotation of glucose and of tetramethyl glucose in aqueous methyl and ethyl alcohols.

(*b*) When the velocity coefficients are plotted against the water content of the solution, a linear relation is seen to extend up to about 50% H_2O in aqueous methyl alcohol and 70% H_2O in aqueous ethyl alcohol.

(*c*) No parallelism can be traced between the velocity of mutarotation and the partial pressure of the water, or the dielectric constant of the water–alcohol mixtures; but attention is directed to certain analogies with data recorded by McCombie and his colleagues for the velocity of saponification of esters dissolved in aqueous alcohols.

We are indebted to the Department of Scientific and Industrial Research for maintenance grants (to E.M.R. and I.J.F.) received during the period in which this research was carried out.

CCXXVI.—*The Reimer–Tiemann Reaction with* m-*Chlorophenol.*

By HERBERT HENRY HODGSON and THOMAS ALFRED JENKINSON.

A MIXTURE of 4-chloro-2-hydroxy- and 2-chloro-4-hydroxy-benzaldehyde in almost equal quantities has been obtained from *m*-chlorophenol by the Reimer–Tiemann reaction. The constitutions of the two aldehydes were determined by converting the methyl ethers into the corresponding methoxy- and hydroxy-benzoic acids, and confirmed by preparing 4-chloro-2-methoxybenzaldehyde from 4-nitro-2-methoxytoluene and 2-chloro-4-hydroxybenzaldehyde from 2-chloro-4-nitrotoluene.

EXPERIMENTAL.

4-Chloro-2-hydroxy- and 2-Chloro-4-hydroxy-benzaldehyde.—An intimate mixture of slaked lime (140 g.), sodium carbonate (160 g.), *m*-chlorophenol (56 g.), water (1000 c.c.), and chloroform (104 g.) was submitted to the usual Reimer–Tiemann procedure. 4-Chloro-2-hydroxybenzaldehyde (13 g.) was removed by steam distillation, the operation being stopped when the much less volatile 2-chloro-4-hydroxybenzaldehyde began to pass over. The hot liquor in the flask was filtered from tar and, on cooling, deposited 2-chloro-4-hydroxybenzaldehyde (13 g.) in pale yellow, feathery needles.

With alcoholic potash in place of the lime–soda mixture, the reaction proceeded much more vigorously and produced more tar. Aqueous sodium and potassium hydroxides gave intermediate results.

4-Chloro-2-hydroxybenzaldehyde is very volatile in steam, being removed even from its yellow solutions in caustic alkalis. It is appreciably soluble in water and sulphurous acid, readily soluble in the usual organic solvents, and crystallises from alcohol or dilute acetic acid in long, colourless needles, m. p. 52·5° (Found: Cl, 22·6. $C_7H_5O_2Cl$ requires Cl, 22·7%). It has an odour resembling that of walnuts, gives a brown precipitate with ferric chloride, does not reduce ammoniacal silver nitrate or Fehling's solution, and is very resistant to acetylation and to oxidation by acid, neutral, or alkaline potassium permanganate. Although not readily methylated, yet it benzoylates easily under suitable conditions. In aqueous solution, it gives with copper and chromium sulphates, on careful treatment with dilute aqueous sodium hydroxide, a bright green *copper* salt and a dark green *chromium* salt. The *oxime* is fairly readily soluble in hot water, easily soluble in alkalis, alcohols, and glacial acetic acid, but less soluble in chloroform, and crystallises from alcohol in colourless

needles, m. p. 155° (Found: Cl, 20·8. $C_7H_6O_2NCl$ requires Cl, 20·7%). The p-*nitrophenylhydrazone* crystallises from glacial acetic acid in orange needles, m. p. 257° (Found: Cl, 12·2. $C_{13}H_{10}O_3N_3Cl$ requires Cl, 12·2%), and gives a dark cherry-red colour with aqueous sodium hydroxide. The *semicarbazone* is readily soluble in alkalis, moderately easily soluble in alcohol, and separates from glacial acetic acid in very pale yellow clusters of micro-crystals, m. p. 212° (Found: Cl, 16·8. $C_8H_8O_2N_3Cl$ requires Cl, 16·6%). The *benzoate* is best prepared by dissolving the aldehyde (0·6 g.) in ether (2 c.c.), adding pyridine (0·1 c.c.), and then a solution of benzoyl chloride (0·5 g.) in ether (2 c.c.); after vigorous shaking, removal of the ether, and extraction of the product with warm dilute hydrochloric acid, the white, waxy residue is washed with water and crystallised from alcohol, from which it separates in long, colourless needles, m. p. 98·5° (Found: Cl, 13·5. $C_{14}H_9O_3Cl$ requires Cl, 13·6%).

4-*Chloro*-2-*methoxybenzaldehyde* is obtained in only moderate yield by direct methylation. It has a faint sweet odour, is readily soluble in the usual organic solvents, and crystallises from alcohol in colourless needles, m. p. 74° (Found: Cl, 20·9. $C_8H_7O_2Cl$ requires Cl, 20·8%).

Alternative method of preparation. 4-Nitro-2-methoxytoluene (5 g.), dissolved in alcohol (20 c.c.), was added gradually to a hot solution of sodium hydroxide (3 g.) and sulphur (2 g.) in water (30 c.c.), and the mixture was heated for an hour on the water-bath. The alcohol and 2-methoxy-*p*-toluidine were then removed in steam, and the residue (2 g.) of crude 4-amino-2-methoxybenzaldehyde was dissolved in hot dilute sulphuric acid (30%), and converted by the Sandmeyer method into 4-chloro-2-methoxybenzaldehyde; after crystallisation from alcohol, this (Found: Cl, 20·7%), alone or mixed with the substance described above, melted at 74°.

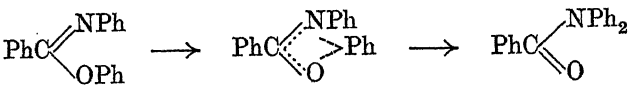
The *oxime* crystallises from hot water in long, colourless needles, m. p. 132° (Found: Cl, 19·1. $C_8H_8O_2NCl$ requires Cl, 19·1%). The p-*nitrophenylhydrazone* separates from glacial acetic acid in bright orange clusters of micro-crystals, m. p. 238° (Found: N, 13·6. $C_{14}H_{12}O_3N_3Cl$ requires N, 13·7%), and develops with alkali a less intense but more violet colour than the unmethylated *p*-nitrophenylhydrazone. The *semicarbazone* crystallises from glacial acetic acid in very pale yellow, almost colourless micro-plates, m. p. 228° (Found: Cl, 15·5. $C_9H_{10}O_2N_3Cl$ requires Cl, 15·6%). 4-*Chloro*-2-*methoxybenzoic acid*, prepared by oxidising the aldehyde with aqueous alkaline potassium permanganate, crystallises from alcohol in clusters of micro-crystals, m. p. 148° (Found: Cl, 19·1.

$C_8H_7O_3Cl$ requires Cl, 19·0%). 4-Chloro-2-hydroxybenzoic acid was obtained by boiling the preceding acid with hydriodic acid (*d* 1·7); it was slowly volatile in steam, crystallised from water in fine, colourless needles which sublimed with slight decomposition at about 209° and melted at 211° (Varnholt, *J. pr. Chem.*, 1887, **36**, 27, gives m. p. 207°) (Found: Cl, 20·4. Calc.: Cl, 20·5%), and gave a reddish-violet colour with ferric chloride.

The 2-chloro-4-hydroxybenzaldehyde obtained as described above crystallised from mineral or glacial acetic acid in colourless needles, m. p. 147—148° (Gattermann, *Annalen*, 1907, **357**, 334, gives m. p. 146·5°) (Found: Cl, 22·6%). It does not react with ammoniacal silver nitrate or Fehling's solution, and gives only a slight precipitate with ferric chloride. The *copper* and *chromium* salts are of a lighter green colour than those of the 4-chloro-isomeride. The p-*nitrophenylhydrazone* crystallises from alcohol in dark red plates and from glacial acetic acid in vermilion-red clusters of micro-crystals, m. p. 288° (decomp.) (Found: Cl, 12·1. $C_{13}H_{10}O_3N_3Cl$ requires Cl, 12·2%) and gives a bluer red with caustic alkalis than the 4-chloro-isomeride. The *semicarbazone* crystallises from alcohol in yellow clusters of micro-crystals, m. p. 214° (Found: Cl, 16·8. $C_8H_8O_2N_3Cl$ requires Cl, 16·6%), the *acetate* from dilute acetic acid in colourless needles, m. p. 51·5° (Found: Cl, 17·8. $C_9H_7O_3Cl$ requires Cl, 17·9%), and the *benzoate* from alcohol in colourless needles, m. p. 96·5° (Found: Cl, 13·6. $C_{14}H_9O_3Cl$ requires Cl, 13·6%).

2-Chloro-4-hydroxybenzaldehyde was also prepared, in almost quantitative yield, by treating 2-chloro-4-nitrotoluene with sodium hydroxide and sulphur (see above), diazotising the resulting amino-compound, and boiling the very stable diazo-compound with 40% sulphuric acid for 20 minutes.

The following derivatives were prepared in the same way as the corresponding 4-chloro-isomerides: The p-*nitrophenylhydrazone* separates from dilute acetic acid in orange-red needles, m. p. 249° (Found: N, 13·8. $C_{14}H_{12}O_3N_3Cl$ requires N, 13·7%), and gives a reddish-violet colour with aqueous-alcoholic alkali. The *semicarbazone* crystallises from alcohol in clusters of colourless micro-crystals, m. p. 240° (Found: Cl, 15·7. $C_9H_{10}O_2N_3Cl$ requires Cl, 15·6%). 2-*Chloro-4-hydroxybenzoic acid* crystallises from water (charcoal) in colourless needles, m. p. 159° (Found: Cl, 20·3. $C_7H_5O_3Cl$ requires Cl, 20·5%), and gives no definite colour with ferric chloride.



The authors desire to thank the British Dyestuffs Corporation for gifts of chemicals.

TECHNICAL COLLEGE, HUDDERSFIELD. [*Received, April 30th*, 1927.]

CCXXVII.—*Imino-aryl Ethers. Part V. The Effect of Substitution on the Velocity of Molecular Rearrangement.*

By Arthur William Chapman.

In Part III (J., 1925, **127**, 1992), it was shown that *N*-phenylbenziminophenyl ether (I) could be completely converted into benzoyldiphenylamine (II) on heating. The change, which is unimolecular, was found to be best represented in terms of partial valencies (compare Robinson, *Mem. Manc. Lit. Phil. Soc.*, 1920, **64**, No. 4; Mumm, Hesse, and Volquartz, *Ber.*, 1915, **48**, 379) thus :

(I.)  (II.)

When translated into the terms of the electronic theory, this formulation is ambiguous, since the migrating group may (*a*) carry with it both its shared electrons, (*b*) leave them behind, or (*c*) carry one and leave the other.

It seemed desirable to study the effect of replacing the migrating phenyl group in *N*-phenylbenziminophenyl ether by other groups, since according to (*a*) it would be expected that the relative attraction for electrons and the velocity of migration of different groups would follow the same order, but according to (*b*) the two values should be in the opposite order, whilst if (*c*) were correct the velocity of migration of a group should be independent of its attraction for electrons.

A number of *N*-phenylbenzimino-ethers, RO·CPh:NPh (III), having different groups (R) attached to the oxygen atom, were made and their velocities of rearrangement were compared. A special experiment showed that these changes were not appreciably reversible. It was found that the groups could be arranged in the following order of descending ease of migration : *o*-nitrophenyl > 2 : 4 : 6-trichlorophenyl > *p*-acetylphenyl > 2 : 4-dichlorophenyl > *o*-chlorophenyl > *m*-chlorophenyl > *p*-chlorophenyl and α- and β-naphthyls > phenyl and *o*-anisyl > *m*-anisyl > *p*-anisyl > methyl.

The velocities of migration of these groups are in the same order as the dissociation constants of the corresponding carboxylic acids and phenols ($R\cdot CO_2H$ and R·OH) and it must therefore be concluded that the mechanism of the isomeric change is represented by (*a*). Steric effects were evidently negligible, since the *o*-substituted compounds underwent rearrangement more rapidly than the corresponding *m*- and *p*-compounds.

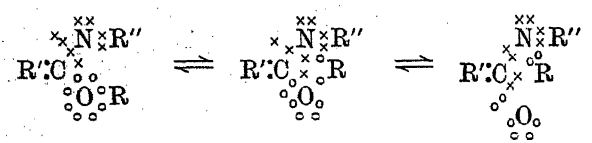
Confirmatory evidence was then sought from the effect, on the

velocity of migration of a standard (phenyl) group, of variation of the groups attached to the nitrogen and carbon atoms. A number of *N*-substituted benziminophenyl ethers (IV) and *N*-phenylaryliminophenyl ethers (V) were accordingly prepared.

(IV.) PhO·CPh:NR PhO·CR:NPh (V.)

The greater the attraction of the group R for electrons in either (IV) or (V), the less readily will the oxygen atom release the electrons which bind it to the phenyl group, and hence, according to mechanism (*a*), the lower will be the velocity of rearrangement of the imino-ether.

This was indeed found to be the case, the ease of migration of the phenyl group being in the following order: *for various groups attached to the nitrogen atom* (*type* IV) *p*-anisyl>phenyl>*p*-chlorophenyl and α-naphthyl>*m*- and *o*-chlorophenyl and 2 : 4-dichlorophenyl>2 : 4 : 6-trichlorophenyl, *and for various groups attached to the carbon atom* (*type* V) *p*-anisyl>phenyl>*p*- and *o*-chlorophenyl>*p*-nitrophenyl and 2 : 4 : 6-trichlorophenyl.



The isomeric change to a substituted amide which occurs when an imino-ether is heated at a sufficiently high temperature,

$$RO(\text{or } RS)\cdot CR'{:}NR'' \rightleftharpoons O(\text{or } S){:}CR'\cdot NRR'',$$

has now been studied in some detail (compare Part III, *loc. cit.*; Part IV, J., 1926, 2296). The rearrangement has been shown to be intramolecular and does not require any detectable amount of a catalyst. The behaviour of the imino-thioethers showed that, as might be expected, the change is reversible, but in the oxygen ethers equilibrium occurs so far over to the amide side that the reversibility is not appreciable.

The velocity of isomeric change varies greatly with the nature of the migrating group and of the groups attached to the carbon and nitrogen atoms. The greater the attraction of the migrating group for electrons (*i.e.*, the more "negative" it is) the greater the velocity of change, whilst negative groups attached to the carbon and nitrogen atoms retard the rearrangement.

These facts are readily explicable on the assumption that the migrating group carries over to the nitrogen atom the two covalency electrons by which it is bound to the oxygen atom, and the isomeric change can be expressed in symbolic form thus:

(where × represents an electron originally belonging to the nitrogen octet, and o one belonging to the oxygen octet).

The iminoether–amide rearrangement is a typical triad change, and it seems highly probable that the mechanism of a number of other such changes will be found to be explicable in similar terms.

EXPERIMENTAL.

The new imino-ethers required were prepared from the corresponding anilideiminochlorides and phenols by the method used for preparing *N*-phenylbenzimino-*m*-hydroxyphenyl ether (J., 1922, **121**, 1679). Unless otherwise stated, they were crystallised from alcohol, in which they were readily soluble when hot, but only sparingly soluble in the cold.

They were converted into the corresponding amides by heating at 280—310°, the products being purified by crystallisation from alcohol. Where possible, the amides thus obtained were compared directly with specimens prepared by other methods. The identity of two samples of a compound obtained from different sources was always confirmed by the method of mixed melting points.

N-*Phenylbenzimino*-m-*chlorophenyl ether* crystallised in colourless needles, m. p. 71° (Found : N, 4·6. $C_{19}H_{14}ONCl$ requires N, 4·55%). On heating, it was converted into benzoyl-*m*-chlorodiphenylamine (m. p. 101—102°; identical with an authentic specimen).

N-*Phenylbenzimino*-2 : 4-*dichlorophenyl ether*, pale yellow, slender prisms, m. p. 73—74° (Found : N, 4·2. $C_{19}H_{13}ONCl_2$ requires N, 4·1%).

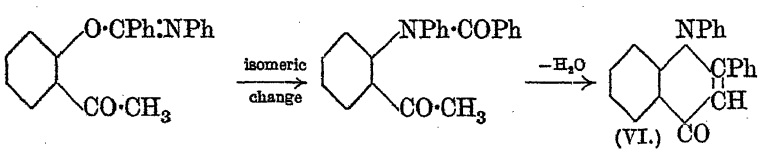
N-*Phenylbenzimino*-2 : 4 : 6-*trichlorophenyl ether*, colourless plates, m. p. 80—81° (Found : N, 3·95. $C_{19}H_{12}ONCl_3$ requires N, 3·7%).

N-*Phenylbenzimino*-o-*anisyl ether*, colourless, slender prisms, m. p. 113° (Found : N, 4·7. $C_{20}H_{17}O_2N$ requires N, 4·6%).

N-*Phenylbenzimino*-m-*anisyl ether* was obtained as a viscous oil which did not crystallise even after standing for 18 months (Found : N, 4·45%). The product of heating this imino-ether was also not obtained in crystalline form.

N-*Phenylbenzimino*-p-*anisyl ether*, colourless plates, m. p. 79—80° (Found : N, 4·8%).

N-*Phenylbenzimino*-p-*nitrophenyl ether*, pale yellow plates, m. p. 76—77° (Found : N, 8·9. $C_{19}H_{14}O_3N_2$ requires N, 8·8%). All attempts to cause this imino-ether to undergo isomeric change were unsuccessful. Decomposition with formation of tar occurred even at 150°.



N-*Phenylbenzimino*-α-*naphthyl ether* crystallised from light petroleum in crusts, m. p. 89° (Found : N, 4·6. $C_{23}H_{17}ON$ requires

N, 4·3%). On heating, it gave benzoylphenyl-α-naphthylamine (m. p. 152°; identical with an authentic specimen).

N-*Phenylbenzimino*-β-*naphthyl ether* crystallised in thin leaflets from alcohol, in which it was only sparingly soluble at the boiling point; m. p. 127—128° (Found: N, 4·5%). It was hydrolysed by 50% sulphuric acid to β-naphthyl benzoate (m. p. 106—106·5°) and on heating gave benzoylphenyl-β-naphthylamine (m. p. 147°; identical with an authentic specimen).

N-*Phenylbenzimino*-p-*acetylphenyl ether*, m. p. 94—95° (Found: N, 4·6. $C_{21}H_{17}O_2N$ requires N, 4·45%).

N-*Phenylbenzimino*-o-*acetylphenyl ether*, m. p. 92—93° (Found: N, 4·6%). Instead of yielding benzoyl-*o*-acetyldiphenylamine when heated, it was converted into a basic compound, which crystallised from alcohol in thin leaves, m. p. 268°. The change was practically complete in 90 minutes at 267° (Found: C, 85·1; H, 5·1; N, 4·8; *M*, by Rast's micro-method, 285. $C_{21}H_{17}O_2N$ requires C, 80·0; H, 5·4; N, 4·45%; *M*, 315. $C_{21}H_{15}ON$ requires C, 84·8; H, 5·1; N, 4·7%; *M*, 297). The loss of a molecule of water had evidently occurred and 1 : 2-*diphenyl*-4-*quinolone* (VI) was formed thus,

the second stage being analogous to the formation of 4-hydroxy-2-phenylquinoline from benzoyl-*o*-aminoacetophenone (Camps, *Arch. Pharm.*, 1901, **239**, 597).

N-o-*Chlorophenylbenziminophenyl ether*, prepared from *benz*-o-*chloroanilideiminochloride* (b. p. 204°/10 mm.) and phenol, crystallised in slender prisms, m. p. 65—66° (Found: N, 4·4. $C_{19}H_{14}ONCl$ requires N, 4·55%). On heating, it was converted into benzoyl-*o*-chlorodiphenylamine (m. p. 95°; identical with an authentic specimen).

N-m-*Chlorophenylbenziminophenyl ether*, prepared from *benz*-m-*chloroanilideiminochloride* (b. p. 211—213°/14 mm.), crystallised in rosettes of pale yellow, stout prisms, m. p. 66° (Found: N, 4·5%). It gave benzoyl-*m*-chlorodiphenylamine on heating (m. p. 100—101°; identical with an authentic specimen).

N-p-*Chlorophenylbenziminophenyl ether*, prepared from *benz*-p-*chloroanilideiminochloride* (b. p. 220—224°/20 mm.), formed stout prisms, m. p. 110° (Found: N, 4·4%). It yielded benzoyl-*p*-chlorodiphenylamine on heating (m. p. 110°; identical with an authentic specimen).

N-2 : 4-*Dichlorophenylbenziminophenyl ether*, stout prisms, m. p. 57—58° (Found : N, 4·0. $C_{19}H_{13}ONCl_2$ requires N, 4·1%). In this and several subsequent preparations the iminochloride was not distilled, but, after treatment of the anilide with phosphorus pentachloride and removal of the phosphorus oxychloride under reduced pressure on the water-bath, the residue was dissolved in dry ether and added directly to an alcoholic solution of sodium phenoxide.

N-2 : 4 : 6-*Trichlorophenylbenziminophenyl ether*, stout prisms, m. p. 88·5° (Found : N, 3·8. $C_{19}H_{12}ONCl_3$ requires N, 3·7%).

N-2 : 4 : 6-*Trichlorophenylbenzimino*-2 : 4 : 6-*trichlorophenyl ether*, colourless needles, m. p. 141°, sparingly soluble in boiling alcohol (Found : N, 3·0. $C_{19}H_9ONCl_6$ requires N, 2·9%). Heated at 250—260° for 2 hours, it was mostly recovered unchanged, but at 280—300° *benzoyl*-2 : 4 : 6 : 2′ : 4′ : 6′-*hexachlorodiphenylamine* (m. p. 194—195°. Found : N, 3·0%) was produced. The isomerisation of this imino-ether was therefore much slower than that of the corresponding *N*-phenylbenzimino-2 : 4 : 6-trichlorophenyl ether.

N-p-*Anisylbenziminophenyl ether*, prepared from *benz*-p-*anisidideiminochloride* (yellow flakes, m. p. 55°, b. p. 269—273°/162—180 mm. with some decomposition), formed yellow crystals, m. p. 100° (Found : N, 4·6. $C_{20}H_{17}O_2N$ requires N, 4·6%).

N-o-*Nitrophenylbenziminophenyl ether*, stout prisms, m. p. 67—68° (Found : N, 9·0. $C_{19}H_{14}O_3N_2$ requires N, 8·8%). Several unsuccessful attempts to cause rearrangement of this imino-ether were made. At 200—220°, it remained unchanged and above that temperature decomposed, giving much tar.

N-α-*Naphthylbenziminophenyl ether* formed a very viscous oil which would not crystallise (Found : N, 4·1. $C_{23}H_{17}ON$ requires N, 4·3%). On heating, it underwent isomeric change into benzoylphenyl-α-naphthylamine (m. p. 148—150°; identical with an authentic specimen).

N-*Methylbenziminophenyl ether* was prepared by Hantzsch's method (*Ber.*, 1893, **26**, 926) from benzmethylamideiminochloride and solid sodium phenoxide. It was obtained as colourless crystals, m. p. 30—31° (Found : N, 6·5. $C_{14}H_{13}ON$ requires N, 6·6%). On hydrolysis with 50% sulphuric acid, phenyl benzoate (m. p. 69—70°; not depressing the m. p. of an authentic specimen) was obtained. This imino-ether also decomposed without undergoing isomeric change.

N-*Phenyl*-o-*chlorobenziminophenyl ether*, prepared from o-*chlorobenzanilideiminochloride* (yellow prisms, m. p. 59°, b. p. 235°/60 mm.), formed colourless plates, m. p. 100° (Found : N, 4·8. $C_{19}H_{14}ONCl$ requires N, 4·55%).

N-*Phenyl*-p-*chlorobenziminophenyl ether*, from p-*chlorobenzanilide*

iminochloride (b. p. 219°/17 mm.), formed pale yellow crusts, m. p. 64—65° (Found : N, 4·3%).

N-*Phenyl*-2 : 4 : 6-*trichlorobenziminophenyl ether*, colourless prisms, m. p. 94—95° (Found : N, 3·5. $C_{19}H_{12}ONCl_3$ requires N, 3·7%).

N-*Phenyl*-p-*methoxybenziminophenyl ether*, m. p. 86—87° (Found : N, 4·4. $C_{20}H_{17}O_2N$ requires N, 4·6%). This compound appeared to be dimorphous. On crystallisation from alcohol, long needles first appeared. These gradually dissolved and were replaced by stout prisms. No difference in the m. p.'s of the two forms was observed.

N-*Phenyl*-o-*nitrobenziminophenyl ether*, thin leaves, m. p. 141—142° (Found : N, 9·0. $C_{19}H_{14}O_3N_2$ requires N, 8·8%). Heated for 2 hours at 230—240°, the material remained practically unchanged. Above this temperature it decomposed, yielding a coke-like residue.

N-*Phenyl*-p-*nitrobenziminophenyl ether*, long, yellow prisms, m. p. 102—102·5° (Found : N, 8·55%).

Benzoyl-2 : 4-*dichlorodiphenylamine*, obtained by heating either *N*-phenylbenzimino-2 : 4-dichlorophenyl ether or *N*-2 : 4-dichlorophenylbenziminophenyl ether, formed crusts, m. p. 109° (Found : N, 4·2. $C_{19}H_{13}ONCl_2$ requires N, 4·1%).

Benzoyl-2 : 4 : 6-*trichlorodiphenylamine* was prepared from *N*-phenylbenzimino-2 : 4 : 6-trichlorophenyl ether and *N*-2 : 4 : 6-trichlorophenylbenziminophenyl ether and obtained in long prisms, m. p. 149° (Found : N, 3·75. $C_{19}H_{12}ONCl_3$ requires N, 3·7%).

Benzoyl-o-*methoxydiphenylamine*, prepared from *N*-phenylbenzimino-*o*-anisyl ether, formed hard crusts, m. p. 117° (Found : N, 4·7. $C_{20}H_{17}O_2N$ requires N, 4·6%).

Benzoyl-p-*methoxydiphenylamine*, obtained from either *N*-phenylbenzimino-*p*-anisyl ether or *N*-*p*-anisylbenziminophenyl ether, formed slender prisms, m. p. 121° (Found : N, 4·8%).

Contrary to the statement of Mumm, Hesse, and Volquartz (*loc. cit.*), *N*-phenylbenzimino-*o*-nitrophenyl ether underwent isomeric change at 165°. The dark oil obtained by heating this imino-ether (10 g.) for 1 hour at 165° was covered with ether; *benzoyl*-o-*nitrodiphenylamine* (4 g.) slowly crystallised in yellowish leaves, m. p. 134° (unchanged by recrystallisation from alcohol) (Found : N, 8·8. $C_{19}H_{14}O_3N_2$ requires N, 8·8%).

Benzoyl-p-*acetyldiphenylamine*, prepared from *N*-phenylbenzimino-*p*-acetylphenyl ether, formed leaves, m. p. 136—137·5° (Found : N, 4·4. $C_{21}H_{17}O_2N$ requires N, 4·45%).

Each of the following five amides was prepared by heating the corresponding imino-ether, and also from diphenylamine and the appropriate acid chloride.

o-*Chlorobenzoyldiphenylamine*, large prisms, m. p. 142—143° (Found : N, 4·8. $C_{19}H_{14}ONCl$ requires N, 4·55%).

p-*Chlorobenzoyldiphenylamine*, fine leaves, m. p. 138—138·5° (Found : N, 4·3%).

2 : 4 : 6-*Trichlorobenzoyldiphenylamine*, flat prisms, m. p. 118—119° (Found : N, 3·6. $C_{19}H_{12}ONCl_3$ requires N, 3·7%).

p-*Methoxybenzoyldiphenylamine*, prisms, m. p. 139—140° (Found : N, 4·3. $C_{20}H_{17}O_2N$ requires N, 4·6%).

p-*Nitrobenzoyldiphenylamine*, yellow prisms, m. p. 156—157° (Found : N, 9·05. $C_{19}H_{14}O_3N_2$ requires N, 8·8%).

2 : 4 : 6-*Trichlorobenzanilide*, prepared from 2 : 4 : 6-trichlorobenzoyl chloride and aniline, formed long needles, m. p. 197° (Found : N, 4·4. $C_{13}H_8ONCl_3$ requires N, 4·7%).

Comparison of the Rates of Change of the Imino-ethers.—The comparison was made by measuring the amount of change which took place when each compound was heated for a given time at a definite temperature. Test-tubes, each containing 2 g. of an imino-ether, were immersed together for the standard time (90 minutes) in a thermostat, strictly comparable results thus being obtained even if slight fluctuations occurred in the temperature.

As many of the mixtures thus obtained exhibited great reluctance to crystallise from the fused material, analysis by melting- or freezing-point methods was excluded, and therefore the following chemical method was adopted.

About 0·5 g. of the mixture was weighed into a stoppered flask and dissolved in dry ether, 25 c.c. of an approximately *N*/5-solution of sulphuric acid in dry ether were added, and the mixture was kept for 3 hours to permit complete separation of the imino-ether sulphate as crystals or as an oil. The liquid was then filtered into a separating funnel containing water, the residue and the filter were washed with a little dry ether, and the contents of the funnel were shaken and titrated with *N*/5-sodium hydroxide and phenolphthalein. The difference between this titration and a blank, in which 25 c.c. of the standard acid were used, corresponded with the amount of imino-ether in the weighed material. The estimation was carried out in duplicate.

Control experiments showed that this process gave results agreeing to within a few units % with the calculated figure, the imino-ether sulphate being assumed to have the formula $RO{\cdot}CR{:}NR,H_2SO_4$. The error appeared to be constant for each imino-ether and the results in the tables below have been corrected accordingly—the corrections do not affect the arrangement of the imino-ethers in order of ease of isomeric change.

The imino-ethers containing the 2 : 4 : 6-trichlorophenyl group and *N*-phenylbenzimino-*o*-nitrophenyl ether did not give insoluble sulphates by this method, and the products obtained from them

were examined separately. In the case of *N*-phenylbenzimino-2 : 4 : 6-trichlorophenyl ether, the melting points of the heated samples were compared with those of known mixtures of the imino-ether and benzoyl-2 : 4 : 6-trichlorodiphenylamine. The products from the *N*- and *C*-trichlorophenyl compounds were crystallised from alcohol, and the unchanged compounds weighed. *N*-Phenylbenzimino-*o*-nitrophenyl ether underwent rearrangement at so low a temperature as to leave no doubt as to its position in the series.

The change of *N*-phenylbenziminomethyl ether was studied separately by Lander's method (J., 1903, **83**, 406) : 10 g., heated in a sealed tube at 300—330° for 2 hours, gave 2·5 g. of benzoylmethylaniline (m. p. after recrystallisation 57° ; did not depress the m. p. of an authentic specimen).

The results obtained were as follows :

O-*Substituted ethers*, RO·CPh:NPh.

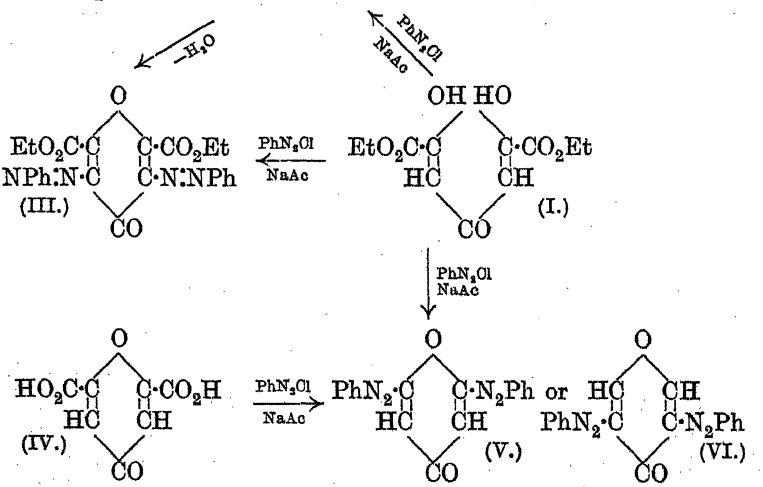
Benzoyl-2 : 4 : 6-trichlorodiphenylamine and benzoyl-*p*-methoxydiphenylamine were unchanged after heating for 1 hour at 240—250°

and 250—270°, respectively, showing that the isomeric changes into these compounds were not appreciably reversible.

Part of the cost of this research has been defrayed by a grant from the Research Fund of the Chemical Society, to whom the author desires to express his thanks.



THE UNIVERSITY, SHEFFIELD. [*Received, May 3rd*, 1927.]

CCXXVIII.—*The Action of Diazonium Salts on Pyrones and their Parent Substances. Part I.*

By REGINALD THOMAS MULLEN and WILLIAM HAUGHTON CROWE.

IN connexion with the unsettled question of the constitution of mixed aliphatic aromatic azo-compounds, evidence in favour of the azo-structure has now been obtained, since ethyl acetonedioxalate (I), on treatment with benzenediazonium chloride in presence of sodium acetate, yields a mixture of *ethyl dibenzeneazoacetonedioxalate* (II) and *ethyl dibenzeneazochelidonate* (III). The former, on boiling with alcohol, loses water, ethyl dibenzeneazochelidonate being formed, with an ease that suggests the azo-structure.

$CO_2Et{\cdot}CO{\cdot}CH(N_2Ph){\cdot}CO{\cdot}CH(N_2Ph){\cdot}CO{\cdot}CO_2Et$ (II.)

Chelidonic acid (IV) reacts with benzenediazonium chloride to give an azopyrone (V or VI), formula (V) being the more probable because this substance could not be obtained by hydrolysis of the ester (III). The azopyrone was also formed to some extent during

the reaction between benzenediazonium chloride and ethyl acetonedioxalate. The replacement of carboxyl by azo-groups has been observed in other cases (compare Japp and Klingeman, J., 1888, **53**, 519; Bamberger, *Ber.*, 1892, **25**, 3547).

In the presence of sodium acetate, benzenediazonium chloride reacts with 2 : 6-dimethylpyrone and with diacetylacetone to give 3-*benzeneazo*-2 : 6-*dimethylpyrone* and 3 : 5-*dibenzeneazo*-2 : 6-*dimethylpyrone*, respectively.

Experimental.

Ethyl Dibenzeneazoacetonedioxalate (II).—Ethyl acetonedioxalate (prepared by Claisen's method, *Ber.*, 1891, **24**, 111, which gives a better yield than Willstätter's, *Ber.*, 1904, **37**, 3734) (7·8 g.) was added to an aqueous solution of benzenediazonium chloride (from aniline, 5 g., and hydrochloric acid, 13 c.c.). Addition of alcohol (59 c.c.) and much sodium acetate produced a heavy, red precipitate, which was filtered off and thoroughly washed by grinding with water; the aqueous-alcoholic filtrate slowly deposited a chocolate-coloured substance. The red product was crystallised from 80% alcohol and then from benzene–light petroleum (40% benzene), large, dark red prisms, m. p. 130°, soluble in organic solvents, being obtained (Found: C, 59·2; N, 12·0. $C_{23}H_{22}O_7N_2$ requires C, 59·2; N, 12·0%).

Ethyl Dibenzeneazochelidonate (III).—When the red precipitate formed by diluting the alcoholic filtrate from the crystallisation of the foregoing substance with water was crystallised from benzene–light petroleum, red needles were obtained, m. p. 117°, of a substance which was identical with that formed when ethyl dibenzeneazoacetonedioxalate was boiled with alcohol and the product crystallised (Found: C, 61·4; H, 4·5; N, 12·5. $C_{23}H_{20}O_6N_4$ requires C, 61·6; H, 4·5; N, 12·5%). It was readily soluble in organic solvents.

2 : 6-*Dibenzeneazopyrone*.—The chocolate-brown substance mentioned above crystallised from alcohol in chocolate-brown prisms, m. p. 131°, which were soluble in the common organic solvents (Found: N, 18·4. $C_{17}H_{12}O_2N_4$ requires N, 18·4%).

Action of Benzenediazonium Chloride on Chelidonic Acid.—Chelidonic acid (3 g.), obtained by repeatedly evaporating ethyl acetonedioxalate with concentrated hydrochloric acid (Claisen, *loc. cit.*), was added to a solution of benzenediazonium chloride (aniline, 5 g.; hydrochloric acid, 13 c.c.; water, 30 c.c.: sodium nitrite, 5 g.; water, 15 c.c.). The brown precipitate obtained on addition of an excess of sodium acetate crystallised from alcohol in chocolate-brown prisms, m. p. 131° (Found: C, 67·1; H, 3·6; N, 18·4%). A mixed-melting point proved this substance to be 2 : 6-dibenzeneazopyrone (above).

3-*Benzeneazo*-2 : 6-*dimethylpyrone*.—A solution of benzenediazonium chloride at 0° (aniline, 13 g.; hydrochloric acid, 26 c.c.; water, 60 c.c.: sodium nitrite, 13 g.; water, 30 c.c.) was treated with dimethyl pyrone (6 g.) and then with sodium acetate. After 2 days, the tarry product was filtered off and extracted several times with light petroleum–benzene (90% light petroleum); the *pyrone* obtained from the extract crystallised from light petroleum–benzene in yellow leaflets, m. p. 92° (Found : N, 12·5. $C_{13}H_{12}O_2N_2$ requires N, 12·3%).

3 : 5-*Dibenzeneazo*-2 : 6-*dimethylpyrone*.—To a solution of benzenediazonium chloride (aniline, 4·3 g.; hydrochloric acid, 9 c.c.; water, 20 c.c. : sodium nitrite, 4·3 g., in water, 10 c.c., was added until a blue colour was obtained on starch–iodide paper), diacetylacetone (2·5 g., prepared by boiling dimethylpyrone with baryta, acidifying the solution, and extracting it with ether; *Annalen*, 1890, **251**, 256) was added, followed by sodium acetate. The solution became yellow and then a light red substance was slowly precipitated. After 12 hours, this was filtered off, washed with cold water, and crystallised from benzene, from which it separated in light red needles, m. p. 150° (Found : N, 16·8. $C_{19}H_{16}O_2N_4$ requires N, 16·9%). It was soluble in organic solvents, but insoluble in water.

The authors wish to express their indebtedness to Professor J. N. Collie, F.R.S., and Professor A. W. Stewart for their interest in this research.

CCXXIX.—*Metallic Hydroxy-acid Complexes. Part IV. Complexes formed by Copper with the Monobasic Monohydroxy-acids.*

By IAN WILLIAM WARK.

THE author has suggested (J., 1923, **123**, 1816) that the stability of the metallic derivatives of a hydroxy-acid may be expected to increase with the acidity of the hydroxylic hydrogen. Thus, although the derivatives of lactic acid (*loc. cit.*) and of glycollic acid (Pickering, J., 1911, **99**, 1347) are easily hydrolysed, it was anticipated that the increased acidity of the hydroxyl group in mandelic and salicylic acids would lead to the formation of more stable complexes. These conclusions have now been verified experimentally.

It has previously been shown that the composition of sodium cuprilactate is most probably $Na_2[(\cdot O\cdot CHMe\cdot CO_2\cdot)_2Cu]$. In order to ascertain whether this compound is representative of a general series formed by the simpler hydroxy-acids, some work with the complexes formed by glycollic, mandelic, and salicylic * acids has been undertaken, and has established the fact that sodium cuprilactate is a definitely representative compound.

After a satisfactory general method of attack had been devised, it seemed desirable to ascertain whether the dihydroxy-phenols and the amino-acids would yield to a similar treatment. Accordingly, the copper derivatives of pyrocatechol and glycine were treated in alcoholic solution with sodium methoxide. Although blue complexes were formed in each case, no stable derivative could be isolated; and the complexes readily decomposed with the precipitation of cuprous or cupric oxide. Cupric phenylglycine is practically insoluble in a solution of sodium methoxide.

The constitution of the complexes will be discussed in a subsequent communication.

Experimental.

A. *Preparations in Aqueous Solution.*

Cuprimandelates.—Cupric *i*-mandelate (Winkler, *Annalen*, 1836, **18**, 320), which is anhydrous when dried at 100°, was obtained as a pale blue, sparingly soluble monohydrate by mixing solutions of sodium mandelate and cupric chloride [Found: Cu, 16·3; H_2O, 5·2. $Cu(C_8H_7O_3)_2,H_2O$ requires Cu, 16·6; H_2O, 4·7%].

Action of alkali on cupric mandelate. Since cupric mandelate is not wetted by water, it was necessary to wet it with alcohol in order to effect solution in alkali. Two equivs. of caustic soda ($N/2$) dissolve 1 mol. of the mandelate, presumably according to the equation $2NaOH + Cu(C_8H_7O_3)_2 = 2H_2O + Na_2[Cu(C_8H_6O_3)_2]$. This solution deposits cupric hydroxide on standing. It may be stabilised by the addition of excess of sodium mandelate [compare cupric lactate (*loc. cit.*, where the reasons for this stabilising effect have been discussed)].

After the addition of slightly less than two equivs. of caustic soda, the solution becomes alkaline to phenolphthalein, but provided that

* The aromatic β-hydroxy-acids of the salicylic acid type resemble the aliphatic α-hydroxy-acids with respect to complex formation (Weith, *Ber.*, 1876, **9**, 342; Pickering, J., 1912, **101**, 174; Beilstein, 3rd Edn., II, 1492; Piria, *Ann. Chem. Pharm.*, 1855, **17**, 262). Piria states that cupric salicylate readily gives moderately stable derivatives, $K_2[Cu(C_7H_4O_3)_2],4H_2O$ and $Ba[Cu(C_7H_4O_3)_2],4H_2O$, resembling the above cuprilactate, but he gives no experimental detail or analytical figures in support of this contention. Kahlenberg (*Z. physikal. Chem.*, 1895, **17**, 577) has found that, in the presence of sulphate ions, the concentration of the copper ions in a solution containing the complex cuprisalicylate is of a low order of magnitude.

a sufficient excess of the sodium mandelate is present, further addition of caustic soda does not precipitate cupric hydroxide, even in boiling solution. Such an alkaline solution, however, readily oxidises glucose.

Salts of Cuprimandelic Acid.—I. *Sodium cuprimandelate,* $Na_2[Cu(C_8H_6O_3)_2]$.

The chemistry of this compound is discussed in Section B.

II. *Sodium hydrogen cuprimandelate,* $NaH[Cu(C_8H_6O_3)_2]$. A concentrated solution of 1 mol. of cupric mandelate in 2 mols. of caustic soda, which has been stabilised by the addition of sodium mandelate, deposits slowly on standing a copious crop of fine, pale blue crystals. These are but slightly soluble in water. Analysis showed them to contain sodium and copper in the proportion 1 : 1, whereas the synthetic proportion was 2 : 1 {Found : Na, 5·2; Cu, 13·4; H_2O, 15·6. $NaH[Cu(C_8H_6O_3)_2],4H_2O$ requires Na, 5·0; Cu, 13·8; H_2O, 15·7%}. Evidently as the compound separates some alkali is liberated; if the solution is exposed to the air, carbon dioxide is absorbed and crystals of sodium carbonate begin to form. This compound is regarded as an acid salt, for 1 mol. of caustic soda dissolves it according to the equation $NaH[Cu(C_8H_6O_3)_2] + NaOH = Na_2[Cu(C_8H_6O_3)_2] + H_2O$, but again, on evaporation, the pale blue acid salt crystallises out. Cuprimandelic acid must be considered a fairly weak acid if carbonic acid is able to extract some of the alkali from its normal salt in this way, even when allowance is made for the fact that the acid salt is rather sparingly soluble.

III. *Silver cuprimandelate.* A neutral solution of sodium cuprimandelate, prepared by treating an excess of cupric mandelate * with caustic soda solution, is rapidly filtered into a solution of the calculated quantity of silver nitrate; a pale blue precipitate of *silver cuprimandelate* is formed immediately: $Na_2[Cu(C_8H_6O_3)_2] + 2AgNO_3 = 2NaNO_3 + Ag_2[Cu(C_8H_6O_3)_2]$. The salt is quite stable on boiling, but darkens after exposure to light for several months {Found : Ag, 36·8; Cu, 11·4. $Ag_2[Cu(C_8H_6O_3)_2]$ requires Ag, 37·3; Cu, 11·0%}. (The author is indebted to Mr. W. J. Lawrence for this analysis and that of the following mercurous salt.)

IV. *Mercurous cuprimandelate* may be prepared in a like manner to the silver salt, which it resembles in appearance {Found : Hg, 47·4; Cu, 7·2. $Hg_2[Cu(C_8H_6O_3)_2],5H_2O$ requires Hg, 46·9; Cu, 7·4%}. On prolonged heating, the mercury volatilises with the water of crystallisation, leaving pure cupric mandelate.

V. *Ferric cuprimandelate* also may be prepared by double decomposition. If excess of ferric chloride be present, a yellow or red solution is formed. With calculated quantities of the reagents, a

* It is advisable to use only small quantities of the cupric mandelate and to work rapidly, for the solution of sodium cuprimandelate is somewhat unstable

yellowish-brown, crystalline precipitate forms on boiling {Found : Fe, 7·5; Cu, 12·7; H_2O, 16·8. $Fe_2[Cu(C_8H_6O_3)_2]_3,14H_2O$ requires Fe, 7·7; Cu, 13·1; H_2O, 17·3%}.

VI. *Cupric cuprimandelate* was prepared as a pale blue, crystalline powder by double decomposition {Found : Cu, 29·3.

$$Cu[Cu(C_8H_6O_3)_2]$$

requires Cu, 29·6%}. There was no loss in weight on heating to 130°.

B. *Preparations in Non-aqueous Solvents.*

The main difficulties encountered in the present work arise from the ease with which the complexes are hydrolysed. Hence it was decided to use cupric salicylate, which is soluble in alcohol, acetone, and even chloroform, and exclude all traces of water. Later, it was found possible to deal in a similar manner with the mandelate, glycollate, and lactate, although they themselves are practically insoluble in these solvents.

I. *Sodium Cuprisalicylate.*—As a starting point, normal cupric salicylate is readily obtained by the method outlined by Pickering (*loc. cit.*). Piria (*loc. cit.*) has reported that this compound easily breaks down into free salicylic acid and the basic salicylate. Indeed, on prolonged heating at 110°, some of the acid volatilises, leaving dark brown patches of the basic salt, which should be regarded as the cupric salt of cuprisalicylic acid, $Cu[Cu(C_7H_4O_3)_2]$. Normal cupric salicylate crystallises both from alcohol and from acetone with solvent of crystallisation. Solutions in both solvents readily deposit dull green crystals of the basic salt. To a solution of cupric salicylate in ethyl alcohol was added an alcoholic solution of sodium ethoxide, such that the proportion was approximately 2Na : Cu. A pale green crystalline precipitate formed immediately and was collected, washed, and dried over concentrated sulphuric acid in a vacuum desiccator. It is soluble in water but rapidly undergoes hydrolysis to cupric hydroxide {Found : Cu, 16·3; Na, 12·3. $Na_2[Cu(C_7H_4O_3)_2]$ requires Cu, 16·6; Na, 12·1%}.

II. *Sodium Cuprimandelate.*—It was pointed out in Section A that disodium cuprimandelate cannot be isolated readily from its aqueous solution. It can, however, be obtained by dissolution of 1 mol. of anhydrous cupric mandelate in an alcoholic solution of 2 mols. of sodium ethoxide :

$$2NaOEt + Cu(C_8H_7O_3)_2 = Na_2[Cu(C_8H_6O_3)_2] + 2EtOH.$$

This solution was rapidly filtered while hot, and on standing overnight pale blue crystals separated {Found : Na, 9·2; Cu, 12·7. $Na_2[Cu(C_8H_6O_3)_2],2C_2H_5{\cdot}OH$ requires Na, 9·2; Cu, 12·7%}. The loss in weight on drying at 90° was 17·8% (Calc. for $2C_2H_5{\cdot}OH$, 18·3%); at 100° the compound gradually decomposed giving the odour of benzaldehyde.

III. *Sodium Cupriglycollate.*—Cupric glycollate, the starting point, has been described by Pickering (J., 1911, **99**, 1347), Fahlburg (*J. pr. Chem.*, 1873, **7**, 339), and Heintz (J., 1861, **14**, 439). Pickering and Kahlenberg (*loc. cit.*) have both investigated the action of aqueous alkalis upon this salt. Pickering came to the conclusion that for the formation of a neutral complex the ratio KOH : Cu was 1·64, and by the addition of alcohol he precipitated from the colloidal solution so formed an emulsion in which K : Cu = 1 : 1. These conclusions, if verified, would stamp the glycollate as being quite exceptional. Pickering also described a strongly alkaline compound in which the proportion was 2K : Cu.

Finely powdered, anhydrous cupric glycollate, although it dissolves in an alcoholic solution of sodium ethoxide, readily gives rise to an insoluble derivative. Consequently, sodium methoxide was substituted: $2NaOMe + Cu(C_2H_3O_3)_2 = Na_2[Cu(C_2H_2O_3)_2] + 2MeOH$. A fine crop of bright blue crystals formed over-night {Found: Na, 13·7; Cu, 19·0; loss at 110°, 23·2. $Na_2[Cu(C_2H_2O_3)_2],2\frac{1}{2}CH_3{\cdot}OH$ requires Na, 13·6; Cu, 18·8; $2\frac{1}{2}CH_4O$, 23·7%}. At temperatures higher than 110°, decomposition occurred. An aqueous solution deposited copper hydroxide in a few minutes.

IV. *Sodium Cuprilactate.*—The reactions of this compound in aqueous solution were discussed in an earlier paper (*loc. cit.*). Finely powdered, anhydrous cupric lactate, dissolved in the theoretical quantity of sodium ethoxide, deposits slowly on standing a pale violet, crystalline salt of low density {Found: Na, 12·8; Cu, 16·6; loss at 110°, 13·1. $Na_2[Cu(C_3H_4O_3)_2],2C_2H_6O$ requires Na, 12·2; Cu, 16·8; $2C_2H_6O$, 12·2%}. Heating to higher temperatures rapidly decomposed the compound.

C. *Measurements of Hydrogen-Ion Concentration.*

Darmois (*J. Phys. Radium*, 1924, [vi], **5**, 225), using the quinhydrone electrode, has investigated the action of caustic soda on cupric malate (compare J., 1923, **123**, 1831). He followed the effect produced by the gradual addition of alkali to a solution containing cupric malate, confirming the results of the work cited above. It seemed that this method, which owes its application to the fact that the electrode functions whilst there is still insufficient hydrogen present to allow the reaction $Cu^{\cdot\cdot} + H_2 = 2H^{\cdot} + Cu$ to proceed, would be useful in deciding quickly, without the necessity for laborious analyses such as have been outlined in the preceding sections, whether all these cupric salts behaved in a similar manner to the cupric mandelate, the derivatives of which were, at the time, the only series which had been investigated.

The method failed when any alkali metal was present, for the quinhydrone was oxidised and a deposit of cuprous oxide formed

However, some useful results were obtained before alkali had been added. According to the views advanced by the author, the cupric salts from which the complexes are derived are usually isomeric with the parent acids of the complexes themselves. Thus it was shown that cupric malate, $CuC_4H_4O_5$, is isomeric with cuprimalic acid, $H{\cdot}CuC_4H_3O_5$, and that in solution both compounds exist side by side. Likewise one might expect isomerism between cupric lactate and cuprilactic acid, cupric salicylate and cuprisalicylic acid, etc. Hence it seemed advisable to estimate roughly the hydrogen-ion concentrations in solutions of the various cupric salts under investigation. The quinhydrone electrode is useful for this purpose, and the results were checked by means of indicators, as shown in the following table.

	Cupric salt employed.	Salicylate.	Glycollate.	Lactate.
p_H	By indicators	4	5	5
	By quinhydrone–quinol electrode	3·5	4·7	4·7

Cupric salicylate is markedly acidic compared with the glycollate or lactate. One might expect, therefore, that cuprisalicylic acid would be a stronger acid than cuprilactic or cupriglycollic acid, and that its salts would be more stable—a prediction abundantly verified by experiment. It is unfortunate that cupric mandelate is not sufficiently soluble to enable a comparison with the other salts to be made.

Summary.

1. It has been shown that several monobasic monohydroxy-acids, *viz.*, lactic, mandelic, glycollic, and salicylic acids, all give rise to similar copper-containing complex acids.

2. The sodium salts of these complex acids have been isolated from alcoholic solutions. Their formulæ are of the type

$$Na_2[(\cdot O\cdot CHR\cdot CO_2\cdot)_2Cu]$$

and they all hydrolyse readily in aqueous solution.

3. The derivatives of cuprimandelic acid, which are more stable in aqueous solutions than most of the other complexes, have been investigated more fully.

4. The hydrogen-ion concentrations in solutions of the cupric salts of lactic, glycollic, and salicylic acids have been estimated.

The author wishes to express his thanks to the Commissioners for the Exhibition of 1851 for a Scholarship which enabled him to carry out that portion of the work which was performed in California.

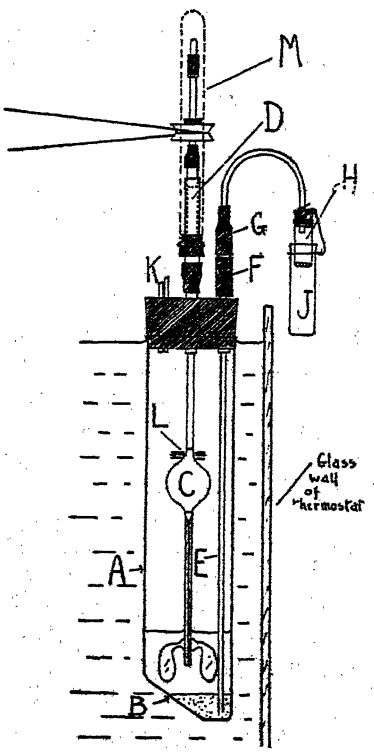
CCXXX.—*The System Ferric Oxide–Arsenic Acid–Water at Low Concentrations of Arsenic Acid.*

By NORMAN HOLT HARTSHORNE.



THIS work was undertaken (*a*) to discover whether any of the numerous ferric arsenates described in the literature were merely stages in a series of adsorption compounds, as in the case of the ferric phosphates (Carter and Hartshorne, J., 1923, **123**, 2223); and (*b*) to test the usefulness of the viscometer-stirrer employed by the author to determine the transition points of salt hydrates (J., 1924, **125**, 2097) in the investigation of ternary systems. It was thought that this apparatus would afford a rapid means of determining the attainment of equilibrium, thus avoiding the wastage involved in test analyses, and that the curves obtained by plotting the time of flow of the saturated solutions against the concentration of one of the components would show breaks indicating the limits of stability of the various solid phases, thus saving some of the laborious analyses inherent in heterogeneous equilibrium work.

Metzke (*Z. anorg. Chem.*, 1899, **19**, 457) describes the following ferric arsenates: The basic salts, $3Fe_2O_3,2As_2O_5,17$ and $16{\cdot}5H_2O$; $4Fe_2O_3,3As_2O_5$, 33·5, 20·5, and $15{\cdot}4H_2O$, the last approximating to the naturally occurring pharmacosiderite; the neutral salts $Fe_2O_3,As_2O_5,10,9,4$ (artificial scorodite), and $1H_2O$; the acid salts $2Fe_2O_3,3As_2O_5,22{\cdot}5H_2O$ and $Fe_2O_3,3As_2O_5,16{\cdot}7H_2O$. He accepts the view that the acids corresponding to these salts are formed from As_2O_5 by the replacement of the oxygen atoms by hydroxyl groups. On this basis, a compound of the type $5Fe_2O_3,3As_2O_5$ is missing, but Metzke thinks it possible that the compounds $3Fe_2O_3,2As_2O_5,17$ and $16{\cdot}5H_2O$ are mixtures of this pentabasic salt with one less basic. Verneuil and Bourgeois (*Compt. rend.*, 1880, **90**, 223) also prepared artificial scorodite, whilst Duncan (*Pharm. J.*, 1905, **20**, 223) describes the neutral salt $Fe_2O_3,As_2O_5,2H_2O$, which is dehydrated at 100°. Ježek and Siňek (*Z. Kryst. Min.*, 1914, **54**, 88) state that an anhydrous neutral salt is formed as a deposit of black prismatic crystals in the Deacon chlorine process. Other ferric arsenates, most of which approximate to those given above, are described by workers in the early part of the last century, notably Berzelius, but the inaccurate analytical methods available at that time and the exhaustive nature of Metzke's researches make it unnecessary to specify them. The following ferric arsenates occur in nature: pharmacosiderite, $4Fe_2O_3,3As_2O_5,15H_2O$; white iron-sinter, $2Fe_2O_3,As_2O_5,12H_2O$; and scorodite, $Fe_2O_3,As_2O_5,4H_2O$.

EXPERIMENTAL.

The system was studied at 25°. The apparatus used for preparing the equilibrium mixtures and collecting the phase samples is shown in Fig. 1. The solubility tube, A, was about 6 cm. wide and 26 cm. long, having a bottom so shaped as to collect the solid at the foot of the tube, E. This shape is very useful when (as was often the case in the present investigation) the amount of solid is small. It is important that the sloping portion, B, should be sufficiently steep. The viscometer-stirrer, C, was the same as that used in the previous work (*loc. cit.*), *i.e.*, with a capillary diameter of about 0·75 mm. It was supported by a glass bearing with thrust surfaces ground to a good fit and packed with vaseline contained in the tube, D. This type of bearing is simple to make, trustworthy, and sufficiently air-tight in cases where rigorous sealing of the solubility tube is unnecessary. Any vaseline which ran down the stem of the viscometer was caught by the rings of filter paper at L. These were changed occasionally and were quite effective in preventing contamination of the mixtures. The apparatus for collecting the phase samples is shown connected to the solubility tube by means of the rubber tube, F (which normally was closed by a piece of glass rod), and the sliding connexion, G. It consisted of the collecting tube, E, the weighed filter, H, and the weighing bottle, J, being thus merely a modification of the apparatus used previously for ferric and ferrous phosphates (*loc. cit.*; Carter and Hartshorne, J., 1926, 363), the most important difference being that it was not now necessary to filter the samples at thermostat temperature, since this was not far removed from that of the room. Dry air for forcing the samples through the filter was admitted through the tube, K. During this operation,

FIG. 1.

the stirrer bearing was sealed by the tube, M, after removal of the pulley. The samples were subsequently dissolved in hydrochloric acid and diluted to a standard volume. The solubility tube was supported in a glass-sided thermostat maintained at 25° ± 0·02° by means of an ordinary gas regulator.

Some difficulty was experienced in finding a suitable starting point for the preparation of the equilibrium mixtures. Arsenic acid ($H_3AsO_4,\frac{1}{2}H_2O$) was prepared by the oxidation of A.R. arsenious oxide (B.D.H.) according to the method described in Vanino's "Präparative Chemie," 1921, Vol. I, p. 215. Ferric hydroxide, prepared by the method used in the ferric phosphate work, could not, however, be dissolved in a solution of the arsenic acid; in spite of many variations in the conditions, only very small proportions were attacked. This is no doubt to be attributed to the small solubility of the ferric arsenates in arsenic acid, for in some cases microscopic examination showed that the ferric hydroxide particles were coated with arsenate, which prevented further action. It has been found that in solutions containing up to 22% of As_2O_5 the solubility at 25° never exceeds 0·1% of Fe_2O_3. The difficulty was eventually overcome by adding hydrochloric acid to the mixture. The ferric chloride thus formed reacted with the arsenic acid, and on repeated evaporation to dryness the ferric arsenate was freed from all but a trace of hydrochloric acid. The mixture, especially when concentrated, had a greenish-blue tint. On one occasion after an evaporation disc-shaped particles separated similar to those observed by Metzke (*loc. cit.*) when attempting to prepare artificial scorodite. The greenish-blue colour of these and other preparations is also mentioned by Metzke and is evidently due to a complex ferriarsenic acid or acids, analogous to the pink ferriphosphoric acids. This view is supported by the observations of Metzke and earlier workers, that the neutral and acid arsenates dissolve in concentrated ammonia, and by that of Duncan (*loc. cit.*), that oxidised solutions of ferrous arsenates respond very faintly to the thiocyanate test for ferric iron.

The mixture thus prepared was the basis of all the equilibrium mixtures studied. A portion, suitably diluted with water and freed from large lumps of solid, was transferred to the solubility tube, and after equilibrium had been reached and the necessary phase samples collected, water or syrupy acid was added and a new equilibrium reached, and so on.

Some difficulty had been anticipated in keeping the capillary of the viscometer clean. The method of washing with a few drops of water cannot be used in ternary systems of the present type, since the addition of water in large excess to most of the saturated

solutions results in the precipitation of neutral or basic salts. In the present work, a dilute solution of arsenic acid was found quite satisfactory as a wash liquid, and a few drops of this were blown down the viscometer from a wash-bottle every time the composition of the mixture was changed. Such a procedure was neither permissible nor necessary in order to obtain concordant results for successive readings of the same equilibrium. In order to provide for cases in which suitable wash liquids cannot be found for a ternary system, the author has devised an apparatus in which the stirrer and viscometer are separate, the latter being instantly removable for cleaning without disturbing the rest of the apparatus. So far, however, it has been found quite unnecessary to use it. Moreover, in ternary systems the temperature is kept constant, and consequently crystallisation in the capillary through temperature changes cannot occur. When readings are being taken with the viscometer, it is essential that the air expelled from the solubility tube by the falling liquid should be able to escape easily. In the previous work, the stirrer bearing provided an adequate leak, but in the present case it was found necessary to remove the glass plug from the tube, F (Fig. 1). When equilibrium was established the readings agreed to within 0·4 sec., and frequently to within 0·2 sec. The agreement is closer than in the previous work, but the percentage error remains about the same.

The analysis of the phase samples was effected as follows. The arsenic was separated by reduction with hydrazine and subsequent distillation as arsenious chloride. The apparatus used was that described by Jannasch and Seidel (*Ber.*, 1910, **43**, 1218), with the addition that the receiver was cooled in a large beaker of water and was furnished with a water trap to prevent any escape of arsenic. (These precautions are, however, probably unnecessary.) An aliquot part of the phase sample solution was measured into the distillation flask, concentrated hydrochloric acid was added until the volume was about 110 c.c., and the solution was saturated with hydrogen chloride; 3 g. of hydrazine sulphate and 1 g. of potassium bromide were then added, and the liquid was distilled until only 30—40 c.c. remained. The distillate was titrated as described below. High results are obtained unless the flame is screened from all but the bottom of the flask by an asbestos ring with a wire gauze centre: without this precaution, the flask becomes heated above the liquid and hydrazine distils over. The amount of arsenic in the reagents was found to be negligible. The use of a continuous stream of hydrogen chloride during the distillation was found, in agreement with Jannasch and Seidel, to be quite unnecessary for the complete volatilisation of the arsenic.

The distillate was titrated with potassium iodate solution, according to the method described in Scott's "Standard Methods of Chemical Analysis," 1922, Vol. I, p. 44. The iodate solution was standardised against resublimed A.R. arsenious oxide (B.D.H.). Owing to the distillation, the arsenious chloride solution was more dilute than is usual in this titration, and the reaction was consequently slower; it was therefore necessary to add the last few c.c. of the iodate very cautiously, waiting 5 minutes between each addition. As a check, the solution was titrated back with a standard arsenite solution, but the first drop almost invariably restored the colour to the chloroform.

The iron in the liquid phase was determined colorimetrically with ammonium thiocyanate—it never exceeded 0·1% as Fe_2O_3. In the solid phases, it was determined either (1) gravimetrically as oxide in the residue from the arsenic distillation, after decomposing the excess of hydrazine with nitric acid; (2) by titration of the residue with potassium dichromate, after removing the hydrazine with nitric acid and expelling the latter by evaporation; or (3) by direct titration of the phase sample solution with potassium dichromate. Stannous chloride was used as a reducing agent in the dichromate titrations. Methods (1) and (2) were both unsatisfactory because the weights of iron in the quantities of solution necessary to obtain a convenient amount of arsenious chloride were small. By using method (3) more solution could be titrated, and it was found by experiment that, provided the concentration of hydrochloric acid was not too high, the presence of the small amounts of arsenate involved did not appreciably affect the results. To ensure that the hydrochloric acid concentration was sufficiently low, the phase sample solutions were diluted with water before reduction by the stannous chloride, until in the cold the colour due to the ferric chloride was a pale yellow.

Results.

The results are in Table I. The composition of the phases is expressed in terms of Fe_2O_3 and As_2O_5, and, in the case of mixtures 1—13, as $FeAsO_4$ and H_3AsO_4 also. This second mode of expression is made possible by the absence of basic solid phases, and its object is to bring out more clearly the orientation of the conjugation lines when the results are plotted. If Fe_2O_3 and As_2O_5 are used as plotting components, the diagram is confined within an area which is very narrow in the direction $Fe_2O_3 \longleftrightarrow As_2O_5$, and its significance is difficult to appreciate. Mixtures 14—20 are not so treated because their percentages of Fe_2O_3 in the liquid phase were only determined approximately. Graphic expression is, however, not

TABLE I.

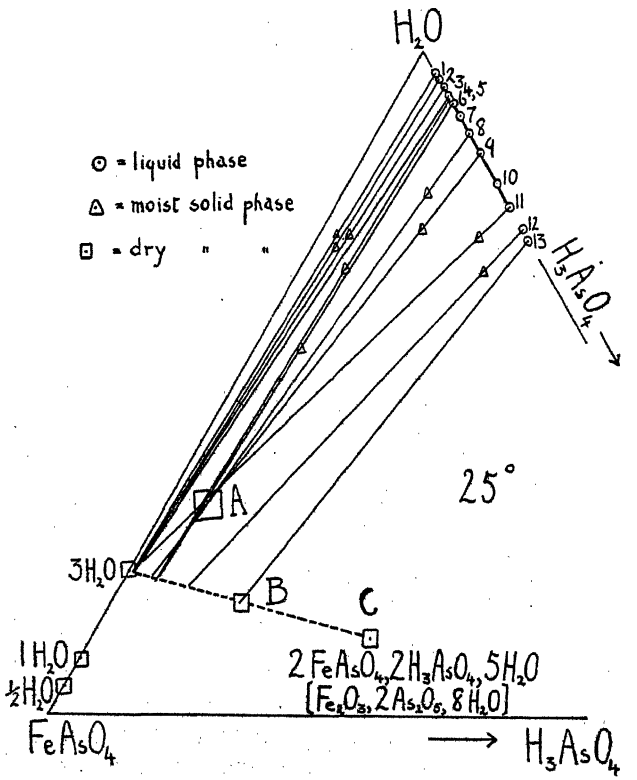
Composition and Appearance of Solid Phases.—*Mixtures* 1—10: Fe_2O_3,As_2O_5,xH_2O, with adsorbed acid. Amorphous.

Mixtures 11—13: Fe_2O_3,As_2O_5,xH_2O (with adsorbed acid) + $Fe_2O_3,2As_2O_5,8H_2O$. Amorphous and needles.

Mixtures 14—20: $Fe_2O_3,2As_2O_5,8H_2O$ (Calc.: Fe_2O_3, 20·94; As_2O_5, 60·21%). Needles.



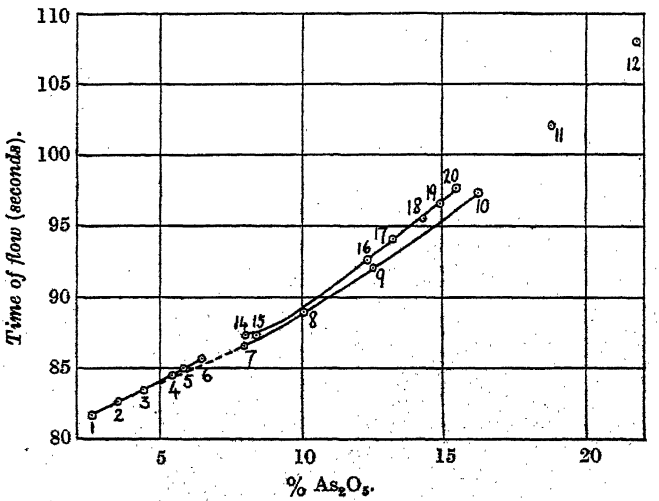
so necessary for those mixtures, for the compositions of their solid phases were found by analysis of the dried solid. Fig. 2 shows mixtures 1—13 plotted on a triangular diagram, and Fig. 3 shows the times of flow of the liquid phases (excluding mixture 13) plotted against their content of As_2O_5.

From Table I, it is seen that the percentage of ferric oxide in all the liquid phases is extremely small: even mixtures 14—20 which are metastable show only about 0·1%. It was feared at first that this small solubility would render the viscosity measurements useless through their not differing appreciably from those of aqueous arsenic acid solutions. The curves in Fig. 3 show, however, that mixtures 14—20 have a distinctly higher viscosity than the others at the same acid concentrations; on the assumption that the viscosity increases with solubility, this confirms the metastability of these

mixtures. Further, a distinct break occurs between mixtures 6 and 7, the significance of which is discussed later.

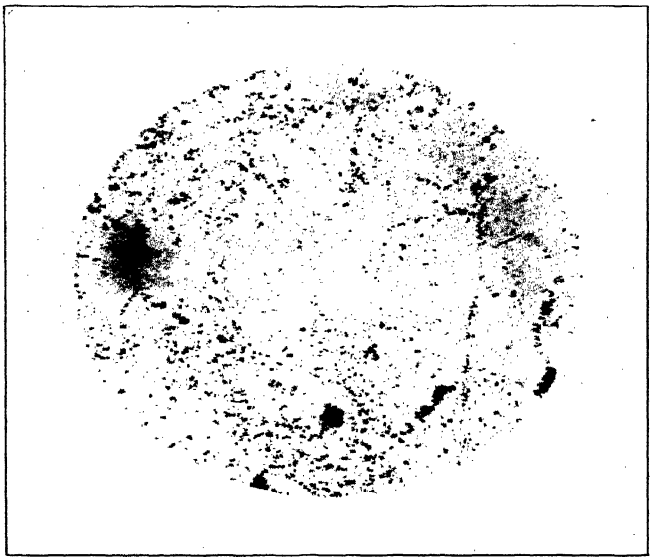
From Table I it will be seen that the mixtures 11—13 possessed the same two solid phases. It is evident that in these cases equilibrium was not attained, since theory demands that there shall be only one composition for a solution in equilibrium with any two

FIG. 2.



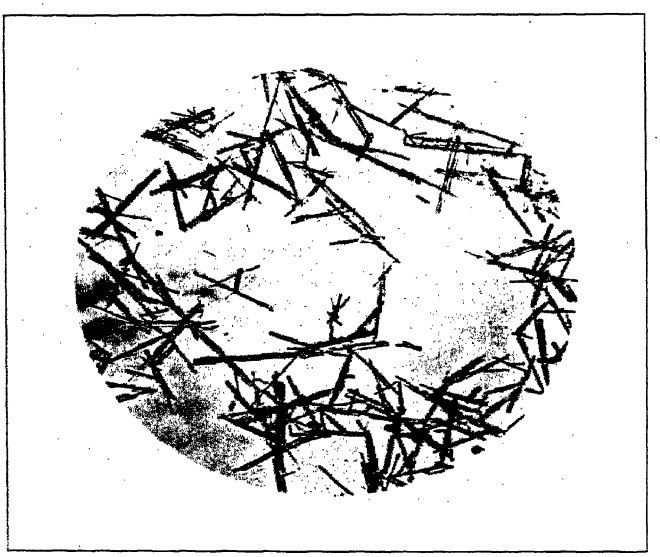
solid phases at constant temperature. This is not to be attributed to any failure to take the usual precautions to ensure the attainment of equilibrium, for the stable solid phase was presumably present in each case, and stirring was continued long after any change in the viscosity of the solution and in the appearance of the solid under the microscope had ceased (the mixtures were stirred for 35, 6, and 26 days, respectively). Rather must it be ascribed to an extreme sluggishness in approaching equilibrium. This was also experienced in the ferric phosphate work in this region, and is no doubt due to

the low solubility of the solid phases. In view of this, it is impossible to be certain to what extent equilibrium was reached in the other mixtures. The least doubt would appear to attach to mixtures 14—20 which possessed a single well-defined crystalline solid phase. These, however, were metastable.



The solid phase of mixtures 1—10 was seen under the microscope to be very finely divided, the average diameter of the particles being 1·0—1·5 μ. Under crossed Nicols and an oil-immersion objective they showed no trace of colour and may therefore be described as amorphous. Fig. 4 is a photomicrograph of the solid phase of mixture 1 which is typical of the whole series. The conjugation lines

FIG. 3.



of these mixtures together with that of mixture 11, which for all practical purposes may be included with them since the proportion of acid salt which it contained was exceedingly small, suggest (see Fig. 2) that the solid is a neutral ferric arsenate containing varying amounts of adsorbed arsenic acid. In this respect the system is similar to the ferric phosphate system (*loc. cit.*). Marked adsorption is indeed to be expected in these cases, for the solid is finely divided and amorphous. This factor limits the value of any conclusions drawn from the conjugation lines, and further evidence is necessary to show where they end. In the present case an attempt to provide this was made by analysing the dried solid phase of mixture 13 (point B). This contained both the neutral arsenate and the acid salt $Fe_2O_3,2As_2O_5,8H_2O$ (point C), so that extrapolation of the line

FIG. 4.

Fe_2O_3,As_2O_5,xH_2O *and adsorbed acid.*
Average diameter of particles : 1·0—1·5 μ.

FIG. 5.

$Fe_2O_3,2As_2O_5,8H_2O$.
(× 260).

[*To face p.* 1767.]

CB gives information as to the water content of the former. As will be seen from the figure, this leads to the composition

$$FeAsO_4,3H_2O \text{ (or } Fe_2O_3,As_2O_5,6H_2O).$$

No great reliance can, however, be placed on the accuracy of the determination of the point B, since it is probable that the solid suffered some change in composition during the drying process on account of its fine state of division and the presence of adsorbed acid. (The solid was washed with anhydrous ether which was then removed in a current of dry air.)

It will be noticed that the lines fall into two groups, *viz.*, 1—4 and 5—11, the latter converging approximately on the point A. It does not appear, however, that this has any significance, for the point A is far removed from the line CB, and, moreover, no simple formula can be assigned to it. The break in the viscosity curve between mixtures 6 and 7 (see Fig. 3) may be due to a small change in the solid phase, but it is more probably due to incomplete attainment of equilibrium, especially as the order in which the mixtures were prepared was from Nos. 6 to 1 followed by a reversion to No. 7, *i.e.*, to the mixture on the other side of the break. Possibly the true course of the curve is as represented by the broken line drawn from 3 to 7.

If the conjugation lines reach as far as the line CB produced, the diagram shows that certain of them cross over the others. This, too, indicates that equilibrium was not attained, for it implies that a mixture of the three components lying within the crossing region has a choice of equilibrium states. A similar arrangement of lines was observed in the ferric phosphate work at 25° (*loc. cit.*, p. 2226), but its significance was not then appreciated. For the present, the solid phase in equilibrium with mixtures 1—10 is described as Fe_2O_3,As_2O_5,xH_2O (where x is probably not far removed from 6), containing adsorbed acid.

Mixtures 14—20 were made by stirring another portion of the starting material with arsenic acid solutions of progressively decreasing strengths. They were all metastable, as both the analyses and the viscosity curves show. The solid consisted of small needle-shaped crystals (see photomicrograph, Fig. 5) which could be easily filtered; they were dried by washing with ether and underwent no visible change. They were therefore analysed dry in two cases and the results are given in Table I. From these figures and from the crystalline form, it was concluded that they were $Fe_2O_3,2As_2O_5,8H_2O$, isomorphous with $Fe_2O_3,2P_2O_5,8H_2O$ (*loc. cit.*, p. 2230). The analytical figures are not as close to this composition as is desirable, but they do not agree with any other known or anticipated compound. The inaccuracy is probably due to the smallness

of the crystals, the relatively large surface magnifying the effect of incipient decomposition. The error is in the basic direction, which is in agreement with this explanation. This compound does not appear to have been described before. Its constitution and that of its phosphate analogue cannot be explained in any simple manner on the assumption that the salts are formed simply by the replacement of acid hydrogen by ferric iron. This is further evidence that the salts are complex. A formula analogous to that given by Weinland and Ensgraber to the phosphate would serve also for the arsenate, *viz.*, $[Fe(AsO_4)_2]H_3,2{\cdot}5H_2O$. No sign of Metzke's compound, $2Fe_2O_3,3As_2O_5,22{\cdot}5H_2O$, has been found.

Summary.

The system ferric oxide–arsenic acid–water has been studied between the concentrations 2·6 to 23·13% of As_2O_5 at 25°. Within this range the following solid phases have been found: The neutral salt, Fe_2O_3,As_2O_5,xH_2O (where x is probably not far removed from 6), carrying varying amounts of adsorbed arsenic acid; and the acid salt, $Fe_2O_3,2As_2O_5,8H_2O$, which has apparently not been described before. No basic salts were obtained. A feature of the system was the sluggishness with which equilibrium was approached even in the presence of the stable phase, and it is evident that in some cases it was not attained.

The author's stirrer-viscometer was used in this work in order to test its usefulness in the investigation of ternary systems. No difficulty was experienced in obtaining readings concordant to within 0·5% and frequently less. The system did not, however, afford much opportunity for making use of viscosity measurements.

In conclusion, the author wishes to express his thanks to Dr. J. F. Spencer for his helpful interest in this work.

CCXXXI.—*The Preparation and Hydrolysis of the Isomeric β-Tolylethyl Bromides.*

By JOHN BALDWIN SHOESMITH and ROBERT JORDAN CONNOR.

IN a recent paper (Shoesmith and Slater, J., 1924, **125**, 2278), comprising one of a series of investigations on the polar and other factors which govern the reactivity of halogens in substituted halogenated benzenoid derivatives, the transmission of a powerful alternating influence from the methyl group of the tolyl radical

to halogen (*a*) directly attached to the same benzene nucleus and (*b*) removed by one carbon atom from the nucleus was demonstrated by the great difference in reactivity of the halogens in the isomeric iodotoluenes, $CH_3 \cdot C_6H_4I$, and ω-bromoxylenes, $CH_3 \cdot C_6H_4 \cdot CH_2Br$, and by the manner in which the order of ease of replacement of the bromine atoms in the latter case is dependent on the reagent used.

The interesting problem as to how far the influence of the methyl group extends beyond the benzene ring has now been investigated, the isomeric β-tolylethyl bromides having been prepared and submitted to the action of hydrolysing and reducing agents. The compounds are very different from the ω-bromoxylenes and very similar to one another in chemical and physical properties. They are quite stable towards aqueous alcohol at 76° and towards an aqueous acetic acid solution of hydrogen iodide. Differences in the rate of hydrolysis by aqueous-alcoholic sodium hydroxide have been observed and the order is : unsubs. (1·25) > *m*(0·83) > *p*(0·7) > *o*(0·6), but the differences are exceedingly small. (The figures in brackets denote the reciprocal of the time taken for half hydrolysis of the bromide at 76°, *i.e.*, an approximate rate of hydrolysis; compare Shoesmith and Slater, J., 1926, 214.) There appears to be a very slight residuum of alternating effect, and all the substituted compounds are slightly more difficult to hydrolyse than β-phenylethyl bromide—the reverse of the case in the corresponding benzyl bromides.

The *o*-isomeride is the most difficultly hydrolysable. The anomalous position of *o*-isomerides has been repeatedly stressed (as has also the fact that this is not due to steric influences; Shoesmith and Slater, J., 1926, 215). Olivier has arrived independently at the same conclusion (*Rec. trav. chim.*, 1926, **45**, 452, 710). As yet no satisfactory explanation has been given of the factors governing the reactivity of ortho-substituted benzyl bromides, save that there is here present an influence which renders them less reactive to hydrolysing and more reactive to reducing agents (*e.g.*, hydrogen iodide) than would be expected from any of the various theories put forward to explain enhanced and subdued reactivity.

It may now with certainty be concluded that those influences the effect of which was demonstrated so clearly in the isomeric ω-bromoxylenes are only feebly transmitted through the α-carbon atom of the side chain in the β-tolylethyl bromides, a conclusion of special interest in view of recent observations (Ing and Robinson, J., 1926, 1656; Goss, Hanhart, and Ingold, this vol., p. 250) that a very appreciable general effect due to positively charged nitrogen

is transmitted through two singly bound carbon atoms directly attached to the benzene nucleus.

EXPERIMENTAL.

The isomeric β-tolylethyl bromides were prepared according to the general scheme:

$$CH_3\cdot C_6H_4Br \xrightarrow{Mg} CH_3\cdot C_6H_4\cdot MgBr \xrightarrow{CH_2Cl\cdot CH_2\cdot OH} CH_3\cdot C_6H_4\cdot CH_2\cdot CH_2\cdot OH \xrightarrow{PBr_5} CH_3\cdot C_6H_4\cdot CH_2\cdot CH_2Br.$$

The Isomeric β-Tolylethyl Alcohols.—Grignard's method (*Compt. rend.*, 1905, **141**, 44) was modified in several important particulars. To the bromotoluene (64 g., carefully freed from traces of possible phenolic impurities) in 250 c.c. of dry ether, 9 g. of magnesium were added and, when the vigorous reaction ended, dry, freshly distilled ethylene chlorohydrin (10 g.), dissolved in an equal volume of dry ether, was slowly dropped in. After the vigorous reaction had abated, the ether was distilled away and the residue was heated under 14 mm. pressure at a temperature not exceeding 180—200° for 2 hours to remove toluene, ditolyl, etc.; it was then mixed with ice and after 30 minutes the decomposition was completed by the addition of the calculated quantity of sulphuric acid in ice-water. The ethereal extract of this solution was dried, the ether distilled away, and the residue heated for about 10 minutes with aqueous-alcoholic potash. Extraction with ether, drying, and distillation, finally in a vacuum, then gave the β-tolylethyl alcohol in 20—24% yield, and no improvement could be effected. The alcohols had b. p.'s: *o*-isomeride, 115—116°/13 mm. (compare Grignard, *loc. cit.*); *m*-isomeride, 115—117°/13 mm. (Braun, Grabowski, and Kirschbaum, *Ber.*, 1913, **46**, 1266); and *p*-isomeride, 116·5—118°/14 mm. (Grignard).

The Isomeric β-Tolylethyl Bromides.—As hydrogen bromide has no effect on these alcohols, the bromides were prepared by adding phosphorus pentabromide (60 g.) to 15 g. of the respective β-tolylethyl alcohols, dissolved in 50 c.c. of dry benzene, the reaction being controlled by shaking in ice-water and completed by heating for 1 hour at a temperature not exceeding 50°. The mixture was then poured on excess of ice, and the bromide was extracted with ether, dried over sodium sulphate, and distilled in a vacuum. The distillate was washed with water to remove final traces of phosphoryl bromide, dried, and redistilled. The bromides all boiled, as expected, at a lower temperature than the corresponding alcohols. They had b. p.'s: *o*-compound, 99—100°/10 mm.; *m*-compound, 101—103°/11 mm.; and *p*-compound, 103·5—105°/11 mm. They con-

tained hydrolysable bromine: *o*-isomeride, 39·4; *m*-isomeride, 39·8; and *p*-isomeride, 40·3% ($C_9H_{11}Br$ requires hydrolysable Br, 40·2%). They are stable, sweet-smelling, non-pungent, non-lachrymatory oils, thus differing sharply from the corresponding ω-bromoxylenes.

β-Phenylethyl bromide was prepared from freshly distilled, commercial β-phenylethyl alcohol in a similar manner and, for comparative purposes, to make quite sure that only the *ethyl* bromides are formed by the action of phosphorus pentabromide on the alcohols, a sample was prepared by a method suggested to us by Professor Lapworth. A mixture of β-phenylethyl alcohol (20 g.) and constant-boiling hydrobromic acid (50 c.c.) was boiled under reflux for 4 hours. The bromide so formed was washed with water until free from halogen acid, dried, and distilled. The samples obtained by the two methods had identical boiling points, 89—89·5°/12 mm., estimations of hydrolysable bromine showed they were pure, and later the rate of hydrolysis showed they were identical.

Behaviour towards Hydrogen Iodide.—All the bromides were stable to hydrogen iodide in aqueous acetic acid at 100° for 4 hours. For comparative purposes, some unpublished observations, made in collaboration with Dr. R. H. Slater, on ω-bromo-*m*- and -*p*-xylenes are given in order to stress the differences observed in the two cases. These figures were obtained in a similar manner, but at 110° (experience has shown that slightly different results are obtained at the two temperatures); t, w, and x have the usual significance.

TABLE I.

	ω-Bromo-*m*-xylene.		ω-Bromo-*p*-xylene.*

* The *p*-isomeride is not reduced by hydrogen iodide in glacial acetic acid at 25°. Its reduction at 110° shows the powerful reducing action of the aqueous acetic acid reagent at this temperature.

Hydrolysis of the Isomeric β-Tolylethyl Bromides.—The bromides were stable to aqueous alcohol at 76° for 4 hours. Comparative hydrolysis figures were obtained as follows: The bromide (approx. 0·50 g.) was dissolved in 75 c.c. of absolute alcohol, 25 c.c. of *N*/10-sodium hydroxide were added, and the volume was made up to 103 c.c. Aliquot portions (20 c.c.) were heated in a thermostat at 76° (b. p. of carbon tetrachloride) for definite times, and the amount

of hydrolysis which had taken place was estimated by titrating the unused alkali with standard hydrochloric acid. The results are in Table II.

TABLE II.

The order of reactivity with *N*/30-alcoholic potassium hydroxide at 25° was exactly the same.

The authors wish to acknowledge the receipt of a grant from the Earl of Moray Research Fund, and also a Carnegie Teaching Fellowship to one of them (J. B. S.), which enabled this investigation to be carried out.

EDINBURGH UNIVERSITY. [*Received, May 4th*, 1927.]

CCXXXII.—*Reduction of Silver Compounds in Alkaline Solution.*

By WALTER FARMER and JAMES BRIERLEY FIRTH.

THE object of the present investigation was to ascertain the conditions of experiment leading to the production of a maximum yield of metallic silver when ammoniacal solutions of certain silver compounds are reduced in the presence of aluminium and aqueous caustic alkali.

The reduction of silver oxide, prepared from silver nitrate, may be simply represented by the equations

(i) $6AgNO_3 + 6KOH = 3Ag_2O + 6KNO_3 + 3H_2O$,
(ii) $2Al + 6KOH = 2Al(OK)_3 + 3H_2$,
(iii) $3Ag_2O + 3H_2 = 6Ag + 3H_2O$,

one g.-atom of aluminium being equivalent to 3 g.-atoms of silver.

Preliminary experiments indicated that, in the absence of aluminium, heating of ammoniacal silver solutions in the presence of potassium hydroxide was followed by detonation. Addition of potassium hydroxide to concentrated solutions of silver compounds in aqueous ammonia caused the formation of black pre-

cipitates. Hydrolysis in the presence of traces of aluminium led to the detonation of such reaction mixtures. Hydrolysis of the dried black precipitates by potassium hydroxide gave silver oxide as the final product. In the presence of ammonia, spongy silver was formed. Analysis of the dried black precipitates by the Kjeldahl method showed that they were mixtures of silver nitride with relatively small quantities of silver oxide.

Experimental.

Series I.—An ammoniacal solution of silver nitrate containing 2 g. of the salt, 25 c.c. of ammonia (*d* 0·880), and 25 c.c. of water was treated with 25 c.c. of 3*N*-potassium hydroxide, and heated at 100° in a water-bath. At once a black film began to form on the walls of the reaction vessel, and its appearance was followed by an explosion which shattered the reaction vessel. This phenomenon occurred in three consecutive experiments, detonation taking place after a lapse of 12, 14, and 15 minutes from the commencement of the reaction.

Series II.—Aqueous silver nitrate solutions of various concentrations were treated with just sufficient ammonia (*d* 0·880) to redissolve the precipitated silver oxide, and to each solution were added 10 g. of potassium hydroxide dissolved in 15 c.c. of water. A brown precipitate formed; this was followed by a black precipitate as more caustic alkali was added. The final heavy precipitate was uniformly black in colour. The reaction vessel was then placed in a water-bath and heated to 100°. The black precipitate was thereby progressively reduced to a grey, metallic powder. The reduced metal was filtered, washed, dried, and analysed. In all cases, the filtrates were free from silver. Under the conditions of these experiments, it was observed that quantities of silver nitrate not exceeding 5 g. could be quantitatively reduced to metal. Attempts to reduce the silver salt in larger quantities invariably led to the explosion of the product. Typical results are given in Table I.

Table I.

Wt. of $AgNO_3$ (g.).....	0·5	1·0	2·0	3·0	4·0	5·0
% Ag ppd.	99·82	99·85	99·91	99·83	99·87	99·89
% Ag in ppt.	99·61	99·70	99·82	99·80	99·84	99·85

The conversion of the black precipitate into metallic silver was associated with the evolution of a gas, which was found to be nitrogen. The results of a quantitative examination of this reaction are summarised in the first two lines of Table II, and the last

lines show that the nitrogen evolved is chemically equivalent to the silver nitrate used. A similar result was obtained with silver chloride.

TABLE II.

Wt. of $AgNO_3$ (g.)	0·1619	0·2269	0·3176	0·4035	0·5892
Nitrogen (c.c. at *N.T.P.*)...	3·41	4·86	6·72	8·62	12·41
$AgNO_3$ (mg.-equiv.)	0·95	1·33	1·87	2·37	3·47
$\frac{1}{3}N$ (mg.-equiv.)	0·91	1·30	1·80	2·31	3·33

Series III.—Several samples of the black product were prepared as in Series II, 0·5 g. of silver nitrate being used in each case. Ordinary test-tubes were used as reaction vessels. One fragment of aluminium filings was quickly dropped into each reaction mixture, and the tubes were immediately immersed in vessels containing water at known temperatures. The observations were as follows:

(*a*) At 50°, crackling sound; (*b*) 60°, report; tube intact; (*c*) 70°, report, but louder; tube intact; (*d*) 90°, explosion; tube shattered; (*e*) 100°, violent explosion; tube shattered.

Analysis of the Black Precipitate.—A quantity of the black precipitate was prepared as in Series II. After 15 minutes, the supernatant liquor was decanted off, and the precipitate was washed by decantation with water and transferred to a filter. After thorough washing with water, the black precipitate was washed into a small tared evaporating dish, the excess of water evaporated on the water-bath, and the final drying completed by preserving over concentrated sulphuric acid. The product, which did not smell of ammonia, was then analysed. Owing to the great instability of the product, which exploded on percussion and even on touching with a spatula, it was deemed advisable to analyse it in bulk according to the following scheme:

(*a*) The black product was hydrolysed by means of strong caustic alkali, and the evolved ammonia estimated by absorption in standard sulphuric acid.

(*b*) The residual silver oxide was washed, dried, weighed, converted into nitrate, precipitated as chloride, and weighed in this form.

(*c*) The alkaline filtrate, from which the black product had been isolated, was examined for dissolved silver, which was precipitated and weighed as chloride. A typical result is given in Table III.

TABLE III.

Wt. of black ppt.	= 1·123 g.	$AgNO_3$ precipitated	= 85·13%
Nitrogen in ppt.	= 3·59%	$AgNO_3$ remaining in solution	= 15·03%
Ag in ppt.	= 95·48%		

From the above result, it would appear that the product was not homogeneous. In order to test this view the final, dry, black precipitate, prepared as above, was extracted several times with 50 c.c. of 10% ammonia solution. Analysis of the product after extraction and of the ammoniacal extract gave the following result.

TABLE IV.

Wt. of ppt. before extraction	= 1·132 g.	% of total $AgNO_3$ ppd.	= 84·68
Wt. of ppt. after extraction	= 0·989 g.	% of $AgNO_3$ in extract	= 10·33
Nitrogen in ppt.	= 4·11%	% of $AgNO_3$ in solution	= 15·19
Silver in ppt.	= 95·50%		

From a series of experiments, it was ascertained that a similar black precipitate containing nitrogen could be obtained when silver chloride was used instead of silver nitrate.

Series IV.—Reduction at 100°, *in ammoniacal solution, using varying quantities of aluminium and definite amounts of dissolved silver in the presence of potassium hydroxide.* The required quantity of the silver compound, containing silver equivalent to that present in 2 g. of the nitrate, was treated in an ammoniacal solution, containing 25 c.c. of ammonia (*d* 0·880) and 25 c.c. of water, with 25 c.c. of 3*N*-potassium hydroxide. A definite quantity of aluminium filings was then added and the reduction carried out at 100°; a black product was deposited, the colour of which changed rapidly to grey; from this stage onwards the quantity of the reduced metal increased continuously throughout the experiment. The final product formed grey, coherent masses of reduced silver possessing a vesicular structure. The reduction was complete in 1½ hours, and the reaction liquid was then treated with 10 c.c. of ammonia (*d* 0·880), allowed to stand for 15 minutes with frequent shaking, diluted with half its bulk of distilled water, and filtered through a tared Gooch crucible. The reduced silver was thoroughly washed, dried at 100°, weighed, and analysed. The results for silver nitrate are given in Table V, and those for silver oxide and silver chloride were very similar.

TABLE V.

Al used (g.)	0·05	0·10	0·20
Ag ppd., %	99·88	99·82	99·79
Ag in ppt., %	99·83	99·89	99·87

Series V.—A solution was prepared exactly as in Series IV, a strip of sheet aluminium was placed in it, and, immediately, a black deposit formed on the surface of the metal. After 30 seconds, the strip was removed, the deposit transferred to a beaker by means of a jet of water, and the strip reimmersed in the silver solution. This was repeated (10 times) until the deposit had

obtained in a quantity sufficient for analysis, which showed it to be elementary silver.

Series VI.—Ammoniacal solutions of silver nitrate were prepared, the ammonia content being just sufficient to retain the silver in solution. 2 C.c. of ammonia (*d* 0·880) were added, *i.e.*, excess sufficient to prevent the formation of black precipitates (total maximum bulk, 10 c.c.). Each solution was treated with 2 g. of potassium hydroxide dissolved in 5 c.c. of water, the required quantity of aluminium added, and the dissolved silver submitted to reduction at 100°. The volume of gas evolved was determined, and the gas proved to be nitrogen. Typical results are given in Table VI.

TABLE VI.

Wt. of Al (g.)	0·01	0·01	0·01	0·02	0·03
Wt. of $AgNO_3$ (g.)	0·2884	0·5378	0·7500	0·7500	0·7500
Nitrogen (c.c. at *N.T.P.*)	1·92	7·33	11·97	7·89	3·78
% Ag ppd.	99·52	99·81	99·82	99·88	99·84

It was observed that the evolution of nitrogen was retarded.

The results obtained indicate that the amount of silver reduced is stoicheiometrically equal to the aluminium dissolved *plus* the nitrogen evolved, *i.e.*, that Ag^+ reduced = Al oxidised + NH_3 oxidised, thus (in mg.-equivs.):

⅓Al	1·1	1·1	1·1	2·2	3·3
⅓N	0·5	2·0	3·2	2·1	1·0
Sum	1·6	3·1	4·3	4·3	4·3
$AgNO_3$	1·7	3·2	4·4	4·4	4·4

Series VII.—Reduction at 100°, *in ammoniacal solution, using a fixed quantity of aluminium, and varying amounts of dissolved silver in the presence of potassium hydroxide.* The object of this series was to ascertain the maximum effect of a definite quantity of aluminium under given conditions of experiment. 0·05 G. of aluminium was used in each case. The bulk of the mixed solutions and the concentration of ammonia were similar to those of Series IV. The quantities of silver compound used were equivalent to 2—8 g. of nitrate. In all experiments up to a silver content equivalent to 6 g. of nitrate, a quantitative yield of silver was obtained. The use of more concentrated solutions of silver frequently resulted in explosions. In this series it was observed that the first-formed, coherent masses of silver gradually changed to a granular powder. The results are given in Table VII.

TABLE VII.

Wt. of Ag compd. (g.) ...	2	3	4	5	6
Wt. of Ag ppd. (g.)	1·27	1·90	2·54	3·17	3·80

Series VIII.—Reduction at 100°, *in ammoniacal solution, using definite quantities of aluminium in the presence of potassium hydroxide, the solutions of silver used during the process of reduction being added from time to time in measured volumes of known ammonia and silver content.* From the preceding series it seemed probable that the concentration of the silver salt relative to the ammonia content of the alkaline solution employed is a factor governing the stability of the ammoniacal solutions submitted to reduction. The present series was carried out to test this view.

A solution containing 2 g. of silver salt, prepared as in Series IV, was treated with 0·05 g. of aluminium filings. An additional series of solutions was prepared containing 2 g. of the same silver salt in 25 c.c. of ammonia (*d* 0·880) and 25 c.c. of water. At the end of consecutive intervals of 20 minutes, these solutions were, in turn, added to the reaction liquid undergoing reduction. The total quantity of silver salt thus added was equivalent to 8 g. of the silver salt employed. The resulting reduced silver formed grey, coherent masses. The results are given in Table VIII.

Series IX.—As in Series VIII, activated silver being used instead of aluminium filings. Quantities of reduced silver, prepared as in Series IV, were activated by heating in a vacuum in a quartz tube for 3 hours at 900°, the samples of the metal obtained from the different salts being submitted to heat treatment separately. The method of experiment was as in Series VIII. The total quantity of silver salt added was equivalent to 8 g. of the silver salt used. Two series of experiments were carried out on activated silver from (i) silver nitrate, and (ii) cf. silver chloride. Table IX contains the results for the first series.

Discussion and Conclusions.

Under the conditions of experiment for hydrolysis at 100°, the black precipitates are transformed to metallic silver, while the

reaction liquids are found to be free from dissolved silver. In so far as the black precipitates are unstable in the presence of traces of aluminium, it would seem that deposition of silver nitride, prior to the final separation of metallic silver, is entirely inhibited with respect to the different processes of reduction which proceed without detonation of the reaction mixture.

In the absence of aluminium, the different amounts of dissolved silver quantitatively separated as reduced metal are equivalent to the volumes of nitrogen evolved. In the presence of aluminium, the evolution of nitrogen is inhibited : the formation of this gas does not commence until every trace of metallic aluminium has been dissolved as aluminate.

The quantitative yields of reduced silver obtained under conditions for the production of nitrogen in presence of aluminium would appear, therefore, to be the cumulative effect of two distinct reactions. In the first reaction, metallic silver is separated from the solution in a quantity equivalent to the amount of aluminium employed. The newly deposited silver, being in a finely divided condition, serves to stabilise the ammoniacal solution containing the remainder of the silver present in the dissolved state, and, as in the experiments involving the employment of activated silver (compare Series IX), it imparts to the silver solution the increment of energy necessary for the commencement of the second reaction. The second reaction then proceeds to completion, the deposition of silver being accompanied by the evolution of nitrogen in the proportion of 3 atoms of silver to 1 atom of nitrogen.

It would seem, therefore, that, in the presence of ammonia, caustic alkali effects precipitation of silver nitride, with small amounts of silver oxide, through the formation of an intermediate complex, $(NH_3)_2AgOH$, according to the following equations :

$$\text{(Ai)}\quad (NH_3)_2AgNO_3 + KOH = (NH_3)_2AgOH + KNO_3,$$
$$\text{(Aii)}\quad (NH_3)_2AgCl + KOH = (NH_3)_2AgOH + KCl,$$
$$\text{(B)}\quad 3(NH_3)_2AgOH + 2H_2O = 5NH_4OH + NAg_3,$$
$$\text{(C)}\quad 2(NH_3)_2AgOH + 3H_2O = 4NH_4OH + Ag_2O$$

(compare Bodländer and Fittig, *Z. physikal. Chem.*, 1902, **39**, 597; Straub, *ibid.*, 1911, **77**, 331).

At 100° the reactions represented by (B) and (C) are suppressed, decomposition of the diamminoargentic complex, evolution of nitrogen, and separation of silver taking place according to the equation

$$\text{(D)}\quad 6(NH_3)_2AgOH + 4H_2O = 6Ag + N_2 + 10NH_4OH.$$

It is concluded that the first reaction takes place, in the presence of aluminium, accompanied by changes conveniently represented

by the equations given on p. 1772. The second reaction involves transformations represented by the equations (Ai or Aii), (B), (C), and (D).

The results of Series IV and VII show that the extent of reduction is determined by the conditions of experiment. Thus, in Series VII, 6 g. of silver nitrate in 75 c.c. of reaction solution are completely reduced by the introduction of 0·05 g. of aluminium. By the modifications introduced in Series VIII larger quantities can be reduced without explosion, and 0·05 g. of aluminium reduces 6·694 g. of silver nitrate or 4·827 g. of silver chloride.

Series IX shows that, in absence of aluminium, ammoniacal solutions of silver nitrate or silver chloride may be reduced by means of freshly reduced silver from Series IV, activated by heating in a vacuum for 3 hours at 900°, 1 g. of activated silver being capable of reducing 6·215 g. or 4·082 g. of silver nitrate or chloride, respectively.

The continuous separation of finely divided silver in the form of grey, coherent masses possessing a vesicular structure is constantly exposing an ever-increasing surface of metal to the ammoniacal solution undergoing reduction. Uninterrupted contact between the surface of the newly deposited metal and the solution induces energy changes involving decay in the activity of the reduced metal followed by the separation of further quantities of silver from the solution. Prolonged contact between the reduced metal and the solution ultimately brings about a marked decay in the activity of the reduced metal, and this change is accompanied by the following characteristic effects. The coherent masses of reduced metal gradually break down to a powder, whilst the continued isolation of silver from the solution is ultimately brought to a limit beyond which no further appreciable deposition of reduced metal takes place.

In the presence of relatively large amounts of ammonia, separation of silver from ammoniacal silver solutions can be effected only when a suitable source of energy is introduced into the reacting system. Under given conditions of experiment, aluminium, in the presence of aqueous caustic alkali, may be employed to induce and control the production of reduced silver. When the ammoniacal concentration of the solution undergoing reduction has fallen to a certain limiting value, the concentration of the dissolved silver rises to a value such that it is unnecessary to supply energy to the reacting system: the residual ammonia is then unable to control the reaction, whilst the external heat applied in order to maintain the temperature of the reaction becomes more than sufficient to supply the energy necessary to allow the reaction to continue.

the result that the reaction is accelerated, and ultimately proceeds with explosive velocity. In these circumstances, therefore, the employment of aluminium, in the presence of caustic alkali, is quite unnecessary, and can lead only to an increase in the intensity of the explosive effects observed (compare Baly, *Ann. Report*, 1921, **18**, 40).

UNIVERSITY COLLEGE, NOTTINGHAM. [*Received, April 8th*, 1927.]

CCXXXIII.—*Molecular Volumes at Absolute Zero. Part I. Density as a Function of Temperature.*

By SAMUEL SUGDEN.

DURING the last few years it has been shown by the author and others that there are several empirical relations between surface tension, density, and temperature which hold with considerable accuracy over a large range of the variables concerned. Of these, the most important for the present discussion are van der Waals's equation (*Z. physikal. Chem.*, 1894, **13**, 716) for the variation of surface tension with temperature,

$$\gamma = \gamma_0(1 - T_r)^{6/5} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

and Macleod's relation (*Trans. Faraday Soc.*, 1923, **19**, 38) between surface tension and density,

$$\gamma = C(D - d)^4 \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

In these equations, γ is the surface tension, T_r the reduced temperature, D and d are the densities of the liquid and saturated vapour, respectively, and γ_0 and C are constants.

The first equation has been shown to give the experimental values of the surface tension of non-associated liquids from the ordinary temperature to within a few degrees of the critical point (Sugden, J., 1924, **125**, 32). Equation (2) was shown by the present author to hold for a large number of liquids over a wide range of temperatures. Further, from this equation is derived the formula for calculating the parachor $[P]$ where

$$[P] = MC^{1/4} = M\gamma^{1/4}/(D - d) \quad . \quad . \quad . \quad . \quad (3)$$

(M = molecular weight). This constant is found to be an accurately additive function of certain atomic and structural constants (Sugden, J., 1924, **125**, 1177; Sugden, Reed, and Wilkins, J., 1925, **127**, 1525; Sugden and Whittaker, *ibid.*, p. 1868; Sugden and Wilkins,

ibid., p. 2517; this vol., p. 139), and in particular provides a clear experimental distinction between non-polar and semipolar double bonds.

These two equations, although empirical and at present not related to any theory of the liquid state, are supported by a considerable amount of experimental evidence. From them, it is obviously possible to deduce a number of other relationships between the variables concerned, including a modified form of the Ramsay-Shields equation (compare Ferguson, *Trans. Faraday Soc.*, 1923, **19**, 41, 407). The simplest of these is a relation between density and temperature

$$D - d = D_0(1 - T_r)^{3/10} \quad . \quad . \quad . \quad . \quad . \quad (4)$$

which is obtained by eliminating γ between equations (1) and (2). Abundant material for testing this equation is to be found in the data of Young (*Proc. Roy. Soc. Dublin*, 1910, **12**, 374), which include measurements of the liquid and vapour densities of 30 substances. For all of them equation (4) is found to hold with remarkable accuracy; to save space, however, the calculations will only be given for the liquids to which equation (1) has been applied in a previous communication.

Equation (4) contains two constants, D_0 and the critical temperature, since $T_r = T/T_c$. These were determined by calculating the value of $(D - d)^{10/3}$ at intervals of 40°, since this quantity is a linear function of temperature, and applying the method of "zero sum" (Campbell, *Phil. Mag.*, 1920, **39**, 177; 1924, **47**, 816). The constants obtained in this manner were then used to calculate the density difference $(D - d)$ at each temperature; the results are shown in Table I, from which it will be seen that equation (4) reproduces the experimental data with a high degree of accuracy—in general the difference between the observed and the calculated values of $D - d$ is 1 part in 500 parts. A few greater deviations are found in the neighbourhood of the critical point, but in this region it is difficult to measure the density of the saturated vapour with precision.

The six liquids named in Table I belong to the class of unassociated liquids. Table II gives similar data for two associated liquids, *viz.*, acetic acid and ethyl alcohol, and shows that equation (4) holds for a part of the range; above a definite temperature, however, the density decreases more rapidly than is indicated by the formula, and the critical point is reached at a lower temperature than would be expected from the slope of the density–temperature curve at low temperatures. This effect is scarcely appreciable for acetic acid, but more pronounced for ethyl alcohol. It would seem, therefore, that association has little or no influence on the density, provided

that the degree of association does not change with temperature. This conclusion is supported by the fact that the value of D_0 found for acetic acid is almost identical with that for its isomeride methyl formate, whilst the values for the alcohols, as will be shown in the following paper, are those to be expected from their composition.

The critical temperatures predicted from the density observations are collected in Table III and are compared with the observed values and also with the values deduced from the variation of surface tension with density (Sugden, J., 1924, **125**, 32). It will be seen that, in general, the unassociated liquids give a good agreement between the observed and the calculated critical temperatures, whilst for associated liquids the observed critical temperature is markedly lower than that predicted from the lower part of the density curve.

Since equation (4) represents the variation of density with temperature with great precision as the temperature increases, it is reasonable to suppose that it will also hold as the temperature decreases. The constant D_0 is therefore of considerable interest, since it represents the density of the supercooled liquid at absolute zero. The values of this constant are collected in Table IV, and if

* Calculated from the atomic and structural constants.

these numbers are divided into the molecular weight of the liquid, the molecular volume (V_0) at absolute zero is obtained: this will be referred to as the "zero volume." The column headed $[P]$ gives the calculated value of the parachor for each liquid, and the fifth column shows that the ratio $[P]/V_0$ is nearly constant for the nine

substances tabulated. This constancy must, however, be regarded as fortuitous, since from equations 1, 3, and 4 it is readily shown that

$$[P] = \gamma_0^{1/4} V_0 \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

For organic substances γ_0 has values ranging from about 60 to 80, so the fourth root of this, which gives the ratio $[P]/V_0$, does not vary much. If, however, the range is extended on the one hand to hydrogen, which has a small value of γ_0, and on the other hand to metals and their salts, which have large surface tensions, it is found that the zero volume is no longer proportional to the parachor.

A relation of greater significance is exhibited in Table V, which shows that the zero volume is very nearly a constant fraction of the critical volume. The data for hydrogen are given by Onnes (*Proc. K. Akad. Wetensch. Amsterdam*, 1914, **17**, 528), and those for the other substances by Young (*loc. cit.*). Except in the case of hydrogen the ratio V_0/V_c is very nearly constant over the whole range considered.

Formulæ of the type of equation (1) have been suggested by earlier workers. Thus van der Waals (*Z. physikal. Chem.*, 1894, **13**, 695) gave the equation

$$V - v = mV_c(1 - T_r)^{\frac{1}{2}} \quad . \quad . \quad . \quad . \quad . \quad (5)$$

based on the theory of corresponding states. Here V and v are the specific volumes of vapour and liquid, respectively. Verschaffelt

(Commun. of Leiden, No. 28, 1896) advanced the general formula

$$D - d = mD_c(1 - T_r)^n \quad . \quad . \quad . \quad . \quad . \quad (6)$$

making $n = 0{\cdot}367$ for carbon dioxide. Goldhammer (*Z. physikal. Chem.*, 1910, **71**, 577) tested this formula on Young's density data, using $n = 1/3$ with fairly satisfactory results. It is readily shown that the exponent 3/10 gives results in better agreement with the available data than does Goldhammer's exponent 1/3, for $(D - d)^{10/3}$ is a linear function of temperature (see Table VI), as it should be according to equation (4), whereas $(D - d)^3$ exhibits a temperature coefficient which definitely increases with rise of temperature.

Summary.

1. The variation of density with temperature from the freezing point to the critical point is represented accurately for normal liquids by the equation $D - d = D_0(1 - T/T_c)^{3/10}$, where D and d are the densities of the liquid and saturated vapour, respectively, at $T°$ Abs.

2. This equation also holds for associated liquids over the lower part of the temperature range, and in some cases nearly to the critical point.

3. The "zero volume," V_0, obtained by dividing the molecular weight by the constant D_0, is nearly proportional to the critical volume for a large number of substances.

BIRKBECK COLLEGE (UNIVERSITY OF LONDON),
FETTER LANE, E.C. 4.

[*Received, June 10th,* 1927.]

CCXXXIV.—*Molecular Volumes at Absolute Zero. Part II. Zero Volumes and Chemical Composition.*

By SAMUEL SUGDEN.

IT has been shown (preceding paper) that the influence of temperature on the density of a liquid is represented accurately by the equation

$$D - d = D_0(1 - T/T_c)^{3/10} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where D and d are the densities of the liquid and its saturated vapour, respectively, at a temperature T, and T_c is the critical temperature. The constant D_0 is the density the liquid would have at absolute zero if equation (1) still held; this assumption is probably not far from the truth, since the coefficient of expansion decreases continually as the temperature falls and is already small at the freezing point. In general, equation (1) gives values for D_0 which are about 20% greater than the density at 0°, so that if sufficiently accurate density data over a wide range of temperatures are available, the extrapolation seems to be justifiable.

By dividing this constant into the molecular weight one obtains the "zero volume," V_0, *i.e.*, the molecular volume of a supercooled liquid at absolute zero; this appears to be a very significant constant, for the form of equation (1) shows that zero volumes are proportional to the molecular volumes for a series of liquids at the same reduced temperature, *i.e.*, they are corresponding volumes. It has also been shown in Part I that zero volumes are nearly proportional to critical volumes in a number of cases in which the latter constant has been determined with accuracy.

It will now be shown that zero volumes are an additive function of chemical composition, and can be predicted with considerable accuracy for a large number of substances by adding together suitable constants for the atoms and structures present in the molecule. In the tables, the zero volumes of 284 substances are recorded and compared with the values obtained by adding the constants given in Table II. For 236 substances, or 82% of the number studied, the difference between the extrapolated and the calculated values does not exceed 2%.

The method by which D_0 is calculated from a range of density observations is outlined in Part I (p. 1781). It is obvious that the accuracy of the value found will depend on the accuracy and temperature range of the data employed. For most of the substances studied, densities accurate to 1 part in 1000 parts over a range of 40° or more have been used, and it is estimated that the maximum error in the calculation of D_0 is considerably less than ½%. In a

few cases, the available observations covered a smaller temperature range, and the values of V_0 found may therefore be burdened with a larger error of calculation; these are indicated in the tables by parentheses.

(2) *Evaluation of Constants.*

The first evidence that zero volumes are simply related to chemical composition is given by the fact that position isomerides give nearly the same value for this constant. Some examples are quoted in Table I, and others will be found in the tables which follow.

TABLE I.

Position Isomerides.

$C_2H_4O_2$.	V_0.	C_8H_{10}.	V_0.
Methyl formate	46·7	Ethylbenzene	(99·3)
Acetic acid	46·7	*o*-Xylene	(98·9)
		m- ,, ...	(99·1)
$C_9H_{18}O_2$.		*p*- ,, ...	(100·7)
Ethyl *n*-heptoate	149·6	$C_8H_{10}O$.	
d-β-Butyl *n*-valerate	150·8	Phenetole	105·5
d-β-Hexyl propionate	149·7	*m*-Tolyl methyl ether	(103·9)
d-β-Heptyl acetate	150·5	*p*- ,, ,, ,, ...	(104·0)

It was next found that several homologous series (hydrocarbons, alkyl halides, ethers, esters, ketones, aldehydes, and amines) gave very nearly a constant difference in zero volumes for a difference in composition of CH_2; the values found for this constant ranged from 14·2 to 14·9 in different series with a weighted mean of $CH_2 = 14·5$. From this value, the constant for hydrogen was obtained by subtracting nCH_2 from a series of observations for the paraffins C_nH_{2n+2}, the mean value being H = 6·7, whence C = 1·1. These fundamental constants were then employed to evaluate the constants for other elements and structures.

It soon became apparent that the analysis of zero volumes could be carried out with the same simplicity as is met with in the case of the parachors (Sugden, J., 1924, **125**, 1177). With one or two exceptions (see p. 1796), the same constant serves for a particular atom in all its compounds, and the same constant for a particular structure, no matter what elements are taking part in it. Thus a double bond has the same value in ethylene derivatives, ketones, esters, and benzene derivatives; the last can all be expressed satisfactorily on the basis of the Kekulé formula. The most probable values for a number of atomic and structural constants are collected in Table II.

A clear distinction is also shown between the two types of double bond which have already been differentiated by means of the parachor (Sugden, Reed, and Wilkins, J., 1925, 127, 1525).

TABLE II.

Atomic and Structural Constants.

Atomic constants.		Atomic constants.		Structural constants.	
H	= 6·7	I	= 28·3	Triple bond	= 15·5
C	= 1·1	P	= 12·7	Double bond	= 8·0
N	= 3·6	S	= 14·3	3-Membered ring	= 4·8
O	= 5·0	O (in alcohols)	= 3·0	4-Membered ring	= 3·2
F	= 10·3	N (in amines)	= 0·0	5-Membered ring	= 1·8
Cl	= 19·3			6-Membered ring	= 0·6
Br	= 22·1			Semipolar double bond	= 0·0

is demonstrated by the data in Table III, in which the column headed ΣV_0 gives the sum of the atomic and structural constants for the substance considered except that for the linkage to be determined. By subtracting ΣV_0 from V_0 (obs.) the value shown in the last column for each type of double bond is obtained. It will be seen that, whilst a non-polar double bond gives a nearly constant increase of 8·0 c.c. in the zero volume, a semipolar double bond gives a constant which fluctuates about a value of zero.

TABLE III.

(i) Non-polar double bonds.

Substance.	Formula.	V_0 (obs.).	ΣV_0.	Double bond.
Ethylene	C_2H_4	37·4	29·0	8·4
Propylene	C_3H_6	51·7	43·5	8·2
Benzene	C_6H_6	71·2	47·4	7·9×3
Toluene	C_7H_8	86·7	61·9	8·3×3
Acetone	C_3H_6O	56·0	48·5	7·5
Acetylacetone	$C_5H_8O_2$	84·5	69·1	7·7×2
Methyl formate	$C_2H_4O_2$	56·7	39·0	7·7
Ethyl acetate	$C_4H_8O_2$	76·4	68·0	8·4

(ii) Semipolar double bonds.

Thionyl chloride	$SOCl_2$	58·0	58·1	−0·1
Sulphuryl chloride	SO_2Cl_2	62·6	63·1	−0·25×2
Methyl sulphate	$C_2H_6SO_4$	78·5	75·9	+1·3×2
Ethyl sulphite	$C_4H_{10}SO_3$	101·1	100·9	+0·2
Ethyl ethanesulphonate	"	96·7	"	−2·1×2
Ethyl sulphate	$C_4H_{10}SO_4$	107·3	103·9	+1·7×2
Nitrobenzene	$C_6H_5NO_2$	87·0	85·8	+1·2
Phosphorus oxychloride	$POCl_3$	73·4	75·4	−2·0
Ethyl phosphate	$C_6H_{15}PO_4$	140·5	139·6	+0·9
Phenyl phosphate	$C_{18}H_{15}PO_4$	(230·2)	226·8	+3·4
Nitric acid	HNO_3	32·7	33·3	−0·6
Sulphuric acid	H_2SO_4	47·1	47·7	−0·3×2
Perchloric acid	$HClO_4$	45·7	46·0	−0·1×3

It is noteworthy that the existence of the two types of double bond is now demonstrated by three independent lines of experimental evidence: (1) The different effect produced by these linkages on the parachor (Sugden, Reed, and Wilkins, *loc. cit.*), (2) the evidence from the optical activity of certain sulphur compounds which contain semipolar double bonds (Phillips, J., 1925,

127, 2552; 1926, 2079; this vol., p. 188), and (3) the effect of these two linkages upon the zero volume. The last of these methods has the advantage that it is applicable to associated liquids and shows (compare Table III) that free nitric, sulphuric, and perchloric acids contain, respectively, one, two, and three semipolar double bonds in accordance with the requirements of the octet theory of valency.

(3) *Normal Liquids.*

In this and the following section a comparison is made between the values of V_0 (obs.) derived from the density data and the predicted figure, V_0 (calc.), obtained by adding together the constants recorded in Table II. The column headed "Observer" gives initials only; full references are given on p. 1797.

Table IV gives the data for hydrocarbons.

TABLE IV.

deviations occur in compounds containing several halogen atoms, *e.g.*, ethylene dichloride (No. 35) and acetylene tetrachloride (No. 33). Since, however, carbon tetrachloride gives a satisfactory agreement, it is probable that these discrepancies are due to errors of observation. The long series of esters in Table VIII gives a test of accuracy of the additive properties of V_0 over a large range of molecular weight, and affords, in general, excellent support for the views now advanced.

Table IX contains the data for a number of nitro-compounds for which the structure $-N\begin{matrix}O\\ \diagup\\ \diagdown\\ O\end{matrix}$, containing one non-polar and one semipolar bond, has been assumed. If both the double bonds were non-polar, the value of V_0 (calc.) would have to be increased by 8·0 c.c. and would be much larger than the experimental figures.

The nitriles in Table X are assumed to have the structure $-C\equiv N$, which is confirmed by the good agreement between the observed and the calculated values. The same conclusion has been reached from

study of the parachor of a number of nitriles (Sugden and Wilkins, *loc. cit.*), so that Langmuir's assumption of a special structure containing two kernels within one octet is unnecessary.

(4) *Associated Liquids.*

It has been shown (preceding paper) that acetic acid and ethyl alcohol deviate from the requirements of equation (1) at high temperatures, but that at lower temperatures they give a satisfactory agreement. For acetic acid, in fact, the deviation only becomes appreciable in the neighbourhood of the critical temperature; it is therefore to be expected that the value of V_0 calculated from density observations at lower temperatures will be reproduced by adding together suitable constants from Table II. The data in Table XIII show that this is substantially true for a number of acids.

TABLE XIII.

For the alcohols, association appears to produce a small contraction in volume, and with the exception of methyl and ethyl alcohols the observed values are satisfactorily reproduced (Table XIV) by giving oxygen the value 3·0 in alcohols instead of the usual value O = 5·0. A somewhat larger contraction is found for amines (Table XV), for which N = 0 is used instead of 3·6 as in other nitrogen compounds. This contraction in zero volume is probably not a real change in volume but may be accounted for as follows. It seems probable from the behaviour of acetic acid and ethyl alcohol that equation (1) holds so long as the degree of association remains unchanged with increasing temperature, but that if the degree of association alters then the density decreases with temperature more rapidly than is predicted by this equation. For observations below the boiling point, the effect is small, and produces a small increase in the rate of change of density with temperature, which on extrapolation gives rather too high a value for the zero density, and consequently too small a value for the zero volume. This explanation is supported by the fact that methyl and ethyl alcohols, for which equation (1) holds up to temperatures well above the boiling points, do not exhibit this contraction, but give values for oxygen of about 5·0.

Summary.

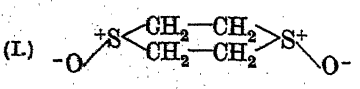
(1) It has been shown that zero volumes can be predicted by adding together certain characteristic constants for the atoms and structures present in the molecule. Of the 284 compounds considered, 236 are within 2% and 149 within 1% of the calculated value. The agreement is not quite so good as is found with the parachor; the zero volume is, however, extrapolated from the

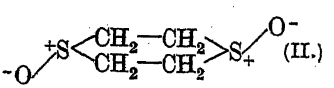
experimental data and is therefore subject to a greater error in its determination.

(2) Non-polar and semi-polar double bonds can be clearly distinguished by their effect upon the zero volume.

(3) The zero volumes of associated liquids, *e.g.*, alcohols and amines, can be predicted by making a small change in the values for oxygen and nitrogen.

BIRKBECK COLLEGE,
UNIVERSITY OF LONDON, E.C. 4. [*Received, June 10th*, 1927.]





CCXXXV.—cis-trans-*Isomerism of Disulphoxides.*

By ERNEST VERE BELL and GEORGE MACDONALD BENNETT.

THE isolation of optically active ethyl *p*-toluenesulphinate (Phillips, J., 1925, **127**, 2552) and optically active sulphoxides of the type RR'SO (Harrison, Kenyon, and Phillips, J., 1926, 2079) proves that the three groups attached to the sulphur atom in these compounds do not lie in one plane with it. It follows that, if two sulphoxyl groups are present in a molecule, two isomerides should arise having the *cis*- and the *trans*-configuration, respectively. No such isomerism has hitherto been observed, although suitable disulphoxides have been known for half a century. We have therefore subjected two such cases to a closer investigation and have in each case isolated a pair of isomeric disulphoxides.

The so-called disulphoxides derived from the disulphides R·S·S·R′ are not in question, for it has become clear that they do not actually possess the disulphoxide structure R·SO·SO·R′, but are of the type R·S·SO_2·R′ (Smiles and Gibson, J., 1924, **125**, 176; Miller and Smiles, J., 1925, **127**, 224).

The simplest case is presented by the disulphoxides (I) and (II) of diethylene disulphide (1 : 4-dithian).

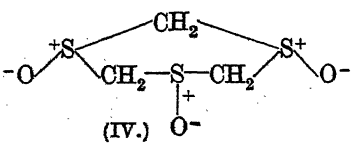
(I.)   (II.)

Here the plane of symmetry present in the molecule of each isomeride excludes the possibility of enantiomorphism. A disulphoxide of 1 : 4-dithian was isolated by Crafts (*Annalen*, 1862, **124**, 110; 1863, **125**, 123), which was soluble in water and separated from it in rhomb-shaped crystals. An examination of the mother-liquor from the crystallisation of this substance has now revealed the presence of an isomeride. The two disulphoxides decompose without melting, and their characterisation has depended on their

differences in solubility and in crystallographic properties. The α-isomeride is monoclinic and its solubility in 90% ethyl alcohol is less than one-fifth of that of the β-form, which is anorthic. The alternative formula $S<\begin{matrix}CH_2—CH_2\\CH_2—CH_2\end{matrix}>SO_2$, which might represent one of the isomerides as structurally isomeric, is inadmissible, for both the α- and the β-isomeride are readily reduced to the parent disulphide, a reaction characteristic of sulphoxides, but never shown by sulphones.

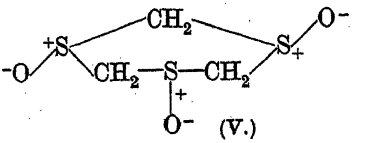
The configurations of these disulphoxides cannot be determined with certainty, but it may be tentatively assumed that the α-isomeride, being the less soluble, is the *trans*-form (II). Attempts to convert one isomeride into the other by heating in aqueous solution alone, or with acetic or hydrochloric acid of various concentrations, were unsuccessful. When heated with 5—20% hydrochloric acid, both disulphoxides behaved as peroxides, yielding dithian itself. The fact that it was not possible to bring about the interconversion of these isomeric disulphoxides is surprising, yet it is in agreement with the stability of the optically active sulphoxides, which showed no marked tendency to racemisation.

There is reason to suppose that the dissolution of an aldehyde or ketone in water involves the formation of a compound of the type $R{\cdot}C(OH)_2{\cdot}R'$, and with the older formulation of sulphoxides their ready solubility in water would by analogy have been attributed to the formation of a corresponding compound $R{\cdot}S(OH)_2{\cdot}R'$. If this were so, it would involve the rapid racemisation of active sulphoxides and the easy interconversion of *cis-trans*-isomerides in aqueous solution. On the other hand, from a consideration of the electronic formulæ it is clear that a compound $R{\cdot}S(OH)_2{\cdot}R'$ cannot exist as such, but only as the two ions: $R:\underset{\underset{H}{\vdots O:}}{\overset{\cdot\cdot}{S}}:R'$ and $:\underset{\cdot\cdot}{\overset{\cdot\cdot}{O}}:H$. Yet solutions of sulphoxides are not markedly alkaline, so that a complex, if it exists, must occur largely in some non-dissociated form. These considerations point to the following formula as a probable one: $\begin{matrix}R\\R'\end{matrix}\!\!>\!S:O:H:O:H$ (compare formulæ suggested for weak nitrogen bases by Moore and Winmill, J., 1912, **101**, 1635; Latimer and Rodebush, *J. Amer. Chem. Soc.*, 1920, **42**, 1419).



The disulphoxide derived from diethyldithiolethane,

$$CH_2(SEt){\cdot}CH_2{\cdot}SEt,$$



was described by Beckmann in 1878 (*J. pr. Chem.*, 1878, **17**, 409). We have examined the oxidation of the closely related dimeth[illegible]

dithiolethane. The product of the reaction is a mixture of two isomeric disulphoxides, $Me{\cdot}SO{\cdot}C_2H_4{\cdot}SOMe$, the α-form, m. p. 163—164°, being less soluble in various solvents than the β-form, m. p. 128—130°. Both are readily reduced to the disulphide. One of these isomerides must be an inactive mixture (or compound) of two enantiomorphs, but it is not possible to discriminate between them. This pair of isomerides is closely analogous to the two diethiodides of the same disulphide which were recently described by Wedekind (*Ber.*, 1925, **58**, 2510).

It follows from the results now described that a cyclic trisulphoxide also should occur in two forms, and it is possible that the two isomeric trisulphoxides of trimethylene trisulphide obtained by Hinsberg (*J. pr. Chem.*, 1912, **85**, 1912; 1914, **89**, 547) are, in fact, the two substances (IV) and (V).

(IV.)

(V.)

The criticisms of Fromm and Schultis (*Ber.*, 1923, **56**, 937), however, suggest the advisability of a reinvestigation of this case.

We are indebted to Professor S. Smiles, F.R.S., for drawing our attention to the isomeric disulphoxides of thianthren (Fries and Vogt, *Ber.*, 1911, **44**, 756). The isomerism in this case is well established, but it has hitherto remained unexplained. It is evidently another example of the phenomenon under discussion.

Experimental.

Oxidation of 1 : 4-*Dithian by Hydrogen Peroxide.*—To a solution of dithian (10 g.) in glacial acetic acid (200 c.c.) at 0°, hydrogen peroxide (2 mols. of 30% aqueous solution), dissolved in an equal volume of acetic acid, was added, and the mixture kept for 24 hours. Most of the acetic acid and any trace of unchanged sulphide were then removed in a current of steam and the solution was evaporated to dryness three times to remove acetic acid (yield, 12·5 g. of crude disulphoxides). The product consisted mainly of the α-disulphoxide, which is undoubtedly that described by Crafts. Crystallisation of the crude mixture from 90% ethyl alcohol (400 c.c.) yielded this compound, and one further crystallisation from 50% ethyl alcohol (50 c.c.) gave the pure substance (7·8 g.) in rhomb- or hexagonal-shaped plates, decomp. 263° (uncorr.) (Found: C, 31·3; H, 5·4; *M*, cryoscopic in water, 142, 149. Calc.: C, 31·55; H, 5·3%; *M*, 152).

The substance is readily soluble in cold water and practically insoluble in absolute ethyl alcohol and other organic solvents. It crystallises in the monoclinic system, having $a:b:c = 1{\cdot}267:1:0{\cdot}979$; $\beta = 104°\ 3'$. Crystals of the habit shown in Fig. 1 were obtained by slow evaporation of an aqueous solution. The following is a list of the forms and the angular measurements observed with three crystals:

	a (100).	*m* (110).	*r* (101).	*R* (1̄01).	*q* (011).
ϕ	0° 0′	*50° 52′	0° 0′	180° 0′	*75° 40′
ρ	90° 0′	90° 0′	46° 18′	28° 32′	*45° 19′

The simpler rhomb-shaped crystals are developed on *R* bounded by *q* and *m*. The angle of the rhomb was observed under the microscope to be about 71° (calc., 71° 6′). The extinction on the face *R* is oblique. The position of the optic axes was not observed. The crystals had $d_4^{20°}$ (vac.) 1·570.

By fractional crystallisation of the material retained in the mother-liquor of this sulphoxide a small amount of another, more soluble substance was obtained, which crystallised in needles from absolute ethyl alcohol. The separation was facilitated by the fact that the two substances, although not very different in microscopic appearance in ordinary light, were sharply differentiated when seen between crossed Nicols. The second isomeride was best obtained thus: The crude mixture of disulphoxides (6·2 g.) was warmed with aqueous alcohol (90%, 200 c.c.), and then cooled in ice, and the solution was filtered. The solid residue (4·3 g.) was almost pure α-disulphoxide. The solution on evaporation left a residue (1·9 g.), which was boiled with enough absolute ethyl alcohol to dissolve about half of it. The solution was filtered and, on cooling, it deposited the β-*isomeride* (0·8 g.), which was pure after one further crystallisation (Found: C, 31·55; H, 5·2; *M*, 132, 144. $C_4H_8O_2S_2$ requires C, 31·55; H, 5·3%; *M*, 152).

β-*Dithian dioxide* separates from aqueous or absolute alcohol in elongated plates or flat needles, decomp. 235—250°. It crystallises in the anorthic system, having the angular elements *ab*, 105° 0′; *d*, 56° 17′; *e*, 127° 14′; *f*, 61° 44′; and *g*, 120° 59′. Crystals of the habit shown in Fig. 2 were obtained by slow crystallisation of an aqueous solution. The following forms and mean angular values were observed with three crystals:

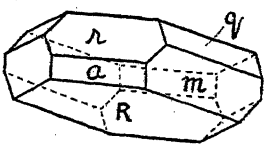
	a (100).	*b* (010).	*c* (001).	*o* (111).
ϕ	0° 0′	*105° 0′	*241° 11′	*60° 28′
ρ	90° 0′	90° 0′	*40° 56′	*37° 29′

The extinction on *a* is at about 4° to the edge *ab*. The biaxial optic picture is seen in convergent light on face *a*, the optic axial

plane being nearly parallel to the edge *ab* and the acute bisectrix nearly normal to *a*. $d_4^{20°}$ (vac.) 1·554.

Determinations of Solubility and Proportion of the Isomerides present.—100 C.c. of ethyl alcohol dissolve less than 1 g. of the α-isomeride at the boiling point, and approximately 0·1 g. at 20°; the β-isomeride is three times as soluble in cold alcohol. The solubilities of the two substances in 90·7% ethyl alcohol were determined accurately in a thermostat at 22·0°. 100 C.c. of solution contained 0·38 g. of α-isomeride and 2·26 g. of β-isomeride. Use being made of these values, the proportion of the two isomerides present in the oxidation product was determined. The mixture (0·4006 g. made by means of hydrogen peroxide) was stirred for several hours in a closed bottle at 22·0° with 90·7% alcohol (25·0 c.c.); 10 c.c. of the solution then contained 0·0557 g. of material (mean

FIG. 1.



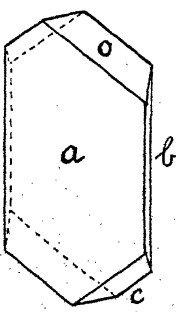


FIG. 2.

value). The influence of each on the solubility of the other being neglected, the two must be present in the proportion of 11·0% of the β- and 89·0% of the α-isomeride. A similar determination on the product of oxidation of dithian in ether by means of nitrous fumes showed the presence of 8·9% of the β-isomeride.

Reduction of the Disulphoxides.—A solution of the α-disulphoxide in acetic acid was boiled with addition of hydrochloric acid and zinc dust in excess. The solution when diluted and cooled deposited crystals of dithian (yield more than 50% of the theoretical), which was identified by direct comparison and the m. p. of a mixture with pure dithian. When the β-disulphoxide was reduced in the same way, dithian was again produced in quantity.

Attempted Interconversion of the Isomerides.—The α-disulphoxide was boiled for several hours in aqueous solution, and a known amount of ethyl alcohol then added. The weight of α-isomeride so recovered was exactly that expected, and therefore no conversion of α- into β-isomeride had occurred. The experiment was repeated with addition of acetic and dilute hydrochloric acids, but no positive

evidence of interconversion was obtained. When either isomeride was heated under reflux or in a sealed tube with hydrochloric acid (5—35%), dithian was always produced; it was identified as before. The second isomeride was in no case detected.

Oxidation of Dimethyldithiolethane.—The dimethyldithiolethane required was obtained very conveniently by methylating dithioglycol with methyl sulphate and aqueous alkali. To the disulphide (10 g.), dissolved in glacial acetic acid (100 c.c.) and cooled, hydrogen peroxide (20 g. of 29·2% aqueous solution) was added, and the mixture kept for 24 hours. The solution was then evaporated twice with addition of water, and the residue (12·5 g.) of mixed disulphoxides fractionally crystallised from ethyl alcohol, a mixture of ethyl alcohol and ethyl acetate (1 : 1), and finally from toluene or xylene. Two disulphoxides were thus separated, of which the α-isomeride was obtained pure more easily, as it was present in the larger quantity.

α-Dimethylethylenedisulphoxide crystallises from ethyl alcohol in monoclinic needles, m. p. 163—164° (Found: C, 31·1; H, 6·5; *M*, cryoscopic in camphor, 159. $C_4H_{10}O_2S_2$ requires C, 31·2; H, 6·5%; *M*, 154). It is readily soluble in water and moderately easily soluble in cold ethyl acetate or hot xylene.

β-*Dimethylethylenedisulphoxide* crystallises from alcohol or ethyl acetate in monoclinic bipyramids, m. p. 128—130° (Found: C, 31·0; H, 6·7%; *M*, 145). It is readily soluble in water or ethyl alcohol and sparingly soluble in ethyl acetate or hot toluene. The solubilities of the two isomerides in ethyl acetate at laboratory temperature are: α-, 0·16 g./100 c.c. (of solution); β-, 0·42 g./100 c.c. The melting point of the β-compound is not depressed by the addition of a little of the α-compound, although such mixtures have a considerable melting interval instead of a sharp melting point.

CCXXXVI.—*Decomposition of some Halogenated Sulphides, and the Nature of the "Polymeric" Ethylene Sulphides.*

By ERNEST VERE BELL, GEORGE MACDONALD BENNETT, and ALFRED LOUIS HOCK.

THE union of an alkyl halide with an alkyl sulphide to produce a sulphonium salt is a reversible reaction, and unsymmetrical sulphonium halides may thus dissociate to yield compounds distinct from those used in their preparation:

$$R_2S + R'I \rightleftharpoons [R_2R'S]I \rightleftharpoons RR'S + RI$$

(Cahours, *Ber.*, 1875, **8**, 825; Klinger and Maassen, *Annalen*, 1889, **252**, 241).

An exactly analogous change was detected in an examination of some δ-substituted sulphides (this vol., p. 477) when a δ-bromobutyl sulphide was found to be transformed by internal salt formation into a cyclic sulphonium salt, $\left[\begin{matrix}CH_2\cdot CH_2\\ \\ CH_2\cdot CH_2\end{matrix}\!\!>\overset{+}{S}\cdot C_4H_8\cdot OH\right]Br$, which dissociated, on heating, with liberation of the cyclic tetramethylene sulphide:

$$Br\cdot R - R - S\cdot R' \rightleftharpoons \left[\begin{matrix}R\\ \\ R\end{matrix}\!\!>\overset{+}{S} - R'\right]Br \rightleftharpoons \begin{matrix}R\\ \\ R\end{matrix}\!\!>S + R'Br.$$

It appeared probable that a similar tendency to the formation of sulphonium salts by self-addition would be a property common to all classes of halogenated sulphides. No such tendency has hitherto been recognised, but we find that some observations of our own on β- and γ-halogenated sulphides and one or two anomalies recorded in the literature may be explained as the results of such processes of reversible sulphonium salt formation.

The self-addition of a halogenated sulphide might evidently be intermolecular or intramolecular. The latter type of reaction involves ring closure, and it may be anticipated that it will only be in evidence when a five- or six-membered ring is concerned, as in the case of the δ-bromo-sulphide. An indication of intermolecular addition in a γ-halogenated sulphide was obtained when γγ′-dichlorodipropyl sulphide was converted by the action of sodium iodide into the corresponding di-iodo-sulphide. The latter decomposed, on keeping, with liberation of trimethylene iodide in quantity, whilst a dark, viscous material was deposited which contained ionic iodine and was probably a mixture of complex substances. This may be explained as follows:

$$2S(C_3H_6I)_2 \rightleftharpoons \left[\begin{matrix}\overset{+}{S}(C_3H_6I)_2\\ \\ C_3H_6\cdot S\cdot C_3H_6I\end{matrix}\right]I \rightleftharpoons \begin{matrix}S\cdot C_3H_6I\\ \\ C_3H_6\cdot S\cdot C_3H_6I\end{matrix} + C_3H_6I_2.$$

The more complex di-iodo-sulphide on the right may undergo further changes of the same kind so that a mixture of substances results.

It is known that most specimens of ββ′-dichlorodiethyl sulphide contain dithian (see, *e.g.*, Davies, J., 1920, **117**, 299), but the reason for its presence has never been elucidated. It has usually been regarded as an impurity introduced at the time of preparation, but there is now no doubt that the proportion of dithian in samples of dichlorodiethyl sulphide increases greatly with the time of keeping. The production of dithian can be explained as due to a series of

reactions involving both the intermolecular and the intramolecular type of addition, thus,

$$2S(C_2H_4Cl)_2 \rightleftharpoons \left[S<\begin{matrix}C_2H_4\cdot\overset{+}{S}(C_2H_4Cl)_2\\C_2H_4Cl\end{matrix}\right]Cl \rightleftharpoons S<\begin{matrix}C_2H_4\cdot S\cdot C_2H_4Cl\\C_2H_4Cl\end{matrix} + C_2H_4Cl_2$$

$$S<\begin{matrix}C_2H_4\\C_2H_4\end{matrix}>S + C_2H_4Cl_2 \rightleftharpoons \left[S<\begin{matrix}C_2H_4\\C_2H_4\end{matrix}>\overset{+}{S}\cdot C_2H_4Cl\right]Cl$$

ethylene dichloride being a second substance produced in the process. We have tested the truth of this scheme of reactions, as far as possible, and have directly confirmed the formation of both dithian and ethylene dichloride in quantity from pure dichlorodiethyl sulphide heated at 180° for 18 hours. A similar reaction doubtless occurs more slowly at the ordinary temperature. If these reactions are reversible at each stage (as shown), the action of ethylene dichloride upon dithian should conversely to some extent yield dichlorodiethyl sulphide, although the amount present in the final equilibrium mixture might be small. We find that dithian heated at 180° with an excess of ethylene dichloride yields a highly vesicant liquid, and the presence of dichlorodiethyl sulphide is proved by the isolation of the crystalline ββ′-diphenoxydiethyl sulphide (Helfrich and Reid, *J. Amer. Chem. Soc.*, 1920, **42**, 1208).

The curious observation of Davies (*loc. cit.*) that potassium cyanide acts on dichlorodiethyl sulphide to furnish the dinitrile, $CN\cdot CH_2\cdot CH_2\cdot S\cdot CH_2\cdot CH_2\cdot S\cdot CH_2\cdot CH_2\cdot CN$, is intelligible from the same point of view. This dinitrile is a by-product evidently derived from an intermediate mononitrile as follows:

$$2CN\cdot C_2H_4\cdot S\cdot C_2H_4Cl \rightleftharpoons \left[\begin{matrix}CN\cdot C_2H_4\cdot\overset{+}{S}\cdot C_2H_4\cdot S\cdot C_2H_4\cdot CN\\C_2H_4Cl\end{matrix}\right]Cl \rightleftharpoons C_2H_4(S\cdot C_2H_4\cdot CN)_2 + C_2H_4Cl_2.$$

The formation and dissociation of a sulphonium salt also explains the anomaly noticed by Clarke (J., 1912, **101**, 1794) in the reaction of phenacyl bromide with dithian. The amount of ionic bromine, observed at intervals by titration, was found to rise at first as expected, but then diminished rapidly. This is clearly evidence of the opening of a ring as follows,

$$S<\begin{matrix}C_2H_4\\C_2H_4\end{matrix}>S + COPh\cdot CH_2Br \rightleftharpoons \left[S<\begin{matrix}C_2H_4\\C_2H_4\end{matrix}>\overset{+}{S}\cdot CH_2\cdot COPh\right]Br \rightleftharpoons S<\begin{matrix}C_2H_4\cdot S\cdot CH_2\cdot COPh\\C_2H_4Br\end{matrix}$$

the bromo-sulphide on the right containing no ionic bromine.

The Nature of the "Polymeric" Ethylene Sulphides.—The reactions

discussed above throw a new light on the nature of the "polymeric" ethylene sulphides, which are produced in a variety of reactions, such as the action of alkali sulphides on ethylene dichloride, ethylene dibromide or dichlorodiethyl sulphide, and by the dehydration of monothioethylene glycol. It is probable that they are all mixtures of substances of high molecular weight having a long open-chain structure of the type $A(S{\cdot}C_2H_4)_n{\cdot}S{\cdot}B$, where A and B may be such groups as $-C_2H_4{\cdot}OH$, $-CH{:}CH_2$, or $-C_2H_4Br$ (Bennett and Whincop, J., 1921, **119**, 1861; *Nature*, 1926, **118**, 555; compare Staudinger, *Helv. Chim. Acta*, 1925, **8**, 67). The composition of these products is approximately that of a polymeride of ethylene sulphide (as is required by the formula provided that n be large), but it has long been known that variable amounts of bromine may be present (Crafts, *Annalen*, 1863, **128**, 220). The recent observations of Sir P. C. Rây and K. C. Bose-Rây (*J. Indian Chem. Soc.*, 1926, **3**, 75) support the idea of the occurrence of such long-chain bromopolyethylene polysulphides.

Two classes of "polymeric" ethylene sulphides were clearly distinguished by V. Meyer (*Ber.*, 1886, **19**, 3262): I, those which when heated did not yield dithian, and II, those which were readily degraded to dithian when heated alone or in solution in various solvents at high temperatures. The latter type of behaviour is to be expected in a bromo-polysulphide, owing to internal self-addition according to the scheme

$$R(S{\cdot}C_2H_4)_n{\cdot}S{\cdot}C_2H_4{\cdot}S{\cdot}C_2H_4Br \rightleftharpoons \left[R(S{\cdot}C_2H_4)_n{-}\overset{+}{S}\!<\!\begin{matrix}C_2H_4\\C_2H_4\end{matrix}\!>\!S\right]Br$$

$$\Downarrow$$

$$R(S{\cdot}C_2H_4)_n{\cdot}Br + S\!<\!\begin{matrix}C_2H_4\\C_2H_4\end{matrix}\!>\!S,$$

and repetitions of the process will liberate successive molecules of dithian, each cycle of changes being analogous to the reactions involved in the decomposition of dichlorodiethyl sulphide.

The existence of the "polymerides" of class I and their failure to yield dithian by a similar process will evidently be accounted for if they contain no halogen, since this is indispensable to sulphonium salt formation, and we find that, as far as evidence is available, "polymerides" which do not contain halogen do in fact belong to this class. Thus the material of Löwig and Weidmann (*Annalen*, 1840, **36**, 321) was found by Crafts (*loc. cit.*) to be free from halogen and to give no dithian on heating. We have confirmed the complete absence of halogen from a specimen of "polymeride" of class I prepared from ethylene dibromide, whilst products of class I from monothioethylene glycol were made from halogen-free materials

(J., 1922, **121**, 2144). These facts support our suggestion that it is the absence or the presence of halogen which determines the chemical differences between " polymerides " of class I and class II. In those of class I the terminal groups in the molecule are probably either $-C_2H_4\cdot OH$ or $-CH{:}CH_2$. Such substances would be likely to react with hydrogen bromide or with ethylene dibromide to yield halogenated polysulphides by such reactions as the following:

$R\cdot S\cdot C_2H_4\cdot OH + HBr = R\cdot S\cdot C_2H_4Br + H_2O$; $R\cdot S\cdot CH{:}CH_2 + HBr = R\cdot S\cdot C_2H_4Br$; $R\cdot S\cdot R' + C_2H_4Br_2 = R\cdot S\cdot C_2H_4Br + R'Br$.

The products would then be liable to the process of degradation with liberation of dithian. This anticipation also has been verified: " polymerides " of class I yield dithian when heated in boiling phenol, provided that hydrogen bromide or ethylene dibromide be added.

The simpler substances $S(C_2H_4\cdot OH)_2$, $C_2H_4(S\cdot C_2H_4\cdot OH)_2$, and $S(C_2H_4\cdot S\cdot C_2H_4\cdot OH)_2$ previously described (Bennett and Whincop, *loc. cit.*), which are not easily decomposed when heated alone, have now been found, as expected, to yield dithian readily when they are heated with a boiling solution of hydrogen bromide in phenol. These three dihydroxy-sulphides are the simplest members of a homologous series of substances, the higher members of which are doubtless present in " polymeric " ethylene sulphides of class I.

Experimental.

Action of Sodium Iodide on γγ'-Dichlorodipropyl Sulphide.—The pure dichloro-sulphide was heated in acetone solution with sodium iodide (3 mols.) until sodium chloride was no longer precipitated. The solution was concentrated, and the crude *γγ'-di-iododipropyl sulphide* thrown out as a heavy oil by dilution. This substance did not crystallise and could not be distilled without decomposition. When kept for several weeks at the ordinary temperature, the liquid deposited a dark resinous material which slowly hardened, but retained pockets of a heavy mobile oil. The solid could not be crystallised; it was partly soluble in water, the solution containing ionic iodine.

The oil was separated, and distilled at 120—130°/50 mm. It was identified as trimethylene di-iodide by direct comparison and by its ready conversion on heating with a solution of sodium phenoxide in phenol into αγ-diphenoxypropane, of which the m. p., 59—60°, was unaltered by admixture of an authentic specimen.

Decomposition of ββ'-Dichlorodiethyl Sulphide.—Freshly redistilled dichlorodiethyl sulphide (2·5 g.) was heated in a sealed tube for 18 hours in the vapour of boiling phenol. When the tube was

opened, a volatile liquid was noticed. The contents of the tube were mixed with an excess of aniline and heated at 100° for an hour and then at the boiling point for a further hour. The excess of aniline and the dithian were removed in a current of steam and the distillate was acidified to dissolve the aniline. The precipitate (0·5 g.; 50% of the theoretical yield) had m. p. 111°, not depressed by admixture of pure 1 : 4-dithian.

The residue from the steam distillation was extracted with ether, and the ether evaporated. The residual oil gave a crystalline sulphate when warmed with sulphuric acid (50%). This salt was crystallised from the filtered solution, and the base liberated from it by ammonia was crystallised from paraffin (b. p. 60°) and identified as ethylenediphenyldiamine, m. p. 60°, not depressed by admixture of an authentic specimen. This proves that the tube must have contained ethylene dichloride when opened.

The Action of Ethylene Dichloride upon Dithian.—Dithian (0·5 g.) and ethylene dichloride (5 c.c.) were heated in a sealed tube for 12 hours at 180°. Evaporation of the ethylene dichloride left a brown oil, which had a strong vesicant action. It was heated with an excess of alcoholic sodium phenoxide, and the solution was acidified and distilled in steam. The residual oil was removed in ether, and the latter evaporated. The viscous residue deposited crystals, which were drained on porous earthenware and recrystallised from paraffin of low b. p. This substance had m. p. 54°, not depressed by admixture of an authentic specimen of ββ′-diphenoxydiethyl sulphide. The two substances were also found by microscopic examination to crystallise identically from ethyl alcohol in bunches of needles with a straight extinction.

Degradation of "Polymeric" Ethylene Sulphide of Class I.—The specimen of "polymeride" was made by the action of alkali sulphide on ethylene dibromide, and had been freed from all trace of "polymeride" of class II by heating in phenol. It gave no dithian when dry-distilled or when heated in boiling phenol for several hours. Repeated tests proved the absence of halogen from this material.

The "polymeride" (30 g.) was heated at 130° for 1 hour with ethylene dibromide (18 g.; 1/5 mol.). Phenol (60 g.) was then added, and the mixture boiled for 3 hours. Addition of an excess of aqueous sodium hydroxide left a crystalline precipitate identified as dithian (6·7 g.).

The "polymeride" (15 g.) was boiled for 2 hours with phenol (60 g.) saturated with hydrogen bromide, and dithian was isolated as before (5 g.).

Production of Dithian from Simpler Hydroxy-sulphides.—Thio-

diglycol, ethylenebis-β-hydroxyethyl sulphide, and sulphidobis-β-hydroxydiethyl sulphide were each boiled for 2 hours with phenol saturated with hydrogen bromide, and the mixture was separated as before. In each case, dithian was identified, the yield from the last-named substance being nearly 50% by weight.

THE UNIVERSITY, SHEFFIELD. [*Received, May 31st*, 1927.]

CCXXXVII.—*Colour and Molecular Geometry. Part V. A Search for a Crucial Test of Colour Theories.*

By JAMES MOIR.

ANY theory of colour must, to be really successful, cover the whole field of absorbing substances—and this not merely qualitatively but quantitatively. It is not sufficient, for example, to establish a scheme in which most "coloured" (*i.e.*, absorbing) substances can be formulated with a little manipulation as "quinonoid" or as possessing alternate double and single linkages, inasmuch as there are plenty of exceptions to these schemes, namely, cases in which the amount of manipulation of the formula required to make it quinonoid is beyond belief (for example, *m*-aminophenol) or even beyond possibility (for example, the coloured solution of dihydroanthracene in concentrated sulphuric acid). It is also not sufficient to establish a scheme in which the various absorption bands of a substance examined in different media are related to one another in the same way as harmonics of a fundamental tone are, inasmuch as the connexion between the value of the fundamental and the chemical constitution has still to be discovered, also the reason why unexpected harmonics such as the 19th appear. A 19th harmonic is only credible if accompanied by the 7th, 13th, and 25th, or similar series; in other words, prime numbers as harmonics require a special explanation.

The author's theory, whilst admittedly a makeshift, is the only one capable of giving predictions of colour from constitution. Its use, however, is very greatly restricted by our lack of knowledge of the actual dimensions of many common molecules. Even the true configuration of benzene is still in doubt,* although the relation between anthracene and naphthalene is considered to be beyond doubt.

* Many writers appear to think that Körner's model is the same as Bragg's—which is not the case. The angle between adjacent carbon atoms in the skew-hexagon is 109° in Bragg's model and 90° in Körner's; consequently the representation of the position of the hydrogen atoms in Körner's model is quite erroneous.

The author therefore presents in this paper an experimental study of some of the oxygen derivatives of anthracene (together with a few of the corresponding derivatives of naphthalene) with the view of providing data for a crucial test of his own and other colour theories, a test founded on the fact that there is hardly any dispute as to the size and spatial configuration of the anthracene and naphthalene molecules.

Tables I and Iᴀ contain the author's observations of the positions of the bands of these oxygen derivatives, made in dilute aqueous sodium hydroxide solution, in presence of sodium sulphite to prevent aërial oxidation.

TABLE I.

Absorption of Hydroxy-derivatives of Anthracene in Excess of Alkali.

	Central λ (in $\mu\mu$) of chief band.	Fainter bands.
1-Hydroxy-9 : 10-dihydroanthracene *	312	Nil.
1-Hydroxyanthracene (α-anthrol)	364	347, 410 broad
2-Hydroxyanthracene (β-anthrol)	335	Nil.
9-Hydroxyanthracene (anthranol)	378	,,
1 : 9-Dihydroxyanthracene (α-hydroxyanthranol)	490	460
2 : 9-Dihydroxyanthracene (β-hydroxyanthranol A)	476	447
3 : 9(or 2 : 10)-Dihydroxyanthracene (β-hydroxyanthranol B)	510	480
1 : 5-Dihydroxyanthracene (rufol)	371	354, 420 broad
2 : 6-Dihydroxyanthracene (flavol)	345	312, 378 broad
2 : 7-Dihydroxyanthracene	390	Nil.
9 : 10-Dihydroxyanthracene (anthraquinol)	495 broad	,,
1 : 5 : 9-Trihydroxyanthracene (anthrarufinanthranol)	427	370
1 : 2 : 10-Trihydroxyanthracene (deoxyalizarin)	480	Nil.
2 : 6 : 9-Trihydroxyanthracene (anthraflavinanthranol)	416	490, 515
2 : 7 : 9-Trihydroxyanthracene (*iso*anthraflavinanthranol)	492	466
2 : 9 : 10-Trihydroxyanthracene (β-hydroxyanthraquinol)	575	685
2 : 6 : 9 : 10-Tetrahydroxyanthracene (hydroanthraflavin)	486	454
1-Hydroxyanthraquinone	480	500
2-Hydroxyanthraquinone	470	495
1 : 2-Dihydroxyanthraquinone (alizarin)	613	568, 523
1 : 4-Dihydroxyanthraquinone (quinizarin)	595	552, 516
1 : 5-Dihydroxyanthraquinone (anthrarufin)	470	500
2 : 6-Dihydroxyanthraquinone (anthraflavin)	430	400, 485
2 : 7-Dihydroxyanthraquinone (*iso*anthraflavin)	475	390, 500

* The author finds that 1-hydroxy-9 : 10-dihydroanthracene (contrary to the statements of Liebermann, *Annalen*, 1882, **212**, 15, and Pleus, *Ber.*, 1902, **35**, 2928) is a phenolic substance closely resembling the cresols and has no colour in alkali. The author's specimen was made by sodium reduction of α-anthrol and agreed in appearance and melting point with the data in the literature.

TABLE Ia.

Absorption of some Corresponding Naphthalene Derivatives in Excess of Alkali.

	Central λ (in $\mu\mu$) of chief band.	Fainter bands.
1-Hydroxynaphthalene	330	Nil.
2-Hydroxynaphthalene	349	,,
1 : 5-Dihydroxynaphthalene	350	,,
2 : 6-Dihydroxynaphthalene	340	356
2 : 7-Dihydroxynaphthalene	338	393
5-Hydroxy-1 : 4-naphthaquinone (juglone)	510	570
5 : 6-Dihydroxy-1 : 4-naphthaquinone (naphthazarin)	619	571

TABLE II.

Sulphonates in Aqueous Alkali.

Name.	Position of bands.
Anthraquinone-1-sulphonate	340 and 385
Anthraquinol-1-sulphonate	493 and 515
Anthranol-1-sulphonate	385 and 363
Anthracene-1-sulphonate	383, 364, 345, 326, and 308
Anthraquinone-1 : 5-disulphonate	333 and 420
Anthraquinol-1 : 5-disulphonate	491, 533, and 590
Anthranol-1 : 5-disulphonate	432, 460, and 490
Anthracene-1 : 5-disulphonate	389, 370, 350, and 305

The first point to be noted from the observations is the very interesting one that both of the anthrols and both of the symmetrical anthradiols are *visibly* coloured in moderately concentrated (N/500) solution, whereas the corresponding derivatives of naphthalene, all of which have absorption bands situated below λ 390 (the usually accepted lower limit of human vision), are not coloured in alkaline solution unless the solutions are very concentrated (over N/10). The α-compounds are more highly coloured than the β-compounds.

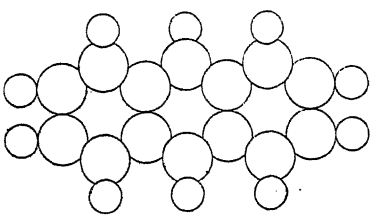
The second point is that the behaviour of the 1 : 5-dihydroxy-compounds is almost the same as that of the 1-hydroxy-compounds and that the 2 : 6-dihydroxy-compounds resemble the 2-hydroxy-compounds in behaviour. This symmetry clearly points to an influence of the centre (or the central plane) of the molecule on the height of colour.

The third point is the high colour (λ above 470) produced when one hydroxyl group is present in the 9-position. All the anthranols and anthraquinols show this, and, as is well known, all the hydroxyanthraquinones can be formulated in an alternative form with an OH-group in position 9. Usually the anthranol has a similar colour to that of the anthraquinone. This high colour is not easy to explain on any theory of colour.

The fourth point is that the highest colours of all occur in 2 : 9 : 10-, 1 : 2 : 9 : 10-, and 1 : 4 : 9 : 10-compounds (the 1 : 9 : 10-compound, α-hydroxyanthraquinol, could not be obtained). This is evidently due to superposition of effects due to the 9 : 10 arrangement—in itself capable of giving a red colour—on effects due to the co-operation of hydroxyl and the anthracene skeleton—in itself capable of giving a yellow colour, as shown above.

The last point is that the phenomena are almost exactly duplicated in the naphthalene series, so that the third ring in anthracene is of little significance. Thus juglone resembles erythrohydroxyanthraquinone, naphthazarin resembles alizarin, and all the mono- and di-hydroxynaphthalenes examined resemble the corresponding derivatives of anthracene. Nevertheless, anthraquinol (red in alkali) does not closely resemble 1 : 4-dihydroxynaphthalene in colour, although the alkaline solution of the latter compound is yellow (in presence of reducing agents to avoid oxidation), in contradistinction to that of ordinary quinol. 9 : 10-Anthraquinol in alkali absorbs from λ 520 to λ 470, 1 : 4-naphthaquinol at about λ 400, and quinol at λ 316.*

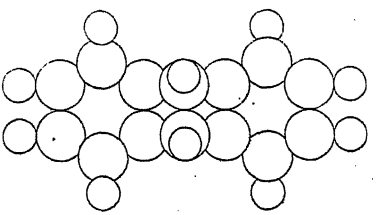
Those who have followed the author's attempts to find a theory of colour will remember that six years ago he put forward a factorial scheme whereby 90% of the data for dicyclic coloured substances could be correctly predicted (J., 1921, **119**, 1654), and later he showed that alteration of the angle between the rings is the reason why dicyclic coloured substances linked by carbon have lower colours than the corresponding substances in which nitrogen or oxygen forms the joint between the rings.



Further consideration shows that this scheme must sometimes break down when there is more than one joint, and this merely because the two joints cannot approach one another closely when one of them is carbon with its comparatively severe bend of 109°. Consequently, the calculated values for dihydroxyxanthhydrol and dihydroxyacridine are slightly incorrect (−3%), whereas those for dihydroxyanthracene, dihydroxyacridone, and dihydroxyxanthone are seriously incorrect (−12 to −25%). This means that the factor 0·65 used for calculating linkage by carbon can only be used once, so that if there is linkage by a second atom (in the ortho-position to the first linkage, of course) it occurs in such a way as to keep the molecule as flat as possible. Bragg's model for anthracene is an example, for, if my 1921 theory had been entirely correct, the anthracene model resulting would have been "buckled" in the

* If these effects are merely due to "loading" of quinol with one or with two benzene rings respectively, they are much the largest loading effects known.

middle, this being the only way in which both the central carbon atoms could make the normal (109°) angle with both rings.



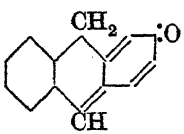
Figs. 1 and 2 represent two possible ways in which Bragg's measurements may be satisfied without any "buckling." Fig. 1, being without a cross bond, really represents dihydroanthracene, but is Bragg's own original diagram, with the β-hydrogen atoms put in the same plane as the β-carbon atoms. Fig. 2 shows the cross bond of anthracene as part of a Dewar–Ingold benzene model (triangular prism). Both models measure 11·18 Å. by 6·00 Å. The dimension 11·18 Å. of anthracene is made up of two ordinary benzene rings each of width 2·57 Å., one central ring of width 2·50 Å., two halves of a carbon atom, equal to 1·54 Å., and two hydrogen atoms, equal to 2·00 Å. The other dimension (vertical) is made up of $2{\cdot}57 \div (\sqrt{3}/2)$ (from the properties of a hexagon), plus two halves of a carbon atom, plus the projection of two hydrogen atoms lying

Fig. 1.

Anthracene (Bragg).
Dihydroanthracene (Moir).

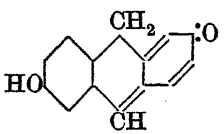
Fig. 2.

Anthracene (Moir).



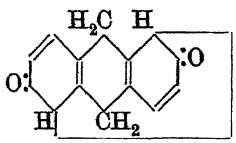
at 109° to the plane of the paper containing the β-carbon atoms. Similarly, if the middle ring be removed, the diagram agrees exactly with that of naphthalene [$(2 \times 2{\cdot}57) + (2 \times 0{\cdot}77) + 2{\cdot}0 = 8{\cdot}68$ for the length, whilst the breadth remains at 6·00 as in anthracene], these dimensions being exactly those given by Bragg. Inferentially also, the dimensions of the benzene molecule become, in this scheme, 6·11 Å. × 6·00 Å., a much closer approach to a true hexagon than one would expect at first sight from a molecule possessing a carbon skeleton of the skew-hexagon nature prescribed by Bragg.

Application of the Model to the Author's Colour Theory.



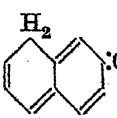
The extreme form of the author's theory, according to which the distance between the centres of the oxgyen atoms of the auxochromes decides the colour, is at once seen to be incorrect, because if this form of the theory were true, the substance flavol (2 : 6-dihydroxy-anthracene), in which the centres of the oxygen atoms are as far apart as possible (10·6 Å. on the model), would possess an absorption

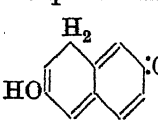
band at λ 850. Similarly, 2 : 6-dihydroxynaphthalene, which has, on the model, a distance of 8·1 Å. between its oxygen centres, would have a band at λ 650. Observation shows that the position of the chief band of both these substances is practically the same (λλ 345 and 340 respectively), both being pale yellow in alkaline solution. Light is now thrown on this obscurity by the fact that β-anthrol and β-naphthol have similar absorptions when examined in alkali solution (λλ 335 and 349 respectively). This shows that the colour vibration (colour orbit on the author's theory) is not from auxochrome to auxochrome, but is from *one* (that is to say, from either) auxochrome to a centre of force near the centre of the molecule.



This idea can be correlated with the quinonoid theory as follows: β-Anthrol can be written as a quinonoid compound (I), and similarly flavol can be written as (II) but cannot be written so as to make the oxygens of *both* auxochromes quinonoid. I assume that such a formulation as (III) is patently absurd.

(I.)



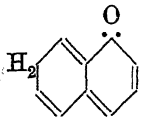


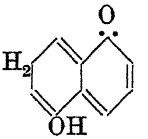
(II.)

(III.)

The cause of the band round about λ 340 in these four compounds (β-naphthol, 2 : 6-dihydroxynaphthalene, β-anthrol, and flavol) thus only concerns one ring. On my theory, λ 340 corresponds to a positive-centre distance of 4·36 Å. if both centres are oxygen atoms,* and about 4·2 Å. if one is a carbon atom. The latter distance on the model agrees with an orbit in which the electron grazes the oxygen atom of the auxochrome and at the other end of the ellipse passes through the double bond outside the para-carbon atom, the positive centres being the auxochrome oxygen and the para-carbon atom. Thus my theory leads to the same result as is reached by the quinonoid theory. The quinonoid formulæ for β-naphthol and 2 : 6-dihydroxynaphthalene involved are (IV) and (V), although they have also been formulated as ortho-quinonoid.

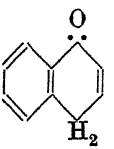
(IV.) 

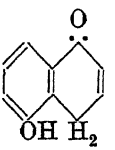




and 

(V.)





The α-compounds may now be considered. α-Naphthol and 1 : 5-dihydroxynaphthalene have much the same absorption as the

* For these calculations involving oxygen atoms alone, I find that the expression $\lambda = 82d - 20$ is sufficiently accurate.

β-compounds just discussed, *viz.*, an average value of 340 for λ. The corresponding distance is again 4·2 Å. and the corresponding quinonoid formulæ are :

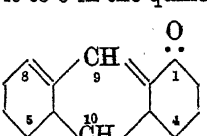
(VI.)  and  (VII.)

Nevertheless, no distance can be found on the model in agreement with these suppositions. Agreement can, however, be obtained if the more customary quinonoid form be assumed, in which

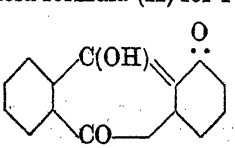
(VIII.)  and  (IX.)

case the distance between oxygen and para-carbon agrees with what is required : the case thus becomes, in this instance, that of phenol with a "load."

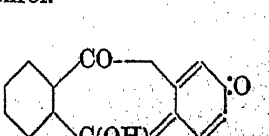
The α-compounds of anthracene have a higher colour than those of naphthalene, due to bands at λλ 368 and 415 (on the average).



Alkaline solutions of 1-anthrol and of rufol (1 : 5-dihydroxy-anthracene) are yellow even in great dilution.



When, however, it comes to finding an explanation of this, it appears that Bragg's work is unfortunately less decisive as to the relative positions of α-groups than of β-groups.



It is usually assumed, nevertheless (as on p. 1813), that α-groups lie in line with the benzene valencies, *i.e.*, inclined to the general plane of the model at the angle of 55° ($\sin^{-1}\sqrt{\frac{2}{3}}$) prescribed by the geometry of the skew-hexagon benzene model. An attempt to depict this *in plano* is shown in Figs. 1 and 2.

I find that an orbit round the α-oxygen and para-carbon atoms does not suit the colour, although the analogous supposition does suit in the case of the β-compounds. Neither does an orbit round the 1-α-oxygen and the 10-*meso*-carbon atom.

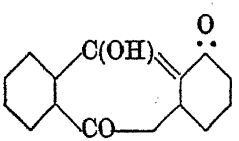
The only orbit which agrees is one which involves the double linkage lying between carbon atom 8 and its neighbour which links it to 9 in the quinonoid formula (X) for 1-anthrol.

(X.)

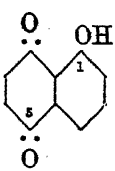
(XI.)

(XII.)

The centre of this unnumbered linking-carbon atom is at approximately the correct distance from the centre of the 1-oxygen atom to account on my theory for the observed band at λ 415 and the yellow colour.



The Hydroxyanthraquinone Dyes.

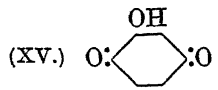


In explaining the colour of these dyes the author accepts the customary theory that the oxygen atoms attached at positions 9 and 10 compete with the hydroxylic oxygen atoms for a tautomerising hydrogen atom, as in the usual formulæ (XI and XII).

The tautomerism of the β-compounds is the ordinary quinonoid one, but in the α-compounds the chemical bonds cannot be arranged so as to show a tautomerism between 1- and 10-oxygens. This need not, however, deter us from conceiving the colour as being due to the movement of a single electron round these two oxygen atoms considered as positive centres—inasmuch as the case is similar to that of the "meta-quinonoid" coloured substances such as *m*-nitroaniline.

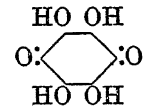
The distances, 6 Å. (α) and 6·5 Å. (β), between the centres of the oxygen atoms in question agree with what is required to explain bands occurring between λ 470 and λ 510. The *quinonoid* formula for erythrohydroxyanthraquinone (XIII) leads to a much smaller

(XIII.)



(XIV.)

distance (2·6 or 2·9 Å. according as the 1- and 9-oxygen atoms are on the same or opposite sides of the general plane of the molecule), a distance corresponding to bands between λ 215 and λ 240 in the low ultra-violet region. Meyer and O. Fischer (*Ber.*, 1913, **46**, 85), in the cases of 1-hydroxyanthraquinone and anthrarufin, observed no bands below λ 265, but the lower limit of their investigation was probably not low enough to reach bands situated at λ 220.



The cause of the colour of juglone (5-hydroxy-1 : 4-naphthaquinone, *i.e.*, 1-hydroxy-5 : 8-naphthaquinone) (XIV) and of 1-hydroxyanthraquinone is the same, an orbit round the oxygens attached in positions 1 and 5. The third ring in 1-hydroxyanthraquinone has no effect, as is seen also to be the case by comparison of the bands of naphthazarin with those of alizarin.

It is a curious fact, however, and one not easy to explain, that colour of this height (λ 480 or so) can arise in compounds of only *one* ring, such as hydroxybenzoquinone and tetrahydroxybenzo-

quinone, when examined in alkaline solution. This is nevertheless not strictly analogous, since in juglone the hydroxyl group is

(XV.)

(XVI.)

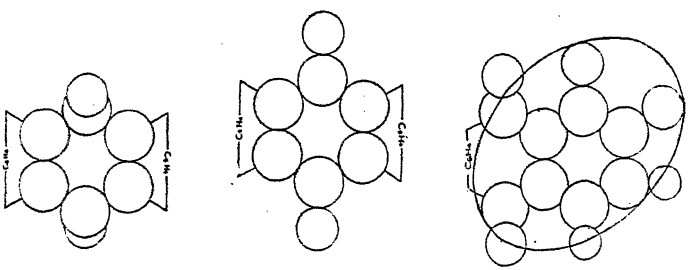
attached, not directly to the quinone ring, but to a carbon atom attached to that ring. Probably a special explanation, similar to that of the high colour of alizarin (see below), is called for here.

The colour of anthrarufin is explained in the same way as that of 1-hydroxyanthraquinone, and the colour of anthraflavin and of *iso*anthraflavin in the same way as that of 2-hydroxyanthraquinone (see p. 1816).

The high colour of alizarin and naphthazarin constitutes part of a general phenomenon seen also in benzeneazopyrocatechol, 3 : 4-dihydroxybenzophenone, etc., whereby the presence of two hydroxol groups adjacent to one another greatly heightens the colour (Table III).

TABLE III.

Substance.	λ.	Comparison substance.	λ.
Benzeneazopyrocatechol ...	480	Benzeneazophenol	433
Phenolpyrocatechol-phthalein	579	Phenolphthalein	554
Pyrocatecholphthalein	652		
o-Hydroxyfluorescein	523+498	Fluorescein	494+457
oo'-Dihydroxyfluorescein ...	550+527		
3 : 3' : 4 : 4'-Tetrahydroxy-benzophenone	449+406	4 : 4'-Dihydroxybenzo-phenone	323



I am of opinion that the explanation is that the electron goes round *both* of the ortho-oxygen atoms as well as the third (distant) oxygen atom (Fig. 5), and thus describes an ovoid orbit which is wider than the normal type of colour ellipse (see J., 1922, **121**, 1810). This connotes a longer path and longer periodic time and higher colour, the eccentricity of the ellipse having been increased. The essential idea in this explanation of the heightening effect of contiguous auxochromes is that the two atoms behave (as in ordinary mechanics) as if their forces were condensed into their "centre of gravity" (the point midway between them), whilst the moving electron has to *touch the outsides* of both of them and so is constrained to move in one plane and thus give an ovoid orbit slightly wider at one end than at the other. In simpler coloured substances, of course, the orbit round two positive centres may be in almost any plane.

The hydroxyanthracenes and the hydroxyanthraquinones having been disposed of, it remains to discuss the colours of the hydroxyanthraquinols and hydroxyanthranols.

(*a*) Anthraquinol itself (in alkali) has a much higher colour than anthraquinone, a phenomenon *sui generis*, since it does not occur in the benzene and naphthalene series, in which the quinol has a lower colour than the quinone. It can only be explained on my theory by supposing the central ring flattened and the two (9 and 10) hydroxyl groups attached outside in the same plane. In this way, the oxygen atoms can be sufficiently separated to agree with the theory and the observed colour (see Table I). In anthraquinone, however, the theory requires that the distance between the oxygen atoms shall be only two-thirds of that required for anthraquinol; this agrees with the ordinary buckled-ring structure. Figs. 3 and 4 represent anthraquinone and alkaline anthraquinol according to the theory.

It is difficult to investigate the hydroxyanthraquinols on account of their great liability to oxidation, but they appear to have even

FIG. 3. FIG. 4. FIG. 5.

Anthraquinone. *Ionised anthraquinol.* *Colour-orbit in alizarin.*

higher colours than anthraquinol, requiring for explanation the ovoid orbit round oxygen atoms situated in the 1 : 9 : 10 and 2 : 9 : 10 positions.

(*b*) The hydroxyanthranols all have much the same colour as anthraquinol, intermediate in "height" between those of the corresponding hydroxyanthracenes and hydroxyanthraquinones. Those of the 1 : 10 and 2 : 10 type have slightly higher colours than those of the 1 : 9 and 2 : 9 type (see Table I). The explanation of their colour on my theory is that the distance between the oxygens is intermediate between that for the hydroxyanthracenes and that for the hydroxyanthraquinones, both of which have been accounted for above.

This shorter distance is accounted for by the fact that the central hydroxyl group of the anthranols is attached in the same way as the *meso*-hydrogen atoms of anthracene. It is thus plain from Fig. 2 that the distance from this hydroxyl to an α- or β-hydroxyl is less than in the case of the hydroxyanthraquinones.

Part II.

Some reference to the views expressed in the Report of the British Association Committee on Spectra and Constitution (1922) is called for from one who still believes that there is a relationship between chemical constitution and the position of absorption bands.

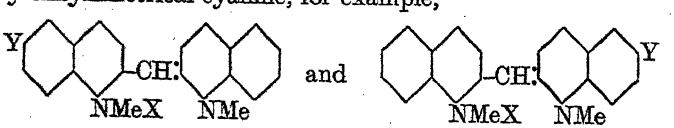
It is, of course, true that the portion of the field of ethereal vibration concerned with colour is less than one five-thousandth of the whole field. The author has, however, shown that the *whole* of the substances chemically related to a single parent substance possessing a band in this minute fraction of the possible field have also a band or bands in this same tiny region (J., 1923, **123**, Tables from p. 2797 to 2803), a fact which if ascribed to coincidence is incredible, but if ascribed to "loading" of the parent substance is eminently reasonable. For example, it appears to be impossible to make any derivative of azobenzene which shall not have a band somewhere between λ 420 and λ 600.

Again, the harmonic results for the anthracene family could be simplified if it is admitted that such of the observations as were made in concentrated sulphuric acid are not directly comparable with those made in alkali. Every such observation should be corrected for the very considerable "loading" effect of the solvent, in the same way as observations in alcohol must be corrected for comparison with observations in water, whereupon the bands coincide.

The case of benzene as studied by McVicker, Marsh, and Stewart is particularly interesting on account of the very definite harmonics arrived at (J., 1923, **123**, 642, 817, 2147). The heads of the Tesla bands were found to be the 33rd, 34th, 35th, 36th, 37th, 38th, and 39th harmonics of a fundamental in the infra-red at $\nu = 987{\cdot}1$ vibrations per cm.* ($\lambda = 10131$ μμ).

The 36th harmonic ($\nu = 35540$, $\lambda = 281\frac{1}{2}$) is the strongest. There is also a fine structure of subsidiary bands, making probably 84 in all between λ 310 and λ 260, all expressible as submultiples of the fundamental (considered as a double band of λλ 10131 and 10162) thus: $\nu = \left\{\begin{matrix}987{\cdot}1\\983{\cdot}6\end{matrix}\right\}\left(1 \pm \frac{n}{216}\right) \times$ harmonics.

Combining this discovery with the knowledge of the positions of two *observed* infra-red bands of benzene at about λλ 1680 and 6750 μμ, we find that we must either assume the real fundamental λ of benzene to be twice that given above (20260 μμ, $\nu = 493{\cdot}5$), in which case the harmonics go up to No. 78; or else keep to the result given above, with no harmonic higher than 39, and explain the band at 6750 μμ by a special hypothesis.



* Stated as 98·71 in their paper, different units being used.

It is fairly clear, however, from the mass of evidence brought forward by Deslandres and referred to later on, that absorption bands possessing a fine structure are caused by the nuclei of the atoms of the molecule and not by the atoms or by the molecule itself.

Part III. Stieglitz's Theory.

Stieglitz, on the contrary, believes with me that there is a connexion between colour and chemical structure or constitution. He has put forward a geometrical theory of the same character as mine (Franklin Institute Centenary Address, 17th September, 1924; *Proc. Amer. Chem. Soc.*, 1920, **43**, 36), but differing fundamentally in that an electron orbit is assumed round *one* atom, but disturbed by the proximity of a second positive centre. The orbit, according to Stieglitz, is not an ellipse round the two positive centres, but is a Cassinian oval round *one* of them, apparently exactly as in Morgan's theory of combination, the electrons being never sufficiently disturbed to become governed by two nuclei (see *Chem. and Industry*, 1924, 1071). A diagram is given there which in my opinion explains the whole subject, not only of chemical combination, but also of absorption and colour. The inner Cassinian ovals (3 in number in Morgan's figure) represent some of the Bohr orbits as disturbed (but not seriously altered) by the proximity of a second positive centre; they represent what happens when electrons are affected by radiation when the second positive centre is distant. The outer ellipse, on the other hand, is the orbit suggested by the present author to explain colour and involves a comparative proximity of two ionised positive nuclei, so that the electron is completely displaced from one and can go round both. An intermediate stage is shown by the permanganate, uranyl, uranous, neodymium, erbium, and praseodymium ions, in which rhythmically related bands occur, but no fine structure in the bands. This is just possibly connected with the intermediate lemniscate orbit.

Stieglitz's theory has not yet had its mathematics worked out and therefore cannot be tested quantitatively against my own, but he produces one case which is inconsistent with my theory (and also inconsistent with the theory of tautomerism), *viz.*, the existence of two distinct dimethylmurexides, one of which is alloxandimethyluramilazomethine and the other dimethylalloxanuramilazomethine. Similarly, on Stieglitz's theory there should be two isomeric forms of every unsymmetrical cyanine, for example,

In Stieglitz's theory, which is founded on the general principle of $\alpha\gamma$-tautomerism, the carbon atom adjoining but outside a double bond is the one round which the perturbed oval orbit is performed by an electron; and the other positive centre is the farthest-away atom of the doubly bonded pair.

Stieglitz's theory gives a better explanation than mine of such problems as the colour of nitrosobenzene, sodium-benzophenone, and other metal-ketyls, and Wieland's substances with bivalent and quadrivalent nitrogen.

Part IV. Deslandres's Theory.

H. Deslandres propounds a law among infra-red absorptions of simple substances whereby they are all connected together, whatever the observed substance may be. He expresses it (*Compt. rend.*, 18 May, 29 June, 17 Aug., and 28 Sept., 1925) in the form $\nu = d_1 q/rs$, in which d_1 is a universal constant or frequency ($1062\frac{1}{2}$ vibrations per cm.), q is the harmonic number of the particular band, r is the number of "octets" in the compound, one being assigned to each hydrogen,* and s is a vulgar fraction (*usually greater than unity*), the value of which is irregular and has not yet been connected with the chemical constitution either of the molecule or of its atoms.

Deslandres's formula can of course be also written: $\lambda = krs/q$, in which q, r, and s are as just defined, but $k = 9412$ $\mu\mu$ when λ is expressed in $\mu\mu$.

Deslandres ascribes the origin of his universal constant to vibration of the α-particle contained in all higher atomic nuclei. This vibration in the nucleus is supposedly synchronous with the irregular motion of the electron in the ovoid orbit suggested by Morgan (see p. 1820).

I have nevertheless thought it interesting to work out what the values of the vulgar fraction are in the compounds discussed at the beginning of the paper.

In constructing the following table the total variation of the constant has been kept less than $\pm \frac{1}{2}\%$, so as to fix the vulgar fraction. The vulgar fractions resulting are *wholly erratic and disconnected*, and therefore have no real existence.

Benzene gives $\nu = 1066/12 \times 100/9 \times$ (harmonics, *viz.*, 6, 33, 34, 35, 36 ... 39) for the brighter bands and $\nu = 1062\frac{1}{2}/12 \times 100/9 \times$ (harmonics) for the satellites. Here 12 is the value of r; and the vulgar fraction s is 9/100. Henri's vapour-absorption results (*J. Phys. Radium*, 1922, 181) give the fraction as 12/125.

Pyridine gives $\nu = 1066/11 \times 5/3 \times$ (harmonics). Here 11 is the value of r and the vulgar fraction is 3/5.

* *E.g.*, five, not one, in methane: three in water, four in hydrogen sulphide and five in carbon disulphide.

Anthracene gives two alternative results, *viz.*,
(*a*) $\nu = 1066\frac{1}{2}/24 \times 9/8 \times$ (harmonics from 53 to 82), or
(*b*) $\nu = 1060/24 \times 10/3 \times$ (harmonics from 18 to 22); plus
$\nu = 1065{\cdot}3/24 \times 16/5 \times$ (harmonics from 19 to 24).
Naphthalene gives $\nu = 1064/18 \times 14/9 \times$ (harmonics from 34).
Anthraquinone gives $\nu = 1064\frac{1}{2}/24 \times 50/11 \times$ (harmonics from 12).
Dihydroanthracene gives $\nu = 1061/26 \times 35/4 \times$ (harmonics from 7).
Anthranol gives $\nu = 1064\frac{1}{2}/25 \times 29/14 \times$ (harmonics from 29).
1-*Anthrol* gives $\nu = 1067/25 \times 23/15 \times$ (harmonics from 36).
2-*Anthrol* gives $\nu = 1066/25 \times 35/8 \times$ (harmonics from 14).
Anthraquinol gives $\nu = 1066/26 \times 60/17 \times$ (harmonics from 11).
2-*Hydroxy*-9-*anthranol* gives $\nu = 1067/26 \times 16/5 \times$ (harmonics from 16).
3-*Hydroxy*-9-*anthranol* gives $\nu = 1063/26 \times 3/1 \times$ (harmonics from 16).
Naphthazarin gives $\nu = 1064/20 \times 38/15 \times$ (harmonics from 12).
Alizarin gives $\nu = 1060/26 \times 5/3 \times$ (harmonics from 23).
Quinizarin gives $\nu = 1065/26 \times 4/1 \times$ (harmonics from 10).
Anthrarufin gives $\nu = 1064/26 \times 11/9 \times$ (harmonics from 35).
Rufol gives $\nu = 1062\frac{1}{2}/26 \times 11/7 \times$ (harmonics from 36).
Flavol gives $\nu = 1060/26 \times 40/9 \times$ (harmonics from 14).
2 : 7-*Dihydroxyanthracene* gives $\nu = 1065/26 \times 16/11 \times$ (harmonics from 41).
1 : 5-*Dihydroxyanthranol* gives $\nu = 1064\frac{1}{2}/27 \times 32/7 \times$ (harmonics from 13).
2-*Hydroxyanthraquinone* gives $\nu = 1065\frac{1}{2}/25 \times 25/13 \times$ (harmonics from 24).
2 : 6-*Dihydroxynaphthalene* gives $\nu = 1070/20 \times 5/2 \times$ (harmonics from 21).
1-*Hydroxyanthraquinone* gives $\nu = 1066\frac{1}{2}/25 \times 12/5 \times$ (harmonics from 19).

For comparison, Deslandres's results for simple compounds have been recalculated to the same basis, and the vulgar fractions come out quite simple and to some extent interconnected, namely, from $\frac{1}{12}$ to $\frac{1}{2}$.

The inference to be drawn from these considerations is that the absorptions of complex organic substances cannot be correlated with sub-atomic constants in the same way as the absorptions of simple substances.

The absorptions of complex and unsymmetrical substances, whilst no doubt *accompanied* by absorptions due to the valency electrons and the nuclei of the atoms, are therefore essentially molecular. These absorptions arise from the relative positions of the unsaturated atoms in the molecule (N, O, S, along with the group C : C), and will in course of time be fully and quantitatively explained either by Stieglitz's theory or my own.

Deslandres's theory and the harmonic part of the theory given in the British Association Report can be incorporated in mine by supposing that the constant 112 in my equation (connecting λ and molecular distance) is proportional to Deslandres's ratio $10^7 . r/1062\frac{1}{2}q$ (r = number of octets, q = harmonic number when the band is not the fundamental). Deslandres's quantity s is then no

longer a whole number or vulgar fraction, but is a function of a molecular distance of the form $a^{3/2}f(e)$, as given in Part I of this series (J., 1924, **125**, 1137).

[*Received, July 6th*, 1926.]

CCXXXVIII.—*Some Observations on the Determination of Surface Tension by Means of Capillary Rise. The Surface Tension of Water, Ethyl Alcohol, Boron Trichloride, and Silicon Tetrachloride.*

By HERBERT MILLS and PERCY LUCOCK ROBINSON.

THE availability of sufficient quantities of boron trichloride and silicon tetrachloride of high purity, together with the absence from the literature of a determination of the surface tension of the former, and the doubtful nature of the value ascribed to the latter, prompted this investigation. To establish the necessary technique, work was begun on water, the value for which has been determined with sufficient frequency to warrant its use for this purpose. Ethyl alcohol was included because of the present uncertainty in the accepted surface tension of this liquid, and also in order to extend certain observations made in the course of the measurements with water.

The capillary-rise method for the determination of surface tension has received considerable attention in recent years, particularly by Richards and Coombs (*J. Amer. Chem. Soc.*, 1915, **37**, 1656, where brief mention is made of previous work), Harkins and Brown (*ibid.*, 1919, **41**, 499), Richards and Carver (*ibid.*, 1921, **43**, 827), and Sugden (J., 1921, **119**, 1483). Study of the literature led at once to a decision to use the important suggestion of Sugden (*loc. cit.*) and Michaelis ("Praktik. d. physikal. Chemie," 1921, 61), *viz.*, that the difference in the capillary rise in two tubes should be used to measure surface tension. This constituted the most convenient method in that it removed at once the difficulty of ascertaining the exact height of the surface of the liquid in the containing vessel, which the elaborate experiments of Richards and Harkins (*loc. cit.*) and their co-workers were designed to overcome. In the present work, however, three instead of two capillary tubes were used, and a vacuum apparatus was devised capable of giving a good fall of liquid surface and of being completely submerged in a thermostat. All measurements were made in an atmosphere consisting solely of the vapour of the liquid in question.

Preliminary work showed that the level of the water in the capillaries fluctuated to an easily measurable extent over a very long period, and furthermore that the movements were not necessarily in the same direction in the three tubes at the same time. All the liquids examined behaved in this way.

Calculation of Surface Tension.

From the general formula relating surface tension to capillary rise, the equation

$$\gamma = r_1 r_2 g(3h + r_2 - r_1)(D - d)/6(r_1 - r_2)$$

may be derived, where r_1 and r_2 are the radii of two capillaries, h is the observed difference in height of two meniscuses in these tubes, D and d are, respectively, the densities of the liquid and the atmosphere over it, and g is the acceleration due to gravity. The value of g used was 981·45, and the surface tension, γ, is expressed in dynes per cm. In this investigation the capillaries were narrow enough to avoid any serious departure of the meniscuses from a hemispherical form, thus rendering unnecessary the corrections suggested by Sugden (*loc. cit.*). The diameters of tubes available were such that the rises in two were to nearly the same height, while that in the third was much lower, and as the proportional error in the measurements of h tends to increase as h diminishes, the smallest difference was not used in the calculation of surface tension.

EXPERIMENTAL.

The Preparation and Calibration of the Capillary Tubes.—The importance of a very rigorous cleaning of the capillary tubes cannot be overestimated: Harkins and Brown (*loc. cit.*), who gave this matter particular consideration, used prolonged passage of the vapour of the liquid concerned in the determination as the final cleaning process before use. The tubes here employed were steeped for several days in a solution of chromic acid in concentrated nitric acid, washed well by drawing water through them, almost submerged for 3 hours in boiling alcohol in such a manner that there was a continuous regular flow of liquid up through them, and finally steamed for 3 hours in the apparatus shown in Fig. 1—A is the capillary under treatment, B the jacket surrounding it, and C a tube of special form delivering steam under pressure from the purest distilled water. For the determinations with water the tubes were put into the apparatus wet from the steaming, but for the other determinations they were drained by holding them in a vertical position and touching the lower end with clean filter paper, and then dried at 110° in an electrically heated oven. After

their introduction into boiling alcohol the capillaries were handled only with several layers of clean filter paper between the fingers and the glass, in order entirely to prevent the possibility of the formation of a grease film.

The calibration of the capillary tubes was effected by three different methods in the case of A, B, and C, using (1) an ordinary physical travelling microscope, (2) a cathetometer, and (3) a travelling microscope, made by the Cambridge Instrument Company, and reading directly to 0·01 mm. and by estimation to 0·002 mm. The last instrument only was used in the case of D, E, and F. The mercury threads employed were weighed, after being removed from the tubes by means of dry air to a small glass weighing-bottle lid, on a special balance with calibrated weights, with the precautions usually taken in precise work. The weighings were to 0·01 mg. The uniformity of the bore was first examined by the introduction of a short thread of pure mercury, the length of which was accurately measured, in overlapping positions, along the whole length to be used. The results obtained by using the Cambridge instrument are in Table I, where the lengths of the threads are given in mm., and the figures marked with an asterisk denote the distance of the middle of the threads from the lower ends of the tubes.

FIG. 1.

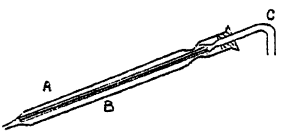

FIG. 2.

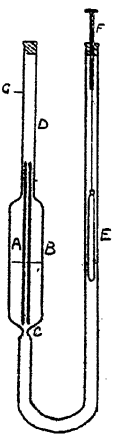

FIG. 3.

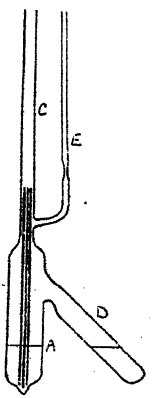

TABLE I.

A.		B.		C.	
8 cm.*	8·235	7 cm.*	10·980	8 cm.*	11·397

	13·477		14·760	2 cm.*	13·164
2·5 cm.*	13·489	1 cm.*	14·757		

The uniformity of the tubes may be expressed as a maximum percentage difference in the length of the threads; the following results are obtained: A, 0·17%; B, 0·09%; C, 0·07%; D, 0·09%; E, 0·08%; F, 0·08%. These tubes compare unfavourably with those of Richards and Coombs (*loc. cit.*), for which uniformity was claimed, and also with those of Harkins and Brown (*loc. cit.*), where the difference was 0·03% on a thread of about 16·8 mm. in length, but they were the best from 50 lb. of capillary tubing, much of it specially drawn for this research, and their selection involved 4 weeks of constant work. The radii were obtained by measuring and weighing three threads about 4 cm. long and one or more shorter threads of pure mercury about 1 cm. long in each tube, the temperature at the time of measurement being noted and the density of the metal being computed (Smithsonian Physical Tables, 7th Edtn.). The observation of Harkins and Brown (*loc. cit.*) that there is a definite sag in the mercury meniscus with the tubes in a horizontal position even when the radius is as small as 0·2 mm. was confirmed; it was corrected for, as suggested by them, by subtracting the length and weights respectively of a shorter thread. The radii of the tubes were determined with the Cambridge measuring microscope, the calibrations being restricted to the lengths actually used, and are believed to have an accuracy of 0·1% and 0·05% for the narrower and the wider tubes respectively.

TABLE II.

Tube	A.	B.	C.	D.	E.	F.

The ends of all tubes were examined for ellipticity with a microscope and found to be satisfactory in this respect.

The Surface Tension of Water.—Preliminary work with three capillary tubes of approximately the bore indicated above showed that definite vertical movement of the meniscuses took place with the tubes either arranged in a triangular formation 4 cm. apart or bound together in a bundle. The results indicated that concordant surface tensions would be obtained from either arrangement provided that sufficient time was allowed to elapse after lowering the level of the liquid. This led to the construction of a vessel of the form indicated in Fig. 2, in which A represents the prepared capillaries, held in position in the wider tube, B, by the taper at C and the extension, D. The fall in level of the liquid was secured by raising the glass plunger, E, which was suspended from the long screw, F. This apparatus, charged with first-quality water, was submerged to the point G in a thermostat at 25° ± 0·01°, and the height of the water in the capillaries was observed by

means of a cathetometer reading to 0·01 mm. at intervals of about 10 minutes for 2·5 hours from the time at which the level of the liquid was lowered. During this period the heights of the menisci in the three tubes fell irregularly, giving, when plotted against time, a sinuous downward-sloping curve, recording maximum falls of 0·72 mm., 0·64 mm., and 0·74 mm., respectively. As the upper part of the apparatus, which was closed with a loosely fitting cork, had protruded from the bath, the fall was ascribed, correctly as it was subsequently proved, to evaporation. This explanation was tested by maintaining the bath at 17·4°, *i.e.*, about 0·5° below laboratory temperature, and repeating the observations without changing the water or re-treating the tubes; 24 observations, spread uniformly over 5 hours, were taken, with the result that sinuous, slightly rising curves were now obtained, showing minimum points 0·12, 0·17, and 0·17 mm., respectively, below the initial heights after about 2·5 hours, and a maximum rise at the end of the period of 0·39, 0·22, and 0·04 mm. above. Such changes could not be explained by either evaporation or irregular drainage, and further investigation was undertaken in an apparatus (Fig. 3) which consisted of a barrel, A, 2·5 cm. wide, terminated below in a cone-shaped point and above in the centrally disposed tube, C, suitable in width for holding steadily the three capillary tubes. The side limb, D, was provided for lowering the level of the liquid, and E with its capillary served for filling and evacuation. This vessel was cleaned with chromic–nitric acid mixture, well washed with distilled water, maintained full of boiling alcohol for 4 hours, and finally well rewashed with best-quality water. When thus prepared, the freshly steamed capillary tubes were slid down C into such a position that the three could be observed from the selected direction, and C was drawn off just above the tops of the capillaries. Water (prepared by treating first-quality distilled water with a trace of alkaline permanganate, redistilling with considerable rejection of head and tail fractions, and again twice distilling the main fraction with rejections) was used for the three final washes in the apparatus. These distillations were carried out successively without delay, and the final material, which was distilled directly into E, served as the sample to be examined. E was at once attached to the pump and the whole of the air was removed, the water being warmed to facilitate this, after which the apparatus was sealed off under the pressure of water vapour only. The surface-tension vessel was completely submerged in a thermostat maintained within $\pm$ 0·01° of the required temperature and, a fall in level of the liquid having been obtained by tilting the apparatus and allowing a portion to run into D, the heights

of the meniscuses were observed with a cathetometer reading to 0·01 mm. The tubes were arranged so that the threads of all could be observed without swinging the telescope of the instrument in a horizontal plane, both they and the cathetometer having been brought to a vertical position. The glass forming the barrel, A, had been carefully selected for uniformity and lack of distortion, and careful measurements, made at different places over the range actually used, indicated that the images of the meniscuses were not appreciably changed in apparent relative position. The regularity of the results derived from different sets of observations bears out this conclusion. Table III gives one complete set (Set K) of observations for water at 25° and indicates the general nature of the fluctuations in height observed throughout this work, namely, that the most rapid and extreme variations are found within the first hour, that these variations grow less with time, and that after a period of about 10 hours they have almost entirely vanished. Table IV gives the surface tension calculated from the data in Table III, and shows that the two values come closer together with the passage of time, the difference falling from 0·26 to 0·07 unit.

			D, F	24·81	72·13	

Table V summarises the data for water using $(D - d)_{25°} = 0{\cdot}99705$ and $(D - d)_{21°} = 0{\cdot}99800$. In Sets I and J only one result is recorded because of the behaviour of tube E, which, although free from irregularity of bore or defect obvious under the microscope,

persisted in preventing water from rising beyond a certain point. Presumably this was due to some condition of the surface of the glass at this point which tended to inhibit wetting.

The Surface Tension of Alcohol.—A vessel similar to that described in the case of water was successively cleaned with chromic–nitric acid mixture, alkali, water, alcohol, and ether, and finally dried along with the capillary tubes, which had been treated as described previously, in an electrically heated oven. The alcohol used in Sets D and E was only roughly dried, that used in Set F was dried rather more thoroughly but still probably contained traces of moisture. Special precautions were, however, taken in the preparation of the alcohol for Set H, which was absolute alcohol redistilled with considerable rejections, refluxed over lime warm from burning for 3·5 days, the lime being changed at the end of the first day and a head and a tail fraction being rejected in the process. In distilling the liquid into the dried-out vessel, special precautions were taken to avoid contact with the air as far as possible; the whole operation lasted less than 0·25 hour and the apparatus was at once evacuated and sealed off. Table VI summarises the results for alcohol, all but Set H being considered as preliminary work with material containing water. The values $(D - d)_{25°} = 0{\cdot}78491$ and $(D - d)_{15°} = 0{\cdot}79352$ were used throughout.

The Surface Tension of Boron Trichloride.—Boron trichloride of high purity (for history of material and manipulation see subsequent paper by Parker and Robinson) was distilled into a similar surface-tension apparatus which had been thoroughly cleaned, dried, and evacuated. Two sets of observations were taken—at 25° with 15 readings, and at 21° with 10 readings. The data are given in Table VII, the values $(D - d)_{25°} = 1{\cdot}3144$ and $(D - d)_{21°} = 1{\cdot}3207$ being used.

The Surface Tension of Silicon Tetrachloride.—The procedure was exactly as with boron trichloride (for history of material and manipulation see Parker and Robinson, *loc. cit.*), but, unfortunately,

TABLE VII.

at the end of the distillations the sudden boiling of a drop or two of liquid in the plunger arm of the special joint caused a fracture, and air entered the apparatus. The broken portion was at once drawn off and the apparatus attached to the pump and evacuated so that exposure to air was not longer than 1·5 minutes. There was no evidence of hydrolysis in the apparatus, nor did the behaviour of the liquids in the capillaries suggest that the admission of air had had any detrimental effect; nevertheless, these results are given provisionally and it is proposed to repeat this portion of the work with other material of similar purity which is available. Table VIII gives these provisional results, 15 observations being taken in each set; $(D - d)_{25°} = 1{\cdot}4685$ and $(D - d)_{21°} = 1{\cdot}4771$ were used.

Discussion.

It has been shown that tubes of a much smaller bore than have usually been employed can be used in the determination of surface tension to a high degree of accuracy by the method suggested by Sugden (*loc. cit.*), but concordant results with two or more such tubes are obtained only several hours after the lowering of the liquid level. The thorough cleaning of the capillaries emphasised by other workers is found to be necessary. Distinct advantage attends the use of three in place of two tubes, and the results are the same whether they be separated from one another by several cm. or bound together in a bundle, the latter arrangement being more convenient. During the first hour or so, the meniscuses in the capillary tubes show slow oscillations, sometimes opposite in direction in two tubes at the same time, or coinciding with no movement in another tube, while the mean heights tend to decrease throughout the same period, and surface tensions calculated from differences in the heights obtained at any moment do not show

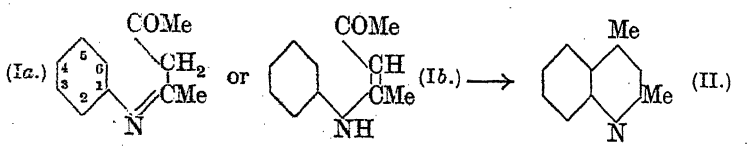
good agreement amongst themselves. These movements gradually decrease and are followed by a series of more or less spasmodic rises which continue, although they may be separated by intervals as long as one or two hours, until the maximum rise for each tube is reached. That these rises are to be ascribed to surface forces, and not to any change in level of the main liquid surface from drainage or other causes, is proved by the fact that they are invariably preceded by a greatly increased curvature of the meniscus, as though the centre were being drawn down, whilst, furthermore, the movements take place at times and to extents which are not the same in the different tubes.

If the forces producing the rises were being applied at the base of the columns, a flattening of the meniscuses and concurrent rises in the three tubes would be anticipated. The whole subject is being investigated, but a careful examination of the available data leads to the conclusion that for the same liquids the changes in the heights of the meniscuses decrease with increasing size of capillary, while the period required to reach the maximum rise and the equilibrium is slightly less in the wider tubes, and that with the same bore the magnitude of these changes in the liquids considered grows less in the order alcohol, water, silicon tetrachloride, boron trichloride. The inference made here is that, after the oscillations of the initial period have damped down, the change in level of the meniscus due to spasmodic rises is probably related to viscosity, for the viscosities of alcohol and water are known to decrease in the order noted, while those of the chlorides, although apparently not determined, are certainly less than that of water. It is suggested that the maximum rise attained when the meniscuses are at rest corresponds to the true static equilibrium between surface energy and gravity, and that the figure calculated from h in these conditions corresponds to the true surface tension. It should be pointed out that, once equilibrium is reached, the meniscuses are not observed to move either of their own accord or when the vessel has been made to tremble by tapping, thus suggesting the stability above implied.

Surface tensions are usually given at 20°, and Table IX records the values now found (in contact with only the vapour of the substance) corrected to this temperature, together with the change per degree.

TABLE IX.

Substance.	γ.	Change in γ per degree.
Water	72·90 ± 0·04	0·15
Alcohol	22·05 ± 0·01	0·09
Boron trichloride	16·70 ± 0·01	0·11
Silicon tetrachloride	19·71 ± 0·01	0·12



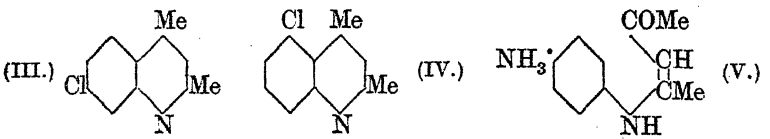
The value for water agrees most closely with the 72·80 of Harkins and Brown (*loc. cit.*), but is much higher than the 72·74 of Richards and Coombs (*loc. cit.*), the 72·70 of Sugden (*loc. cit.*), the 72·61 of Worley (J., 1914, **105**, 266), or the 72·8 given as the most probable value by Freundlich ("Colloid and Capillary Chemistry," 1927, 24). In the case of alcohol there have been numerous previous determinations yielding results varying from 21·2 to 22·4. The value given above agrees closely with the 22·0 of Ramsay and Shields (*Phil. Trans.*, 1893, **184**, 647), and the precautions taken in this work render it the most probable value at the present time. The surface tension of boron trichloride has not hitherto been recorded. Silicon tetrachloride has received attention from Ramsay and Shields (*loc. cit.*), who found $\gamma = 16{\cdot}31$ at 18·9°, *i.e.*, 16·20 at 20°; from Walden (*Z. anorg. Chem.*, 1900, **25**, 218), who found $\gamma = 18{\cdot}20\ (1 - 0{\cdot}00548t)$, *i.e.*, 16·23 at 20°; and from Mendeléev (*Pogg. Ann.*, 1870, **141**, 618), who found 15·13 at the b. p. (57°), which is approximately equivalent to 19·20 at 20°.

UNIVERSITY OF DURHAM, ARMSTRONG COLLEGE,
NEWCASTLE-UPON-TYNE. [*Received, May 9th*, 1927.]

CCXXXIX.—*The Factors controlling the Formation of Some Derivatives of Quinoline, and a New Aspect of the Problem of Substitution in the Quinoline Series.*

By ELWYN ROBERTS and EUSTACE EBENEZER TURNER.

AN apparently excellent method for obtaining quinoline derivatives (II) is that devised by Combes (*Bull. Soc. chim.*, 1888, **49**, 90; *Compt. rend.*, 1887, **106**, 142), namely that of warming, with concentrated sulphuric acid, the condensation products (I*a* or I*b*) of acetylacetone with primary aromatic amines:



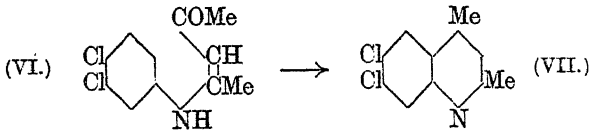
Previous work has shown that most simple substituted anilines condense readily with acetylacetone, even where, as in 2 : 6-dimethoxyaniline, a marked steric effect must be supposed to occur (Turner, J., 1917, **111**, 1), and it has now been found that, although *o*-, *m*-, and *p*-chloro-, 2 : 4-, 3 : 4-, and 3 : 5-dichloro-aniline do so, 2 : 5-dichloroaniline condenses only partially. The case of condens-

ation appears to be affected most by the basicity of the aniline used, for no nitroaniline, simple or complex, can be caused to condense with acetylacetone. It may be noted that acetylacetone condenses less well with most bases than does, for example, salicylaldehyde, which rapidly converts 2 : 5-dichloroaniline into the o-*hydroxybenzylidene* derivative.

The second stage of the Combes quinoline synthesis, namely, the intramolecular condensation of an anil of acetylacetone, is, however, much more definitely affected by the nature of the substituents present. Thus, whilst the condensation products, with acetylacetone, of aniline and *p*-toluidine (Combes, *loc. cit.*), those of 2 : 3-, 2 : 5-, and 3 : 4-dimethoxyaniline, that of 2-bromo-4 : 5-dimethoxyaniline (Lions, Perkin, and Robinson, J., 1925, **127**, 1158), and, as now shown, that of *m*-chloroaniline readily pass into the corresponding substituted 2 : 4-dimethylquinolines, a number of not very dissimilar anils do not, under corresponding conditions, undergo conversion into quinolines to any measurable extent. Into this second class fall the condensation *products*, with acetylacetone, now examined for the first time, of *o*- and *p*-chloroanilines, 2 : 4-, 2 : 5-, and 3 : 5-dichloroanilines, and *o*-anisidine. Koenigs and Mengel (*Ber.*, 1904, **37**, 1322) were similarly unable to obtain 6-methoxy-2 : 4-dimethylquinoline from β-*p*-methoxyanilinopropenyl methyl ketone. Marckwald and Schmidt (*Annalen*, 1893, **274**, 331) showed that, whilst both *m*- and *p*-phenylenediamines condensed with two molecules of acetylacetone, treatment of the products with concentrated sulphuric acid afforded an amino-2 : 4-dimethylquinoline (and not a phenanthroline) in the former case, and no quinoline at all in the second. Incidentally, Bülow and Issler (*Ber.*, 1903, **36**, 4013) effected the conversion of β-*m*-hydroxyanilinopropenyl methyl ketone into a mixture of hydroxy-2 : 4-dimethylquinolines by using, not concentrated sulphuric acid, but hydrogen chloride and glacial acetic acid as the condensing medium.

It appears possible to draw certain definite conclusions from these facts. For example, when a strongly ortho-para directing group is present in the meta-position to the nitrogen atom [3 or 5 in (I)], condensation proceeds readily, even if a similar group is present in an unfavourable position, as in 2 : 5-, 3 : 4-, and 2 : 3-dimethoxyaniline. On the other hand, a strongly ortho-para directing group present in position 4 (I), in absence of other substituents in favourable positions, appears to be sufficient to prevent quinoline formation (*o*- and *p*-anisidine). The effect of chlorine is what would be anticipated from our knowledge of its power as a directive influence. Thus, whilst one chlorine atom in a favourable

position (meta to the nitrogen atom) is associated with exceptional ease of quinoline formation, a chlorine atom in another position prevents condensation (but compare the case of 3 : 4-dichloroaniline, below). It therefore seems that in these cases the ortho-directive influence of the nitrogen atom is, extraordinary though it may appear, feebler than the opposing ortho-para influence of a chlorine atom. Further, whilst steric factors do not prevent the operation of the directive influence of a methoxyl group, they appear to more than neutralise that of even two chlorine atoms. Thus, β-3 : 5-dichloroanilinopropenyl methyl ketone [chlorine in positions 3 and 5 in (I)] cannot be converted into the corresponding quinoline, although the two chlorine atoms and the nitrogen atom would be expected to favour condensation. From this fact, one might deduce that the dimethylquinoline formed from *m*-chloroaniline would be (III) rather than (IV), since the steric effect would operate against the formation of the latter. That this inference is correct is proved



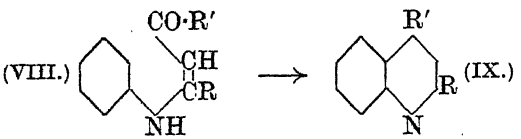
later. It would also appear to follow from this that the compound obtained by Marckwald and Schmidt (*loc. cit.*) from *m*-phenylenediamine is 7-amino-2 : 4-dimethylquinoline. The non-formation of a quinoline from *p*-phenylenediamine is of interest, for, since β-*p*-aminoanilinopropenyl methyl ketone is presumably present as the ion (V) in concentrated sulphuric acid solution, the most favoured position would appear to be that where condensation could occur, but does not.

It is somewhat difficult, on the other hand, to explain why β-*p*-toluidinopropenyl methyl ketone [methyl in position 4 in (I)] is quantitatively converted into 2 : 4 : 6-trimethylquinoline (see Experimental). For, since *p*-chlorotoluene nitrates to roughly equal extents in the 2- and 3-positions (Holleman, *Rec. trav. chim.*, 1909, **28**, 408), the influence of a methyl group should approximate to that of a chlorine atom in type (I). The explanation may be, however, that just as replacement by chlorine, but not by methyl, diminishes the basicity of the aniline molecule, so it diminishes the ortho-para directive influence, already small, of the nitrogen atom in the acetylacetone anils.

Particular interest attaches to the action of sulphuric acid upon the condensation product of acetylacetone with 3 : 4-dichloroaniline (VI). Preliminary experiments showed no condensation, but then, on one occasion, a good conversion into a dichlorodimethylquinoline,

m. p. 119—120°, occurred. Attempted repetition of the successful experiment on at least a dozen occasions never gave an isolable quantity of this product, which, however, has been shown to be 6 : 7-*dichloro*-2 : 4-*dimethylquinoline* (VII).

We regard these results as indicating that in (VI) there is a very delicate balance between the antagonistic and the favourable influences, so that the slightest variation from the ideal conditions for condensation is sufficient to prevent ring closure.



The non-formation of quinoline in the cases referred to above can hardly be due to an initial condensation to the extent of a few units %, the water formed then, with the sulphuric acid, hydrolysing the unchanged anil of a weak base, for if this were so, condensation should have been observed where absolute or slightly fuming sulphuric acid was used.

Partly in order to prove the constitution of the products (III) and (VII), and partly to institute a comparison of the Combes condensation with others leading to the same, and other, quinolines, we next directed our attention to the method first used by Reed (*J. pr. Chem.*, 1885, **32**, 630), but generally known as the Beyer condensation (*ibid.*, 1886, **33**, 393). When heated with a suitably aged mixture of paraldehyde, acetone, and hydrogen chloride at 100° in presence of nitrobenzene, *o*-, *m*-, and *p*-chloro-, 2 : 4-, 2 : 5-, 3 : 4-, and 3 : 5-dichloro-, and 2 : 4 : 5-trichloro-aniline were converted into dimethylquinolines, although in every case the yield was poor. On the other hand, *m*-nitroaniline was apparently unaffected, whilst *o*-nitroaniline was converted in good yield into a *compound* other than the expected 8-nitro-2 : 4-dimethylquinoline. Again, 3-chloro-6-nitro- and 3 : 4-dichloro-6-nitro-aniline were converted into tarry substances from which nothing could be isolated. The object of attempting the latter two condensations was to synthesise reference compounds needed for the elucidation of the structure of (III) and (VII).

When on one occasion 3 : 5-dichloroaniline was heated with a paraldehyde–acetone–hydrogen chloride mixture prepared 2 months previously, no 5 : 7-dichloro-2 : 4-dimethylquinoline was obtained, but, in good yield, a *substance* which has not yet been identified.

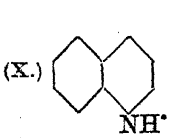
The above results become of even greater interest when the Combes and the Beyer condensation are compared with those of Doebner and von Miller and of Skraup. The last three of these

condensations have been the subject of repeated investigation, but much uncertainty still exists as to the precise mechanism underlying them. Consideration of the papers of von Miller (*Ber.*, 1891, **24**, 1720; 1892, **25**, 2072), Jones and his collaborators (J., 1910, **97**, 632; 1911, **99**, 334; 1912, **101**, 1376), Blaise and Maire (*Compt. rend.*, 1907, **144**, 93; *Bull. Soc. chim.*, 1908, **3**, 658), and Simon (*Compt. rend.*, 1907, **144**, 138) suggests, however, that the four reactions under discussion are similar in one respect, namely, that in the last stage they all appear to conform to the general scheme of (VIII) passing into (IX):

The Skraup, Doebner–Miller, Beyer, and Combes condensations are represented by this scheme when R = R′ = H, R = Me and R′ = H, R = R′ = Me, and R = R′ = Me, respectively. The assumption is not invalidated by the observations of Knoevenagel and his collaborators (*Ber.*, 1922, **55**, 1923; 1923, **56**, 2414), nor can the fact that the so-called "aldol bases" are formed in the Doebner–Miller reaction be regarded as involving a conception essentially different from that represented by the above scheme.

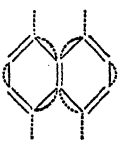
Decker and Remfry (*Ber.*, 1905, **38**, 2773) concluded that both the Skraup and the Doebner–Miller reaction converted mono-meta-substituted anilines into 5-substituted quinolines. A closer examination of the facts, however, shows that this is hardly the case, since Skraup reactions with these compounds actually fall into two classes. Those in which the meta-substituent is meta-directing (NO_2, SO_3H, and CO_2H) give almost entirely 5-substituted quinolines (La Coste, *Ber.*, 1883, **16**, 669; Claus and Stiebel, *Ber.*, 1887, **20**, 3095; Knueppel, *Ber.*, 1896, **29**, 703; Decker, *J. pr. Chem.*, 1901, **63**, 573; **64**, 85; Lellmann and Lange, *Ber.*, 1887, **20**, 1446; Schlossen and Skraup, *Monatsh.*, 1881, **2**, 518; Skraup, *Ber.*, 1882, **15**, 893; Skraup and Bronner, *Monatsh.*, 1886, **7**, 139, 519; Lellmann and Alt, *Annalen*, 1887, **237**, 307), whilst, when the meta-substituent is ortho-para directing (Cl, Br, Me, OH), either a mixture of 5- and 7-derivatives results, or almost exclusively the 7-derivative (La Coste and Bodewig, *Ber.*, 1884, **17**, 926; La Coste, *Ber.*, 1885, **18**, 2940; Claus and Tornier, *Ber.*, 1887, **20**, 2872; Claus and Vis, *J. pr. Chem.*, 1889, **40**, 382; Skraup, *Monatsh.*, 1882, **3**, 381, 531; Skraup, *loc. cit.*; Skraup and Bronner, *loc. cit.*; von Braun, Gmelin, and Schultheiss, *Ber.*, 1923, **56**, 1341). On the other hand, *m*-

nitroaniline gives mainly 5-nitroquinaldine (Decker and Remfry, *loc. cit.*), whilst it does not condense to any observable extent under the conditions of the Beyer synthesis.

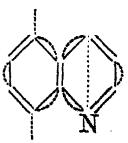


m-Chloroaniline gives rise to a mixture of 5- and 7-derivatives in the Skraup reaction (La Coste, 1885, *loc. cit.*; Claus and co-workers, *J. pr. Chem.*, 1893, **48**, 253, 270), mainly to the 7-derivative in the Beyer reaction, and to the 7-derivative only in the Combes condensation. An inspection of (VIII) and (IX) suggests that the difference in position of condensation in the three reactions mentioned is due to the steric effect of R′. Possibly the same effect prevents the formation of 5-nitro-2 : 4-dimethylquinoline by the Beyer process, since for some reason, not clear at present, the quinoline ring apparently prefers to form in the ortho-position with respect to a nitro-group rather than in the para-position. This point is of considerable interest, since in the nitration of nitrobenzene, more ortho- than para-substitution occurs.

Which constitution (I*a* or I*b*) more accurately represents the constitution of the condensation products of acetylacetone with anilines cannot now be discussed, but we have observed that dibenzoylmethane condenses with freshly distilled aniline to give, as one product, a compound identical with that obtained by Watson (J., 1903, **83**, 1326) by the addition of aniline to benzoylphenylacetylene, CPh:C·COPh. Watson regarded his compound as being either CHPh:C(NHPh)·COPh or NHPh·CPh:CH·COPh, and the formation of the same compound from dibenzoylmethane shows that the latter reacts in the enolic form, to give the second of the two substances formulated, *i.e.*, to give the anilino-derivative and not the phenylimino-compound, COPh·CH_2·CPh:NPh. One of us has previously observed (Turner, *loc. cit.*) that when acetylacetone is heated with excess of aniline it undergoes scission, giving acetanilide. We have now found that benzanilide is formed as a second product when aniline reacts with dibenzoylmethane.



The factors governing substitution in quinoline compounds are apparently less complex than would be assumed from first considerations. Quinoline and 2-methylquinoline both nitrate simultaneously in the 5- and 8-positions (Claus and Kramer, *Ber.*, 1885, **18**, 1243, etc.), whilst 4-methylquinoline, on the other hand (Busch and Königs, *Ber.*, 1890, **23**, 2687), gives only the 8-nitro-derivative, an effect almost certainly due to the steric influence of the methyl group in position 4. 2 : 4-Dimethylquinoline would therefore also be expected to nitrate in position 8, and has actually been found to do so. The *nitro*-compound on reduction gives 8-*amino*-2 : 4-*dimethylquinoline*, and the latter is converted by the Gattermann diazo-method into 8-*chloro*-2 : 4-*dimethylquinoline*,

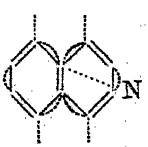


identical with the product of the Beyer condensation, using *o*-chloroaniline.

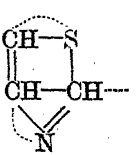
It would be thought that most of the substitution reactions of quinoline could be referred to the presence of the nitrogen atom, but actually this is not the case. Nor is it quite clear by what process conditions of nitration affect the proportion of 5- and 8-substitution in quinoline itself. For example, when quinoline nitrate is added to fuming sulphuric acid, 5-nitroquinoline results (Dufton, J., 1892, **61**, 783), whilst mixed acid converts quinoline itself mainly into the 8-isomeride (Kŏnigs, *Ber.*, 1879, **12**, 449). If the former nitration were explained as that of the ion (X), and the latter as that of the free base, then it would be difficult to explain why *iso*-

(X.)

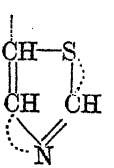
(XI.)



(XII.)



quinoline does not nitrate in position 7 (Claus and Hoffmann, *J. pr. Chem.*, 1893, **47**, 253), and even more so why quinolinium methonitrate also nitrates in positions 5 and 8 (Decker, *Ber.*, 1905, **38**, 1274). A comparison of quinoline and naphthalene appears to solve these difficulties, for, just as the behaviour of naphthalene is tolerably well explained by Thiele's formula (XI), so that of quinoline should be explained, at least to a considerable extent, by (XII), the following two facts being borne in mind: (1) Mills and Smith (J., 1922, **121**, 2724) concluded that in the naphthalene molecule the two central (*i.e.*, un-numbered) carbon atoms are joined by a double bond, (2) the pyridine molecule is markedly non-reactive, a property capable of explanation by formulating it as (XIII), since the highly unsaturated nitrogen atom may be assumed to take up residual affinity from the 4-position. That is, one would expect to find reactivity in the 5- and 8-positions in quinoline, corresponding to the reactivity of the *four* α-positions in naphthalene.



(XIII.)

(XIV.)

(XV.)

(XVI.)

Indeed, the application of similar reasoning to the *iso*quinoline and thiazole molecules suggests an alternative explanation of the interesting results obtained by Mills and Smith (*loc. cit.*), *viz.*, in

*iso*quinoline, chlorine * should be more reactive (towards hydriodic acid and red phosphorus) in position 1 than in position 3, and in thiazole, since the nitrogen atom is less saturated than the sulphur atom (compare XV and XVI), reactivity should be associated more with position 2 than with position 4—which is actually the case. If this explanation is correct, reactivity should also be greater in position 5 than in position 4.

If (XIV) accurately represents the *iso*quinoline molecule, the known nitro-derivative might be expected to be the 5- rather than the 8-compound.

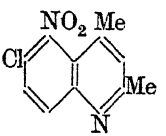
Quinoline actually resembles naphthalene very strongly in its substitution reactions, since α-nitronaphthalene corresponds with either 5- or 8-nitroquinoline. The analogy becomes even more striking when it is realised that, just as naphthalene-α-sulphonic acid is converted by concentrated sulphuric acid under definite conditions into the β-isomeride, so quinoline-5-sulphonic acid is converted by the same reagent at 250—300° into the 6-isomeride (Lellmann and Reusch, *Ber.*, 1889, **22**, 1391).

Nitration of 6-, 7-, and 8-chloro-2 : 4-dimethylquinoline appears to be controlled almost entirely by 5 : 8 reactivity, and by the ortho-para directive influence of the chlorine atom, which can act partly in the same sense. These overcome the steric effects which must be assumed in the case of the 6- and the 7-chloro-compound [compare the nitration, by Armstrong and Wynne, of β-chloronaphthalene, where the α-position *could* be avoided, and is (*Chem. News*, 1889, **59**, 225)]. For example, 6-chloro- and 7-chloro-2 : 4-dimethylquinoline nitrate in positions 5 and 8, respectively. The 8-chloro-compound nitrates in position 5, as is shown by the fact that the *nitro*-compound, on reduction, affords an *amino*-compound which is convertible into 5 : 8-*dichloro*-2 : 4-*dimethylquinoline*, identical with the product of Beyer condensation on 2 : 5-dichloroaniline.

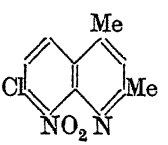
That the ortho-para directive influence of the chlorine atoms in these compounds operates is shown by the results of nitrating 6- and 7-chloro-2 : 4-dimethylquinoline. The effect of 5 : 8-reactivity in the quinoline series is shown very clearly by the fact that 6-bromoquinoline sulphonates in position 8 (Edinger, *Ber.*, 1908, **41**, 937), whilst 6-chloroquinoline sulphonates either in 5 or in 8, according to conditions (Claus and Schedler, *J. pr. Chem.*, 1894, **49**, 355). An even more striking case is that recorded by Kaufmann and Hussy (*Ber.*, 1908, **41**, 1735), who showed that 6- and 7-nitroquinoline nitrate to give, respectively, 5 : 6- and 6 : 8-, and 5 : 7- and 7 : 8-

* The chlorine atom here appears to be of the positive type.

dinitroquinoline, *i.e.*, 5 : 8-reactivity causes some nitration to occur in the ortho-position to a nitro-group.



Dichloro-derivatives of 2 : 4-dimethylquinoline also nitrate quantitatively to give only one product. Thus the 5 : 8-dichloro-derivative gives 5 : 8-*dichloro*-6-*nitro*-2 : 4-*dimethylquinoline*, whose constitution is proved by its conversion, through the corresponding 6-*amino*-compound, into 5 : 6 : 8-*trichloro*-2 : 4-*dimethylquinoline*, also obtained by Beyer condensation of 2 : 4 : 5-trichloroaniline. Nitration of other dichloro-compounds undoubtedly occurs in position 5 or 8, but it has been impossible to prove the constitutions of the products, since the amines obtained by reduction could not be converted into the corresponding chloro-compounds. We have confirmed the observation made by Claus (compare *J. pr. Chem.*, 1894, **49**, 355) that the Sandmeyer reaction is unsuitable in the quinoline series, whereas the Gattermann method gives good results. On the other hand, the success of a replacement of an amino-group by chlorine depends also on the basicity of the amino-compound, and on the rate of diazotisation of the hydrochloride; for example, whilst 8-amino-, 6-*chloro*-5-*amino*-, 8-chloro-5-amino-, and 7-*chloro*-8-*amino*-2 : 4-*dimethylquinoline* diazotise readily, 5 : 8-dichloro-6-amino-2 : 4-dimethylquinoline diazotises slowly, 6 : 8-*dichloro*-5(?)-*amino*- still more slowly, and 5 : 6-*dichloro*-8(?)-*amino*- hardly at all. 5 : 6 : 8-Trichloro-2 : 4-dimethylquinoline does not undergo nitration under the conditions employed.



It was stated above that 3 : 4-dichloroaniline was converted by the Combes reaction into 6 : 7-dichloro-2 : 4-dimethylquinoline, but this fact was only established with considerable difficulty. *o*-Dichlorobenzene was found to condense readily with acetyl chloride under Friedel–Crafts conditions to give 3 : 4-*dichloroacetophenone*, but the nitration of the latter caused unexpected difficulties. These were finally overcome, and the 3 : 4-*dichloro*-2-*nitroacetophenone* obtained was converted into the corresponding *amino*-compound, which, when heated with acetone and a trace of alkali, gave an almost quantitative yield of 6 : 7-dichloro-2 : 4-dimethylquinoline, m. p. 119—120°, identical with the product from 3 : 4-dichloroaniline. The proof of the constitution of this product enabled us to deduce the constitution of the product of nitration of 6-chloro-2 : 4-dimethylquinoline. When this was reduced and the resulting amine was submitted to the Gattermann reaction, a dichlorodimethylquinoline was obtained, also melting at 119—120°; this depressed the m. p. of the synthetic 6 : 7-isomeride, and was therefore 5 : 6-dichloro-2 : 4-dimethylquinoline, since the 6 : 8-isomeride, obtained by Beyer condensation of 2 : 4-dichloroaniline, melted at 148—148·5°.

The chloro-2 : 4-dimethylquinoline obtained by the Combes reaction from *m*-chloroaniline, and therefore either the 5- or the 7-derivative, gave a nitro-compound which was converted into a chloroamino-compound, and thence into a dichloro-compound melting at 104—104·5°. The latter could only be 5 : 6-, 5 : 7-, 5 : 8-, 6 : 7-, or 7 : 8-dichloro-2 : 4-dimethylquinoline. Of these compounds, three were already known, and 5 : 7-*dichloro*-2 : 4-*dimethylquinoline*, obtained by Beyer condensation from 3 : 5-dichloroaniline, was found to melt at 84—86°. It therefore follows that the above chlorodimethylquinoline is the 7-derivative, and the derived dichlorodimethylquinoline the 7 : 8-derivative.

6-*Chloro*-5-*nitro*-2 : 4-*dimethylquinoline* was found not to react with piperidine, and this led us to consider again the work of Mills and Smith (*loc. cit.*). If, with these authors, we assume the presence of a central double bond in the quinoline molecule, the 6-chlorine atom and the 5-nitro-group will be attached to carbon atoms joined by a double bond (XVII), a condition assumed by Borsche and his co-workers (*Annalen*, 1913, **402**, 81; 1926, **447**, 1) to be associated with diminished reactivity of chlorine. One of these assumptions—we think that due to Borsche—appears to be incorrect, since 7-*chloro*-8-*nitro*-2 : 4-*dimethylquinoline* (XVIII), in which almost similar conditions obtain, reacts readily with piperidine to give 8-*nitro*-7-*piperidino*-2 : 4-*dimethylquinoline*.

(XVII.)

(XVIII.)

We have also investigated the chlorination of various chloro-derivatives of 2 : 4-dimethylquinoline in presence of glacial acetic acid and anhydrous sodium acetate. 7-Chloro-2 : 4-dimethylquinoline gave a *trichloro*-derivative, whilst 6- and 8-chloro- and 5 : 6-dichloro-2 : 4-dimethylquinoline gave *tetrachloro*-2 : 4-*dimethylquinolines*, all different. 5 : 8-Dichloro-2 : 4-dimethylquinoline, however, gave a *pentachloro*-2 : 4-*dimethylquinoline*, identical with the product of chlorinating the 6 : 8-compound. All these compounds contain mobile chlorine (of the negative type), showing that chlorination has occurred partly in the methyl groups. Similar compounds were obtained by Kŏnigs from 8-nitro-4-methylquinoline (*Ber.*, 1898, **31**, 2368) and later by Hammick (J., 1923, **123**, 2882). Little can be said with regard to the constitutions of our compounds, except that the pentachloro-compound must, because of its dual origin, contain chlorine atoms in the 5-, 6-, and 8-positions. The

extent to which chlorination occurs is apparently determined neither by the amount of sodium acetate used, nor by the solubility of the compounds actually isolated.

EXPERIMENTAL.

Condensation of Substituted Anilines with Acetylacetone.—The general method adopted was to allow a mixture of the substituted aniline (1 mol.) with 1·1 mols. of acetylacetone to boil gently under reflux for 1—2 hours. The cooled product was then thoroughly shaken with water, benzene added, and the two layers separated. The benzene solution was shaken twice or thrice with water, dried over anhydrous sodium sulphate, and heated at 100° until free from benzene. In most cases, the anil was then pure enough to solidify when cooled.

p-Toluidine.—The anil was obtained in almost theoretical yield, and after one crystallisation from light petroleum (b. p. 40—60°) formed massive prisms, m. p. 68—69°. Combes (*loc. cit.*) gave m. p. 39—40°, whereas in D.R.-PP. 363,582 and 363,583 the m. p. is given as 65·5°. Ferriss and Turner (J., 1920, **117**, 1140) stated that the anil was converted, under the conditions now given for its formation, into 2 : 4 : 6-trimethylquinoline. This, however, is not the case. The anil, β-*p*-toluidinopropenyl methyl ketone, when treated with sulphuric acid by the usual method (see below) was quantitatively converted into 2 : 4 : 6-trimethylquinoline, m. p. 43—45°. The m. p. (63—64°) quoted by Pfitzinger (*J. pr. Chem.*, 1888, **38**, 40) is evidently that of the hydrate, which we have found to melt at 63—65°. The concentrated sulphuric acid solution of the crude quinoline, when treated with potassium dichromate, remained a clear reddish-brown colour after some minutes' boiling, indicating the absence of even small quantities of *p*-toluidine. Such quantitative conversion into a quinoline was not observed with the product from any other substituted aniline.

o-*Chloroaniline.*—β-o-*Chloroanilinopropenyl methyl ketone* was readily formed, and separated from light petroleum (b. p. 40—60°) in small plates, m. p. 66—67° (Found: Cl, 17·1. $C_{11}H_{12}ONCl$ requires Cl, 16·9%).

p-*Chloroaniline.*—β-p-*Chloroanilinopropenyl methyl ketone* was readily obtained, and crystallised from light petroleum (b. p. 40—60°) in rectangular prisms, m. p. 60—61° (Found: Cl, 17·0%).

m-*Chloroaniline.*—β-m-*Chloroanilinopropenyl methyl ketone*, readily formed, crystallised from light petroleum (b. p. 40—60°) in plates; it had m. p. 42°, and b. p. 187°/13 mm. (Found: N, 6·9. $C_{11}H_{12}ONCl$ requires N, 6·7%).

o-*Hydroxybenzylidene*-3-*chloroaniline* was readily obtained, and separated from alcohol in bright yellow needles, m. p. 99° (Found: N, 6·1. $C_{13}H_{10}ONCl$ requires N, 6·0%).

2 : 4-*Dichloroaniline*.—This base condensed readily with acetylacetone. β-2 : 4-*Dichloroanilinopropenyl methyl ketone* separated from aqueous alcohol in needles, m. p. 100·5° (Found: N, 5·8. $C_{11}H_{11}ONCl_2$ requires N, 5·7%). o-*Hydroxybenzylidene*-2 : 4-*dichloroaniline* separated from alcohol in brilliant yellow needles, m. p. 90·5° (Found: N, 5·3. $C_{13}H_9ONCl_2$ requires N, 5·3%).

2 : 5-*Dichloroaniline*.—The condensation of this base with acetylacetone presents two interesting features. When any other of the substituted anilines dealt with was heated with acetylacetone at 100° (the approximate b. p. of such mixtures), water was seen to separate after a few minutes. In the case of 2 : 5-dichloroaniline, however, water only separated from the condensation mixture when the latter was boiling briskly. On cooling it a few degrees, the water redissolved. The second peculiarity observed was the small yield obtained, so that the β-2 : 5-*dichloroanilinopropenyl methyl ketone* was only isolable by distillation under diminished pressure (b. p. 190—200°/15 mm.) of the purified reaction product. It finally crystallised from light petroleum (b. p. 40—60°) in octahedra, m. p. 46°. o-Hydroxybenzylidene-2 : 5-dichloroaniline, on the other hand, was readily obtainable in good yield; the crude product crystallised from alcohol in bright yellow needles, m. p. 107° (Found: N, 5·4%).

3 : 5-*Dichloroaniline*.—Condensation occurred readily, but the β-3 : 5-*dichloroanilinopropenyl methyl ketone* was not obtained crystalline. The 3 : 5-dichloroaniline required was obtained by reducing 3 : 5-dichloronitrobenzene by the iron method, the nitro-compound being prepared as follows (compare Holleman and Reiding, *Rec. trav. chim.*, 1904, **23**, 366): A mixture of 85 g. of 2 : 6-dichloro-4-nitroaniline and 170 c.c. of concentrated sulphuric acid was diazotised at −5° with 56 g. of solid sodium nitrite. The dark paste obtained was slowly run into 600 c.c. of boiling 96% alcohol; immediate decomposition then took place, with the formation of an orange solution. Some sodium sulphate separated, and on diluting the mixture largely with water, the nitro-compound was precipitated. It had m. p. 62—65°, whereas the pure substance melts at 65°.

3 : 4-*Dichloroaniline*.—This base condensed smoothly with acetylacetone to give β-3 : 4-*dichloroanilinopropenyl methyl ketone*, which separated from alcohol in almost colourless needles, m. p. 73° (Found: N, 5·7%). o-*Hydroxybenzylidene*-3 : 4-*dichloroaniline* crystallises from alcohol in long, yellow needles, m. p. 113°

(Found: N, 5·4%). The 3 : 4-dichloroaniline required was prepared by reducing the corresponding nitro-compound by the iron method.

o-*Anisidine.*—Condensation occurred readily to give β-o-*methoxyanilinopropenyl methyl ketone*, which separated from light petroleum (b. p. 40—60°) in plates, m. p. 51—52·5°.

3-*Chloro*-6-*acetamidoaniline.*—This also was found to condense with acetylacetone, but the product, like that from *o*-anisidine, was not further examined, since it gave no quinoline derivative when treated with concentrated sulphuric acid.

3 : 4-*Dichloro*-6-*nitroaniline.*—This base was recovered unchanged after being heated with excess of acetylacetone in a closed tube for 6 hours at 200°. The dichloro-base was readily obtainable by hydrolysing (90% sulphuric acid at 120° for 20 minutes) the corresponding acetyl derivative, the latter being prepared as described by Beilstein and Kurbatow (*Annalen*, 1879, **196**, 225).

Attempted Preparation of 2 : 3-*Dichloroaniline.*—(*a*) The nitration of 3 : 4-dichloroaniline in presence of a large excess of sulphuric acid led to a mixture of products, from which only unchanged base was isolated. It had been hoped that 3 : 4-dichloro-5-nitroaniline would be obtained, and thence, by removal of the amino-group, 2 : 3-dichloronitrobenzene. (*b*) *o*-Chloroacetanilide sulphonated readily when added to cold fuming sulphuric acid (25% SO_3). The solution was treated with nitric acid, and then evidently contained 3-chloro-5-nitro-4-acetamidobenzenesulphonic acid (compare D.R.-P. 206,345, dealing with a similar treatment of *m*-chloroacetanilide). The solution of the nitrosulphonic acid, when diluted slightly and boiled, contained acetic acid, but various methods tried did not give detectable quantities of 2-chloro-6-nitroaniline, from which it had been hoped to prepare 2 : 3-dichloronitrobenzene.

Conversion or Attempted Conversion of Anils of Acetylacetone into Substituted 2 : 4-*Dimethylquinolines.*—The most satisfactory method of effecting this condensation was as follows: The anil was slowly added, as a fine powder, or as a thin stream of liquid, to six times its weight of concentrated sulphuric acid, the latter being kept well shaken, and cooled below 5°. As soon as solution occurred, the mixture was heated for 0·5 hour on the boiling water-bath. The extent of condensation was readily diagnosed by diluting a little of the sulphuric acid solution. In cases of unsuccessful condensation, the odour of acetylacetone became apparent at once, and, usually, the sulphate of the unchanged base separated. Neither of these observations was made in the case of a successful condensation, and the further addition of potassium dichromate then gave an immediate precipitate of the quinoline dichromate

(see above under *p*-toluidine). The isolation of the quinolines presented no difficulty.

β-*Anilinopropenyl Methyl Ketone.*—The yield of pure 2 : 4-dimethylquinoline obtained was 90% on the weight of anil taken, or 75% on the weight of aniline. The success of this condensation appears to depend largely on the purity of the anil, the distillation of which (Combes, *loc. cit.*) is not only unnecessary, but disadvantageous.

The anils from acetylacetone and *o*- and *p*-chloroaniline, 2 : 4-, 2 : 5-, and 3 : 5-dichloroaniline, *o*-anisidine and 3-chloro-6-acetamidoaniline were not converted into the corresponding quinolines by the sulphuric acid method. Use of absolute sulphuric acid, or of slightly fuming acid, or variation of the temperature of heating made no difference to the result.

The anil from 2 : 5-dimethoxyaniline behaved exactly as described by Lions, Perkin, and Robinson (*loc. cit.*), the yield of 5 : 8-dimethoxy-2 : 4-dimethylquinoline being almost quantitative.

β-m-*Chloroanilinopropenyl Methyl Ketone.*—This anil (compare that last mentioned) was converted almost quantitatively into *7-chloro-2 : 4-dimethylquinoline*, the *hydrate* of which separated from aqueous alcohol in colourless needles, m. p. 61° (Found : Cl, 16·7. $C_{11}H_{10}NCl$ requires Cl, 18·5%. $C_{11}H_{10}NCl,H_2O$ requires Cl, 16·9%). Crystallisation of the hydrate from light petroleum afforded the anhydrous base in prismatic needles, m. p. 46·5—48·5° (Found : Cl, 17·9%). The quinoline is obtained in almost theoretical yield if the anil–sulphuric acid solution is heated, not at 100°, but at 130—140°.

7-Chloro-2 : 4-dimethylquinoline hydrochloride forms colourless needles, m. p. 277° (decomp.), soluble in water [Found : Cl (ionisable), 15·8. $C_{11}H_{10}NCl,HCl$ requires Cl (ionisable), 15·6%]. The *sulphate* separates from water in rhombohedra, and the *dichromate* in brilliant yellow needles. The *silver nitrate additive compound*, colourless needles [Found : Ag, 17·8. $(C_{11}H_{10}NCl)_2,AgNO_3$ requires Ag, 17·6%] melts at 197° (decomp.).

In an attempt to synthesise this quinoline, various experiments were carried out on the preparation of 4-chloro-2-aminoacetophenone. (1) This substance could not be isolated from the product of interaction of *p*-chloroaniline with acetic anhydride in presence of zinc chloride, although aniline, under similar conditions, is known to afford *p*-aminoacetophenone (Klingel, *Ber.*, 1885, **18**, 2688). (2) 2 : 4-Dinitroethylbenzene was not converted into 2 : 4-dinitroacetophenoneoxime when kept at room temperature in presence of amyl nitrite and piperidine, although Reich and Nicolaeva (*Helv. Chim. Acta*, 1919, **2**, 84) obtained a small yield of the oxime by using

sodium ethoxide as the condensing agent. (3) 2 : 4-*Dichloroacetophenone* was not converted into 4-chloro-2-aminoacetophenone when heated for 6 hours at 180° with alcoholic ammonia. The 2 : 4-dichloroacetophenone was obtained in 15% yield by condensing *m*-dichlorobenzene with acetyl chloride in presence of aluminium chloride. The majority of the dichlorobenzene was recovered unchanged. 2 : 4-Dichloroacetophenone has m. p. 33—34°, and b. p. 140—150°/15 mm. (Found: Cl, 37·2. $C_8H_6OCl_2$ requires Cl, 37·5%). To a boiling suspension of 1 g. of the ketone in 100 c.c. of 1·5% aqueous sodium hydroxide, were added 2·23 g. of potassium permanganate dissolved in 50 c.c. of water. Immediate oxidation occurred, and the sole product obtained, after crystallisation from aqueous alcohol, was 2 : 4-dichlorobenzoic acid, m. p. 161—162°.

β-3 : 4-*Dichloroanilinopropenyl Methyl Ketone.*—The only successful condensation of this compound was carried out by slowly adding the anil to five times its weight of cooled concentrated sulphuric acid, and heating the resulting solution at 130—140° for 4 hours. On cooling and pouring the mixture into water, a little 3 : 4-dichloroaniline sulphate separated; this was collected. The filtrate was rendered alkaline with ammonia, the precipitated quinoline was removed and dissolved in dilute sulphuric acid, and dilute potassium dichromate solution added. The precipitated *dichromate* (yellow needles, soluble in hot, but insoluble in cold water) was collected, and converted into the free base, which, after crystallisation from alcohol or light petroleum (b. p. 80—100°), formed colourless needles, m. p. 119—120° (Found: Cl, 31·5. $C_{11}H_9NCl_2$ requires Cl, 31·4%). Repetition of this condensation some dozen times under apparently similar conditions never gave rise on any second occasion to isolable quantities of the quinoline. Variation of the concentration of sulphuric acid, or of temperature or of time of heating, or of the conditions of mixing of anil and acid, also led to the same negative result. Saturation of a glacial acetic acid solution of the anil with dry hydrogen chloride (compare Bülow and Issler, *loc. cit.*) or treatment of a similar solution with acetic anhydride, or with acetyl chloride, did not cause ring-closure. The anil was also heated with syrupy phosphoric acid at 130—145° and then at 200° for 2 hours, but after this treatment, only 3 : 4-dichloroaniline was isolated. In the case of the acetyl chloride experiment, a crystalline solid separated after 5 minutes, but then redissolved. Treatment of the anil with a mixture of acetic anhydride and acetyl chloride merely led to the production of 3 : 4-dichloroacetanilide.

6 : 7-*Dichloro*-2 : 4-*dimethylquinoline hydrochloride* forms white needles, m. p. 235°, sparingly soluble in water [Found: Cl (ionisable), 13·6. $C_{11}H_9NCl_2,HCl$ requires Cl (ionisable), 13·5%]. The

chloroaurate forms twig-like, yellow needles, sparingly soluble even in hot water; the *sulphate* forms white needles; the *silver nitrate additive compound* is precipitated when an alcoholic solution of the base is treated with an aqueous solution of silver nitrate. It forms colourless needles, m. p. 218—219°, soluble in hot, but sparingly soluble in cold, alcohol [Found: Ag, 17·7. $(C_{11}H_9NCl_2)_2,AgNO_3$ requires Ag, 17·4%].

Nitration of 6 : 7-*Dichloro*-2 : 4-*dimethylquinoline.*—The method used for nitrating this base, and for all the other quinoline bases mentioned, unless otherwise stated, was as follows: The base was added slowly to five times its weight of a mixture, kept at −5°, of 1 part by weight of fuming nitric acid (*d* 1·5) and 2 parts by weight of concentrated sulphuric acid (*d* 1·84). The resulting solution was kept at the ordinary temperature for 1—2 hours and then poured on ice, and the nitro-compound was isolated either as the sulphate or as the free base.

In the case of 6 : 7-*dichloro*-8(?)-*nitro*-2 : 4-*dimethylquinoline*, the base was crystallised from alcohol, and then formed white needles, m. p. 197° (Found: N, 10·6. $C_{11}H_8O_2N_2Cl_2$ requires N, 10·4%). Nitration of 6 : 7-dichloro-2 : 4-dimethylquinoline with mixed acid at 60° also gave the nitro-compound described above.

Consideration of the other results obtained in this work suggests that the nitro-compound is of the 8- rather than of the 5-type.

Preparation of Substituted 2 : 4-*Dimethylquinolines by the Beyer Process.*—The method adopted was essentially that used by Beyer (*loc. cit.*), but in detail as follows: (*a*) A mixture of 96 g. of paraldehyde and 160 g. of acetone was saturated with dry hydrogen chloride, and left for 3 days. Such a mixture then weighed approximately 425 g. (*b*) The substituted aniline (1 mol.) was thoroughly ground with 3 mols. of concentrated hydrochloric acid, and the mixture added to one of 0·5 mol. of nitrobenzene and 255 g. of the acetone–paraldehyde–hydrogen chloride mixture. The whole was heated at 100° under reflux for 10 hours, and then worked up by an appropriate method, as described under individual compounds.

8-*Chloro*-2 : 4-*dimethylquinoline.*—The reaction mixture obtained from *o*-chloroaniline by the process just mentioned was poured into water; the resulting mixture was repeatedly extracted with ether, and the aqueous-acid layer rendered alkaline with sodium hydroxide. It was then thoroughly extracted with ether, and the ethereal extract was washed with brine and dried over anhydrous sodium sulphate. Evaporation of the ether and distillation of the residue under diminished pressure afforded two fractions, the first consisting of 40% of the original chloroaniline used; the second, b. p. 170—190°/15 mm. (mainly 185°/15 mm.), was 8-*chloro*-

2 : 4-*dimethylquinoline* (yield 25%), which solidified on cooling. After being twice crystallised from light petroleum (b. p. 40—60°), it formed stout, white prisms, m. p. 74° (Found : Cl, 18·6. $C_{11}H_{10}NCl$ requires Cl, 18·6%). The quinoline separates anhydrous from aqueous alcohol in small, rectangular plates. It was unaffected by piperidine after 1 hour's heating at 100°.

Nitration of 8-*Chloro*-2 : 4-*dimethylquinoline*.—The last-named quinoline nitrated readily, and on pouring the nitration mixture on ice a copious white precipitate of the *sulphate* of 8-chloro-5-nitro-2 : 4-dimethylquinoline was obtained. This was collected and treated with aqueous ammonia, and the reddish-brown solid obtained was crystallised from alcohol. The nitro-compound forms pale yellowish-brown prisms, m. p. 107—108° (Found : Cl, 15·1. $C_{11}H_9O_2N_2Cl$ requires Cl, 15·0%) (yield, more than 90%).

8-*Chloro*-5-*amino*-2 : 4-*dimethylquinoline* was prepared by the reduction of the 5-nitro-compound with iron, water, and ferric chloride. The reaction mixture was cooled and filtered. The residue of iron and amino-compound was dried and extracted with benzene. The *amino-compound* separated from the cooled benzene solution in brown prisms, m. p. 170—172° (Found : Cl, 17·1. $C_{11}H_{11}N_2Cl$ requires Cl, 17·2%) (yield, 33%).

Conversion of 8-*Chloro*-5-*amino- into* 5 : 8-*Dichloro*-2 : 4-*dimethylquinoline*.—The chloroamino-compound (4 g.) was ground with 12 c.c. of concentrated hydrochloric acid, and the stiff reddish-brown paste so obtained cooled to −5°. A solution of 1·4 g. of sodium nitrite in 4·5 c.c. of water was slowly added. Diazotisation was rapid, and to the clear solution obtained was added a suspension of 5 g. of copper powder in hydrochloric acid (1 vol. of concentrated acid : 1 vol. of water). A brisk evolution of nitrogen occurred. Removal of the copper left a yellowish solution, which when treated with aqueous ammonia gave an almost theoretical yield of 5 : 8-dichloro-2 : 4-dimethylquinoline as a white precipitate. This, after being twice crystallised from alcohol, formed prismatic needles, m. p. 117—118°, alone or when mixed with 5 : 8-dichloro-2 : 4-dimethylquinoline prepared from 2 : 5-dichloroaniline (see below).

Chlorination of 8-*Chloro*-2 : 4-*dimethylquinoline*.—A solution of 1 g. of the quinoline in 20 c.c. of glacial acetic acid was heated at 60°, saturated with chlorine, and then treated with water. The white precipitate of the *tetrachloro*-compound obtained, after being twice crystallised from alcohol, formed slender needles, m. p. 150—152° (Found : Cl, 47·5. $C_{11}H_7NCl_4$ requires Cl, 48·1%).

6-*Chloro*-2 : 4-*dimethylquinoline*.—The Beyer reaction mixture from *p*-chloroaniline was poured into water, and the product was extracted with ether. The aqueous layer was evaporated to about one-third

of its original volume; a crystalline precipitate of crude hydrochloride was slowly deposited. This was collected, extracted with boiling acetone to remove colouring matter, and then treated with warm aqueous ammonia. The almost pure base so obtained separated from light petroleum (b. p. 80—100°) in stout prisms, m. p. 98—99° (Found: Cl, 16·4%) (yield, 16%). The quinoline crystallises from aqueous alcohol as the *hydrate*, silky needles, m. p. 84—85·5° (Found: Cl, 17·0. $C_{11}H_{10}NCl,H_2O$ requires Cl, 16·9%). The mother-liquor from which the above crude hydrochloride separated was found to contain only *p*-chloroaniline hydrochloride.

The quinoline forms an orange-yellow *dichromate*, which may be crystallised from water.

Nitration of 6-*Chloro*-2 : 4-*dimethylquinoline*.—The nitration mixture, when poured on ice, afforded a crystalline precipitate of the *sulphate* of 6-*chloro*-5-*nitro*-2 : 4-*dimethylquinoline*, which was filtered off and decomposed with warm aqueous ammonia. The practically pure base was then crystallised from alcohol, and formed canary-yellow prisms, m. p. 132—133° (Found: Cl, 15·8%) (yield over 90%). The chloronitro-compound was unaffected when heated for 10 minutes at 100° with excess of piperidine.

6-*Chloro*-5-*amino*-2 : 4-*dimethylquinoline*.—The preceding nitro-compound was reduced with iron powder, aqueous alcohol, and ferric chloride. The reaction mixture was filtered while still hot, the residual iron well washed with alcohol, and the alcoholic extracts and filtrate were evaporated. The solid that separated on cooling crystallised from benzene in pale yellow, prismatic needles, m. p. 131—133° (Found: Cl, 17·2%) (yield, 52%).

Conversion of 6-*Chloro*-5-*amino- into* 5 : 6-*Dichloro*-2 : 4-*dimethylquinoline*.—The base (9·1 g.) was ground with 30 c.c of concentrated hydrochloric acid, and the resulting canary-yellow hydrochloride paste was treated at −5° with a solution of 3·1 g. of sodium nitrite in 5 c.c. of water. Diazotisation was rapid, and to the clear solution so obtained copper and hydrochloric acid were added as usual. The whole assumed a dirty green colour, and suddenly set to a stiff paste. Two volumes of water were then added, the whole was heated to boiling and filtered, and the filtrate was cooled. The resulting yellowish-brown hydrochloride (prisms) was collected and digested with aqueous ammonia. The base so obtained (6 g.), after being crystallised first from alcohol and then from light petroleum (b. p. 80—100°), formed stout, colourless prisms, m. p. 119—120° (Found: Cl, 30·9. $C_{11}H_9NCl_2$ requires Cl, 31·4%). A mixture of this quinoline (then of unknown constitution) with the 6 : 7-dichloro-isomeride (also then of unknown constitution) melted at about 90°.

Chlorination of 6-*Chloro*-2 : 4-*dimethylquinoline*.—A solution, heated at 60°, of 1 g. (1 mol.) of the chloro-compound in 20 c.c. of glacial acetic acid containing 2·2 g. (5 mols.) of fused sodium acetate was saturated with chlorine. No precipitate was formed, but on dilution an oily *tetrachloro*-compound was thrown down. This became solid on standing, and after being crystallised from aqueous alcohol, and then from light petroleum (b. p. 40—60°), formed slender needles, m. p. 75·5—81° (Found: Cl, 48·4. $C_{11}H_7NCl_4$ requires Cl, 48·1%).

Nitration of 5 : 6-*Dichloro*-2 : 4-*dimethylquinoline*.—When the nitration mixture was poured on ice, the free base was precipitated. It crystallised from alcohol, in which it was very sparingly soluble, in silky needles, m. p. 151—152·5° (Found: Cl, 26·2. $C_{11}H_8O_2N_2Cl_2$ requires Cl, 26·2%) (yield, over 90%).

5 : 6-*Dichloro*-8(?)-*amino*-2 : 4-*dimethylquinoline*.—The preceding nitro-compound readily underwent reduction when heated with iron powder, aqueous alcohol, and a little hydrochloric acid. The mixture was finally filtered, the residue well washed with alcohol, and the alcoholic filtrates diluted with water. The precipitated amino-compound (yield, 83%) was dried, and then melted at 118—120° (Found: Cl, 27·6. $C_{11}H_{10}Cl_2N_2$ requires Cl, 29·5%). The crude base was used for the succeeding experiment.

Attempted Conversion of 5 : 6-*Dichloro*-8(?)-*amino*-2 : 4-*dimethylquinoline into* 5 : 6 : 8(?)-*Trichloro*-2 : 4-*dimethylquinoline*.—A suspension of the amino-compound in concentrated hydrochloric acid did not appear to undergo diazotisation when treated with sodium nitrite. Subsequent addition of copper caused no evolution of nitrogen.

Chlorination of 5 : 6-*Dichloro*-2 : 4-*dimethylquinoline*.—When chlorine was passed into a solution of 1·1 g. of the quinoline (1 mol.) in 30 c.c. of glacial acetic acid containing 1·23 g. (3 mols.) of fused sodium acetate, a precipitate of a *tetrachloro*-compound was formed. This separated from alcohol, in which it was very sparingly soluble, in slender needles, m. p. 157—158° (Found: Cl, 48·3. $C_{11}H_7NCl_4$ requires Cl, 48·1%). A mixture of the tetrachloro-compound with the tetrachloro-compound (m. p. 150—152°) obtained from 8-chloro-2 : 4-dimethylquinoline melted below 130°.

Preparation of 7-*Chloro*-2 : 4-*dimethylquinoline by the Beyer Method*.—The reaction mixture obtained from *m*-chloroaniline was poured into water, and the resulting mixture extracted several times with ether. The aqueous layer was basified, and extracted with ether, and the ethereal extract was washed with brine and dried. Distillation of the contained basic mixture under diminished pressure afforded 55% of unchanged *m*-chloroaniline as a first

fraction, and then a 36% yield of crude chloroquinoline, b. p. about 174°/10 mm. The latter partly crystallised on prolonged standing, and the crystalline portion, isolated on porous porcelain, separated from light petroleum (b. p. 40—60°) in prismatic needles, m. p. 42—45°, either alone or when mixed with the product from *m*-chloroaniline and acetylacetone (above). A little of the 5-isomeride was presumably present in the crude basic mixture, but in insufficient quantity for isolation.

7-Chloro-2 : 4-dimethylquinoline was unaffected by piperidine after 1 hour's heating at 100°.

Nitration of 7-Chloro-2 : 4-dimethylquinoline.—For this purpose, the chloro-compound obtained by the more convenient acetylacetone method was used. Nitration, followed by pouring on ice, gave a precipitate of the almost pure *7-chloro-8-nitro-2 : 4-dimethylquinoline* (yield over 95%). Nitration with warm mixed acid gave a similar result, either product separating from alcohol in slender, white needles, m. p. 189—189·5° (Found: N, 12·0. $C_{11}H_9O_2N_2Cl$ requires N, 11·8%).

When the nitro-compound was heated for 0·5 hour at 100° with an excess of piperidine, piperidine hydrochloride separated, and on extensive dilution with water a yellow powder was obtained. This separated from alcohol, in which it was sparingly soluble even when hot, in prisms; a second crystallisation from light petroleum (b. p. 80—100°)–benzene afforded *8-nitro-7-piperidino-2 : 4-dimethylquinoline* in rectangular plates, m. p. 168—170°. When mixed with the original chloronitro-compound, the substance melted at about 140°.

7-Chloro-8-amino-2 : 4-dimethylquinoline.—This substance, which was practically insoluble in hot aqueous alcohol, rapidly dissolved at 90—100° in that solvent in presence of iron powder and a little ferric chloride. Filtration, extraction of the iron powder with alcohol, and evaporation gave a black oil which solidified on cooling, and then crystallised from light petroleum (b. p. 40—60°) in slender, pale yellow needles, m. p. 51—53° (yield 83%) (Found: Cl, 17·4%).

Conversion of 7-Chloro-8-amino-2 : 4-dimethylquinoline into 7 : 8-Dichloro-2 : 4-dimethylquinoline.—The amino-compound was ground with concentrated hydrochloric acid, and the bright yellow hydrochloride paste diazotised at −10° with aqueous sodium nitrite. The clear red diazo-solution tended to undergo spontaneous decomposition, producing a coppery-brown, amorphous solid, but when it was added to a solution of cuprous chloride in hydrochloric acid normal decomposition appeared to occur. The product was treated with excess of ammonia, and the precipitated solid was collected, dried, and extracted with light petroleum (b. p. 40—60°). 7 : 8-

Dichloro-2 : 4-*dimethylquinoline* was then obtained in slender, prismatic needles, m. p. 104—104·5° (yield under 20%) (Found: Cl, 30·7%).

Chlorination of 7-*Chloro*-2 : 4-*dimethylquinoline*.—Chlorination of this base by the usual method in the cold afforded a *trichloro*-2 : 4-*dimethylquinoline*, which separated from alcohol in colourless needles, m. p. 195° (Found: Cl, 41·0. $C_{11}H_8NCl_3$ requires Cl, 40·9%).

6 : 8-*Dichloro*-2 : 4-*dimethylquinoline*.—The condensation mixture obtained by applying the Beyer reaction to 2 : 4-dichloroaniline was poured into water, and the resulting mixture repeatedly extracted with ether. The aqueous layer was boiled until free from ether, and then basified. The solid precipitated, after being collected and dried, was extracted with hot light petroleum (b. p. 80—100°), from which solvent 6 : 8-dichloro-2 : 4-dimethylquinoline separated in slender needles, m. p. 148—148·5° (yield 20%) (Found: Cl, 31·4%). The base separated anhydrous from aqueous alcohol.

Nitration of 6 : 8-*Dichloro*-2 : 4-*dimethylquinoline*.—The nitration solution when poured into a large bulk of water gave a precipitate of crude 6 : 8-*dichloro*-5(?)-*nitro*-2 : 4-*dimethylquinoline*, which separated from alcohol in pale yellow prisms, m. p. 120—122°. A further crystallisation from light petroleum (b. p. 40—100°) raised the m. p. to 122—123° (yield, 80%) (Found: Cl, 26·7%).

6 : 8-*Dichloro*-5(?)-*amino*-2 : 4-*dimethylquinoline*.—Reduction of the corresponding nitro-compound was effected by the usual method, using aqueous alcohol. The iron residue was extracted with hot acetone, and the extracts were evaporated. Crystallisation of the residue from alcohol afforded white, rectangular plates, m. p. 194—195° (yield, 81%) (Found: Cl, 29·6%). The amino-compound was converted by concentrated hydrochloric acid into a stiff, orange hydrochloride paste, which diazotised very slowly. Addition of copper powder caused some nitrogen evolution, but only unchanged base was isolated when the product was worked up.

Chlorination of 6 : 8-*Dichloro*-2 : 4-*dimethylquinoline*.—A solution of 1 g. of the quinoline (1 mol.) in 20 c.c. of glacial acetic acid containing 0·36 g. (1 mol.) of fused sodium acetate was heated at 60°, and saturated with chlorine. The precipitated solid separated from alcohol in needles, m. p. 124—125°, and was a *pentachloro*-quinoline. A mixture with the product obtained by the chlorination of 5 : 8-dichloro-2 : 4-dimethylquinoline (m. p. 127—128°) melted at 125—127°.

5 : 8-*Dichloro*-2 : 4-*dimethylquinoline*.—The product of the Beyer condensation using 2 : 5-dichloroaniline was poured into a large bulk of water, and the black, oily layer separated. The aqueous

layer was treated in the usual manner, and finally gave the dichloroquinoline as a solid, which separated from alcohol or from light petroleum (b. p. 80—100°) in prismatic needles, m.p. 117—118·5° (yield, 29%) (Found: Cl, 31·5%).

5 : 8-*Dichloro*-6-*nitro*-2 : 4-*dimethylquinoline*.—Nitration of the preceding quinoline, followed by dilution, afforded a precipitate which, after treatment with ammonia, separated from alcohol, in which it was very sparingly soluble, in white, slender needles, m. p. 155—157°. It separated from benzene in prisms (yield, over 90%) (Found: Cl, 26·3%).

5 : 8-*Dichloro*-6-*amino*-2 : 4-*dimethylquinoline*.—The nitro-compound underwent reduction with the usual reagents, in presence of aqueous alcohol. The iron residue was extracted for several hours with boiling benzene, the latter then evaporated, and the residue crystallised from benzene; the amino-compound was then obtained in brown octahedra, m. p. 192—193° (yield, 40%) (Found: Cl, 29·5%).

Conversion of 5 : 8-*Dichloro*-6-*amino- into* 5 : 6 : 8-*Trichloro*-2 : 4-*dimethylquinoline*.—The base was converted by concentrated hydrochloric acid into a paste consisting of yellow leaflets, which underwent diazotisation with difficulty. Addition of copper caused nitrogen evolution. Dilute hydrochloric acid was added, and then benzene, the latter to remove a black, tarry by-product. The acid solution, after being basified, gave a small quantity of a dark solid, which was boiled in alcoholic solution with charcoal, and after this treatment separated from alcohol, and later from light petroleum (b. p. 80—100°), in needles, m. p. 111—112·5°. A mixture of this compound with 5 : 6 : 8-trichloro-2 : 4-dimethylquinoline (see below) melted at 112—113·5°.

Chlorination of 5 : 8-*Dichloro*-2 : 4-*dimethylquinoline*.—Chlorination of this base at 60° in glacial acetic acid in presence of sodium acetate (1 mol.) afforded a pentachloroquinoline derivative as a precipitate, which separated, after two crystallisations from alcohol, in slender needles, m. p. 127—128° (Found: Cl, 54·0. $C_{11}H_6NCl_5$ requires Cl, 53·9%).

Preparation of 6 : 7-*Dichloro*-2 : 4-*dimethylquinoline by Beyer's Process*.—The reaction product obtained from 3 : 4-dichloroaniline when worked up in the usual manner gave about 55% of unchanged dichloroaniline, and a fraction, b. p. 180—190°/15 mm., which was evidently a mixture of 5 : 6- and 6 : 7-dichloro-2 : 4-dimethylquinoline. Separation by crystallisation of the dichromates gave a product, m. p. 80—105°, which was converted into a mixture of hydrochlorides. The latter was crystallised from dilute hydrochloric acid, and the hydrochloride of the 6 : 7-base so obtained was

treated with alkali. Crystallisation of the product from light petroleum (b. p. 80—100°) afforded a substance, m. p. 119—120°, which did not depress the m. p. of the quinoline obtained from acetylacetone (Found: Cl, 31·5%).

5 : 7-*Dichloro*-2 : 4-*dimethylquinoline*.—The reaction mixture from the Beyer condensation, using 3 : 5-dichloroaniline, was treated in the usual manner. Basification of the final acid solution gave a solid which was purified only with difficulty, but after being crystallised from light petroleum (b. p. 80—100°) and then from light petroleum (b. p. 60—80°) formed small prisms, m. p. 84—86° (yield, 20%) (Found: Cl, 31·5%).

On the first occasion of attempting this preparation, the paraldehyde–acetone–hydrogen chloride mixture used had been prepared 2 months previously. Condensation, followed by pouring into a large bulk of water, gave a black oil containing suspended solid. This was filtered and pressed, and then thoroughly extracted with a mixture of equal volumes of benzene and light petroleum (b. p. 80—100°). After decantation of the cooled extract, a yellowish-brown solid separated (31 g. from 50 g. of the dichloroaniline). It crystallised from alcohol in yellow leaflets, m. p. 168—169° (Found: Cl, 41·9, 42·0%). This *substance*, which will be examined later, was converted by aqueous ammonia into a second *substance*, which separated from light petroleum (b. p. 40—100°) in bunches of colourless needles, m. p. 69—70° (Found: Cl, 36·5, 36·6%). The second substance readily dissolved in hot dilute mineral acids, the solutions depositing crystalline precipitates on cooling.

5 : 6 : 8-*Trichloro*-2 : 4-*dimethylquinoline*.—Beyer condensation with 2 : 4 : 5-trichloroaniline gave a product, which, on pouring into water, afforded tarry material containing a solid in suspension. The aqueous portion, when basified, deposited tarry material only. The above solid was extracted with boiling hydrochloric acid (concentrated acid : water, 1 : 1), and tar removed. On cooling, 2 : 4 : 5-trichloroaniline hydrochloride separated, and this was removed. The mother-liquor, on basification, afforded the crude trichloroquinoline, which then separated from alcohol and later from light petroleum (b. p. 80—100°) in small, prismatic needles, m. p. 113—114° (Found: Cl, 41·5. $C_{11}H_8NCl_3$ requires Cl, 40·9%). The quinoline does not form a hydrate, and when dissolved in the usual manner in a mixture of nitric and sulphuric acids remained unchanged.

Beyer Condensation with o-*Nitroaniline*.—The condensation product was treated in the usual manner. At the basification stage, a brown, tarry solid was obtained. This readily dissolved in hot alcohol to give a solution, which on cooling deposited crystals.

These dissolved only with difficulty in fresh hot alcohol, from which solvent a *substance* separated in prismatic needles, m. p. 145—147° (12 g. from 35 g. of *o*-nitroaniline).

Beyer Condensation with p-*Nitroaniline.*—The condensation product, when poured into water, deposited a black tar, which was rejected. The aqueous layer was repeatedly extracted with benzene, the latter removed, and alkali added. The *substance* so obtained then separated from alcohol in brownish leaflets, m. p. 159—162° (31 g. from 50 g. of *p*-nitroaniline). This compound and that obtained from *o*-nitroaniline are under investigation.

When *m*-nitroaniline was submitted to the Beyer condensation, only unchanged base was isolated. 3-Chloro-6-nitroaniline and 3 : 4-dichloro-6-nitroaniline, on the other hand, were converted into unworkable tarry products.

3 : 4-*Dichloroacetophenone.*—A mixture of 251 g. of *o*-dichlorobenzene and 229 g. of anhydrous aluminium chloride was slowly treated with 133 g. of acetyl chloride and then heated at 100° for 3 hours. The product was poured on ice, hydrochloric acid added, and the oily material extracted with carbon tetrachloride. Vacuum distillation afforded 130 g. of pure 3 : 4-*dichloroacetophenone*, b. p. 135°/12 mm. (yield, 40%). This became solid on cooling, and then separated from light petroleum (b. p. 80—100°) in bunches of white needles, m. p. 76° (Found: Cl, 37·6. $C_8H_6OCl_2$ requires Cl, 37·5%).

When 2 : 4 : 5-trichlorobenzene was treated in a similar manner, it was unaffected.

Nitration of 3 : 4-*Dichloroacetophenone.*—When the ketone was dissolved either in nitric acid (*d* 1·5) kept at 10—15°, or in a mixture of glacial acetic and fuming nitric acids, it was unaffected. When it was heated with the fuming acid at 50—55°, it was extensively oxidised. Addition of fuming nitric acid to a solution of the ketone in acetic anhydride at 60—70° effected no change. A mixture of fuming nitric and concentrated sulphuric acids at −10° did not affect the ketone, but at 15° caused resinification. A large number of variations of these experiments gave similar results. Finally, nitration was effected by the following method: The ketone was added in small portions to seven times its weight of nitric acid (*d* 1·5), the temperature being allowed to rise to 35—38°, but not above 40°. The solution was kept for 5 minutes, the temperature being maintained between 35° and 38°, and was then poured into a large bulk of water. 3 : 4-*Dichloro*-2-*nitroacetophenone* separated as a pale yellow solid, which was collected, washed, and crystallised from alcohol. It formed irregular plates, m. p. 100—102° (Found: Cl, 30·4. $C_8H_5O_3NCl_2$ requires Cl, 30·4%).

3 : 4-*Dichloro*-2-*aminoacetophenone*.—The nitro-compound underwent rapid and almost quantitative reduction when heated with iron powder, water, and a little ferric chloride. The cooled mixture was filtered, and the solid residue repeatedly extracted with benzene. After concentration of the extract, the amino-compound separated on cooling in yellow prisms, the m. p., 154—156°, of which was not affected by a further crystallisation from acetone (Found: Cl, 34·8. $C_8H_7ONCl_2$ requires Cl, 34·9%).

Condensation of 3 : 4-*Dichloro*-2-*aminoacetophenone with Acetone*.—(*a*) When the amino-compound was heated under reflux in acetone solution, together with a little piperidine, for 6 hours, it was unaffected. (*b*) A mixture of the amino-compound (1 g.), acetone (3 c.c.), and 50% aqueous sodium hydroxide (0·2 c.c.) was heated in a closed tube for 6 hours at 185°. When cold, the tube contained a mass of brown crystals. The contents of the tube were extracted with boiling acetone, the extract was filtered, and the acetone evaporated. The solid residue then crystallised from light petroleum (b. p. 80—100°) in slightly brown needles, m. p. 119—120°. The substance produced no depression of the m. p. of the products obtained by the acetylacetone and Beyer methods (from 3 : 4-dichloroaniline) and was 6 : 7-dichloro-2 : 4-dimethylquinoline. A mixture with 5 : 6-dichloro-2 : 4-dimethylquinoline melted below 90°.

Nitration of 2 : 4-*Dimethylquinoline*.—A solution of the quinoline (102 g.) in 510 g. of concentrated sulphuric acid was slowly treated at 5° with 290 g. of the usual mixture of nitric and sulphuric acids (*i.e.*, an excess for mononitration. Addition of the last half of the mixed acid caused no temperature rise). The solution was poured on ice, and the resulting clear solution basified with ammonia. The precipitated 8-*nitro*-2 : 4-*dimethylquinoline* crystallised from alcohol in brown needles, m. p. 118—119° (yield 93%) (Found: N, 13·7. $C_{11}H_{10}O_2N_2$ requires N, 13·8%).

8-*Amino*-2 : 4-*dimethylquinoline*.—Reduction of the preceding nitro-compound by means of iron powder, water, and ferric chloride proceeded vigorously, but the product was difficult to purify. Repeated extraction with light petroleum (b. p. 80—100°) gave a solution from which tarry matter separated on cooling. When no more tar separated, light petroleum (b. p. 40—60°) was added, whereupon the amino-compound separated in brownish-yellow plates, m. p. 89—92° (yield, 26 g.) (Found: N, 15·9. $C_{11}H_{12}N_2$ requires N, 16·3%). The *picrate* separates from alcohol in bunches of yellow prisms. The sulphate is bright yellow, and sparingly soluble in water. A dilute sulphuric acid suspension diazotised readily, but on heating, the resulting solution gave a product other than the expected hydroxy-compound.

Conversion of 8-Amino- into 8-Chloro-2 : 4-dimethylquinoline.—(*a*) The base was diazotised in hydrochloric acid suspension. Addition of cuprous chloride–hydrochloric acid solution gave an indefinite product. (*b*) The amino-compound (17 g.) was ground with 50 c.c. of concentrated hydrochloric acid, and the resulting orange-red paste treated slowly at −5° with a solution of 6·6 g. of sodium nitrite in 10 c.c. of water. Diazotisation proceeded rapidly, with the formation of a clear solution, to which a suspension of copper powder in hydrochloric acid was added. Nitrogen was at once evolved, and the mixture was diluted with water and filtered. Addition of excess of ammonia gave a gummy precipitate, which was dissolved in a hot mixture of 25 c.c. of concentrated sulphuric acid and 125 c.c. of water. On cooling, the sulphate of 8-chloro-2 : 4-dimethylquinoline separated in pale yellow needles, which were collected, and decomposed with ammonia. The base so obtained, after crystallisation from aqueous alcohol and then from light petroleum (b. p. 40—60°), melted at 74°. A mixture with the base obtained by the Beyer method using *o*-chloroaniline melted at the same temperature.

Condensation of Dibenzoylmethane with Aniline.—A mixture of dibenzoylmethane (1 mol.) and *freshly distilled* aniline (1·25 mols.) was boiled under reflux for 9 hours. On cooling, the whole became solid, and was fractionally crystallised from alcohol. Colourless plates, m. p. 161°, separated first, and these did not depress the m. p. of benzanilide (Found: N, 7·6. Calc.: N, 7·1%). The mother-liquor finally yielded a solid, which separated from benzene–light petroleum in bright yellow prisms, m. p. 102—103° (Found: N, 4·1; *M*, cryoscopic in benzene, 288. Calc.: N, 4·7%; *M*, 299). This substance is evidently identical with that described by Watson (*loc. cit.*).

A few of the experiments described above were carried out by Mr. R. J. W. Smith, M.Sc. The authors desire to acknowledge the receipt of grants from the Research Fund of the Chemical Society in aid of the investigation.

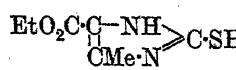
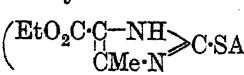
CCXL.—*Gold and Mercury Derivatives of 2-Thiolglyoxalines. Mechanism of the Oxidation of 2-Thiolglyoxalines to Glyoxalines.*

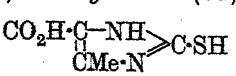


By ISIDORE ELKANAH BALABAN and HAROLD KING.

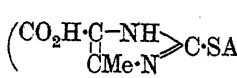


THE application of compounds of gold to the treatment of tuberculosis starts from an old observation by Koch that inhibition of the growth of tubercle bacilli by gold cyanogen compounds occurs at a dilution of 1 in 2 million, but the question as to the chemotherapeutic efficacy of organic gold compounds in tuberculosis is still an open one. Two organic compounds of gold have attained considerable prominence in Germany for the treatment of tuberculosis, namely, 4-amino-2-aurothiolbenzoic acid (krysolgan) (I) (D.R.-P. 349012) and 2-aurothiolbenziminazolecarboxylic acid (triphal) (II) (E.P. 225875 of 1923), but there is no record of the cure of experimental infections of tuberculosis in animals by these substances.

(I.) 



(II.) 



Both substances belong to a common type, of which an indefinite number could be prepared by synthesis, and the present communication is an attempt to determine whether there is any curative action, on experimental tuberculosis in animals, in this type of compound which would justify an extensive programme of syntheses in this field. For this purpose, ethyl 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylate (III) has been chosen as a starting point, as it is fairly readily accessible from ethyl acetoacetate.

(III.) 

(IV.) 

When treated in methyl-alcoholic solution with auric chloride (1/3 mol.), it yields together with other products *ethyl 2-aurothiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylate* (IV), from which the carboxylic acid cannot be obtained without decomposition and separation of gold. The ester (III) can, however, be hydrolysed to *2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylic acid* (V), which under similar conditions yields *2-aurothiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylic acid* (VI).

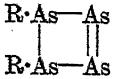
(V.) 

(VI.) 

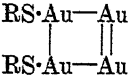
The action of auric chloride on mercaptans was first studied by Zeise (*Ann. Physik*, 1834, **31**, 369), who, from the analysis of the amorphous product, C_2H_5SAu, of the action of auric chloride on ethyl mercaptan, considered that two atoms of chlorine were set free which acted on another portion of the mercaptan. In agreement with this, Hermann (*Ber.*, 1905, **38**, 2813), who examined the action of auric chloride on benzyl and *iso*amyl mercaptans, found the optimum conditions to be given by the equation

$$AuCl_3 + 3R{\cdot}SH = R{\cdot}SAu + RS{\cdot}SR + 3HCl.$$

The auromercaptides were amorphous and the disulphides were definitely identified.



In the present instance, although the optimum conditions are determined by three molecular proportions of the thiolglyoxaline to one of auric chloride, the disulphide which should be produced in this reaction was never found, but only unchanged thiol acid. There is no doubt that the disulphide is initially produced, but, owing to the ease with which it acts as an acceptor for hydrogen, it is reduced during the subsequent operations necessary for its isolation. Attempts to make use of this ease of reversion of the disulphide to the thiol state, by using thiol acid and auric chloride in equimolecular proportion, to simplify the preparation of the 2-aurothiol acid (VI) which can be separated from the 2-thiol acid (V) only by a repetitive salting-out of the amorphous sodium salt of the aurothiol acid, were quite unsuccessful.



When auric chloride in methyl alcohol is added to the above-named thiolglyoxalines in methyl alcohol, there is invariably produced an intense blood-red coloration which persists for about 30 minutes and then fades to a pale yellow. There is no separation of gold. The same reaction is observed in aqueous hydrochloric acid solutions. It was first noted without comment by Gabriel and Pinkus (*Ber.*, 1893, **26**, 2203) for 2-thiol-4(or 5)-methylglyoxaline and by Tanret (*Compt. rend.*, 1909, **149**, 222) for ergothioneine, shown by Barger and Ewins (J., 1911, **99**, 2336) to be identical with 2-thiolhistidinebetaine. It is not, however, given by cysteine, thiocarbamide, allylthiocarbamide, or *p*-thiolphenylethylamine. We are not able to adduce any conclusive evidence as to the nature of this blood-red coloration. Whilst all the 2-thiolglyoxalines examined give the reaction instantaneously, 4(or 5)-*carbethoxy*-5(or 4)-*methylglyoxaline*-2-*disulphide* in methyl-alcoholic solution does not give it at once, but the colour gradually develops, lasts for many hours, and finally disappears. In hydrochloric acid solution the disulphide remains yellow for a few seconds on addition of chloroauric acid and then gives an amorphous, red precipitate

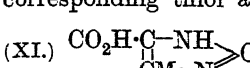
which becomes pale yellow after a few hours. One possibility is that the colour is due to the chromophoric influence of the sulphur atom on intermediate addition compounds of auric chloride with the thiolglyoxalines which gradually disappear as the auric chloride is used up in its reactions with the thiol group. This is supported by the observations of Wohl and Marckwald (*Ber.*, 1889, **22**, 1355), who found that platinum and gold chlorides formed with 2-thiol-1-methylglyoxaline brick-red and deep purple-red crystalline addition compounds, respectively, of the types, 2 base + $PtCl_4$, and base + $AuCl_3$, and of the present authors that the salt of 2-*ethylthiol*-4(or 5)-*methylglyoxaline* with chloroauric acid is red, whereas the addition compound of 2-phenyl-1-methylglyoxaline and auric chloride of the type base + $AuCl_3$ is deep yellow (J., 1926, 589). The other possibility is that the blood-red coloration is due to the transient formation of the free aurous radicals, R·SAu<, which polymerise to form the pale yellow auromercaptides R·SAu:AuS·R or, in general, $(R{\cdot}S{\cdot}Au<)_n$. The properties of these auromercaptides are in agreement with this formulation: they are all amorphous substances with well-marked colloidal properties.

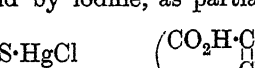
In the reaction of only one other reducing agent with auric solutions have we observed a transient red coloration. In the preparation of sodium gold thiosulphate, $Na_3Au(S_2O_3)_2$, by the action of a neutral solution of gold chloride on sodium thiosulphate, a transient red colour is obtained which, examined spectroscopically, has a similar general absorption in the visible region to the blood-red colour obtained with thiolglyoxalines. In this case also, the reaction is essentially a reduction to the aurous state. Brown's view (*J. Amer. Chem. Soc.*, 1927, **49**, 959) that the colour is due to the formation of sodium aurate does not tally with the colour of alkali aurates, which are pale yellow or pale green.

2-Aurothiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylic acid (VI) prepared as described above invariably contains an excess of combined gold in the approximate ratio of N:Au = 2 : 1·08 which finds a ready interpretation by analogy with the arsenicals. Just as over-reduction of arsinic acids leads to production of polyarsenides, which are usually formulated as in (VII), so here the product probably contains (VIII).

(VII.)

(VIII.)





The reaction of thiolglyoxalines with mercuric salts is in striking contrast to their behaviour towards auric chloride. When ethyl glyoxaline-4(or 5)-carboxylate is digested in alcoholic solution with mercuric acetate, it yields *ethyl* 1-*acetoxymercuriglyoxaline*-4(or 5)-

carboxylate (IX) quantitatively, but ethyl 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylate and the corresponding carboxylic acid, when digested with excess of mercuric chloride, yield *ethyl*

(IX.)   (X.)

2-*chloromercurithiol*-4(or 5)-*methylglyoxaline*-5(or 4)-*carboxylate* (X) and 2-*chloromercurithiol*-4(or 5)-*methylglyoxaline*-5(or 4)-*carboxylic acid* (XI) respectively. These are crystalline compounds and their constitution follows from their behaviour towards sodium hydroxide and ammonium sulphide.

Results of considerable interest have been obtained in an attempt to prepare the disulphide (XII) which should have arisen in the action of auric chloride on 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylic acid (V). It cannot be obtained by oxidation of the corresponding thiol acid by iodine, as partial replacement of the

(XI.)   (XII.)

carboxyl group by iodine takes place, and it is not formed when 4(or 5)-*carbethoxy*-5(or 4)-*methylglyoxaline*-2-*disulphide* (XIII), prepared by the action of iodine upon ethyl 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylate, is hydrolysed by alkalis or acids. After this ester disulphide (XIII) had been boiled for an hour with 10% aqueous sodium carbonate, the products isolated were 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylic acid (V), the corresponding decarboxylated product 2-thiol-4(or 5)-methylglyoxaline, ethyl 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylate (III), and sulphur dioxide. On acid hydrolysis, 2-thiol-4(or 5)-methylglyoxaline was also obtained with other substances. Quantitative estimation of the sulphur dioxide produced showed that 74% of that required by the equation $2RS{\cdot}SR + 2H_2O = 3R{\cdot}SH + RH + SO_2$ was present. The mother-liquor contained sulphate, so that the deficiency in sulphur dioxide is probably accounted for by the reducing action of sodium sulphite on the disulphide, for the disulphide (XIII) is readily reduced to the thiol ester in aqueous solution by sulphur dioxide.

It seems probable that an unstable sulphinic acid is the intermediate product in the above hydrolysis, in which case the reaction would be the reverse of the mode of synthesis of disulphides of Otto and Schiller (*Ber.*, 1876, **9**, 1589):

$$3R{\cdot}SH + R{\cdot}SO_2H = 2RS{\cdot}SR + 2H_2O.$$

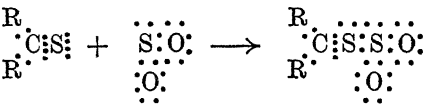
In support of this view, the first sulphinic acid in the glyoxaline series has been prepared and proves to be a very unstable substance

readily yielding sulphur dioxide at room temperature. When 2-thiol-4(or 5)-methylglyoxaline (XIV) is added at 0° to 10% hydrogen peroxide (2 mols.), it is converted for the most part into 4(or 5)-*methylglyoxaline-2-sulphinic acid* (XV) with simultaneous formation of small quantities of 4(or 5)-*methylglyoxaline-2-sulphonic acid* (XVI), 4(or 5)-methylglyoxaline, and sulphuric acid.

(XIII.) $\left(\begin{array}{l}EtO_2C\cdot C\text{—}NH\\ \quad\|\quad\quad\rangle C\cdot S\text{—}\\ CMe\cdot N\end{array}\right)_2$ $\begin{array}{l}CMe\cdot NH\\ \|\quad\rangle C\cdot SH\\ CH\text{—}N\end{array}$ (XIV.)

(XV.) $\begin{array}{l}CMe\cdot NH\\ \|\quad\rangle C\cdot SO_2H\\ CH\text{—}N\end{array}$ $\begin{array}{l}CMe\cdot NH\\ \|\quad\rangle C\cdot SO_3H\\ CH\text{—}N\end{array}$ (XVI.)

The sulphinic acid is a crystalline solid, stable at 0°. It has an acid reaction, but at room temperature it changes after a few hours into a strongly basic liquid containing 4(or 5)-methylglyoxaline and its *sulphite*. It consumes one atom of oxygen when titrated with permanganate at 0°, and is converted by excess of hydrogen peroxide, preferably in the presence of alkali, into the sulphonic acid. The formation of this unstable sulphinic acid is, in fact, exactly analogous to the formation of the somewhat more stable aminoiminomethanesulphinic acid, $NH{:}C(NH_2)\cdot SO_2H$, by the oxidation at 0° of thiocarbamide by hydrogen peroxide (Barnett, J., 1910, **97**, 63).

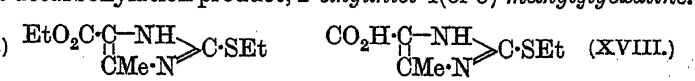


The instability of the glyoxalinesulphinic acid affords a satisfactory interpretation of the desulphuration of 2-thiolglyoxalines by means of nitric acid discovered by Wohl and Marckwald (*Ber.*, 1889, **22**, 575). These authors postulated the formation of an unstable sulphonic acid which was hydrolysed even under the conditions of oxidation:

$$N{:}C(SH)\cdot NH- \longrightarrow -N{:}C(SO_3H)\cdot NH- \longrightarrow -N{:}CH\cdot NH- + H_2SO_4.$$

This explanation was, however, disproved by the observations of Anschütz and Schwickerath (*Annalen*, 1895, **284**, 9), Biltz and Krebs (*ibid.*, 1912, **391**, 203), and Lamb and Pyman (J., 1924, **125**, 707). Biltz and Krebs favoured the view that disulphides are the intermediate products, but the results are much more compatible with the view that an unstable sulphinic acid is formed, and the more unstable it is, the smaller the proportion of sulphonic acid formed in the oxidation and the larger the proportion of desulphurised glyoxaline.

When the alkaline hydrolysate of 4(or 5)-carbethoxy-5(or 4)-methylglyoxaline-2-disulphide (XIII) is acidified to Congo-paper, the solution turns yellow and evolves sulphur dioxide. On removal of this by aspiration, the yellow colour vanishes, but it is restored when sulphur dioxide is passed into the solution. This has been traced to the formation of unstable, yellow or orange-yellow addition



compounds between many 2-thiolglyoxalines and sulphur dioxide in aqueous or acid solution or in the dry state. Quantitative measurement of the amount of sulphur dioxide absorbed by dry 2-thiol-1-phenylglyoxaline showed that exactly one molecule is absorbed under one atmosphere of sulphur dioxide, but on exposure to the air the compound has a half-life period of 10 minutes. The reaction is also given by thiocarbamide, and is strikingly shown by allylthiocarbamide and 2-thiol-1 : 4-dimethylglyoxaline, which are immediately converted into yellow and orange-yellow liquids, respectively, by exposure to sulphur dioxide. The constitution of these labile addition compounds is best interpreted as a simple addition of the sulphur atom of the thiol group to the electromeric modification of sulphur dioxide containing two semi-polar double bonds.

This interpretation does not discriminate between the –NH·C(SH):N– structure and the –NH·CS·NH– structure of 2-thiolglyoxalines. Korczyński and Glebocka (*Gazzetta*, 1920, **50**, i, 378) have described a number of addition compounds of sulphur dioxide with a variety of amines, including thiocarbamide, and attribute their formation to the secondary valencies of the nitrogen atom. Ethyl 4(or 5)-glyoxalinecarboxylate, however, does not add on sulphur dioxide, so that their interpretation does not hold here.

The similarity between thiocarbamides and 2-thiolglyoxalines in their behaviour towards sulphur dioxide extends to the colour reaction described by Sato (*Biochem. Z.*, 1909, **23**, 45) for thiocarbamides, and an improved form of the test is described in the experimental portion together with a number of other colour reactions which may prove of service in this field.

In order to characterise 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylic acid (V) more fully, it has been converted by esterification by alcoholic hydrogen chloride (compare Burtles, Pyman, and Roylance, J., 1925, **127**, 588) into *ethyl 2-ethylthiol*-4(or 5)-*methylglyoxaline*-5(or 4)-*carboxylate* (XVII), which on hydrolysis yields 2-*ethylthiol*-4(or 5)-*methylglyoxaline*-5(or 4)-*carboxylic acid* (XVIII) and its decarboxylation product, 2-*ethylthiol*-4(or 5)-*methylglyoxaline*.

The acid (XVIII) forms a *monohydrochloride* and a *semihydrochloride* and thus resembles some of the amino-acids, such as glycine and *dl*-alanine, which form normal and semi-hydrochlorides,

and the many anomalous amine salts recorded by Werner (*Ber.*, 1903, **36**, 149). The majority of these were formulated by Werner in terms of co-ordinated hydrogen : $XH + 2NR_3 = X{\cdot}H\begin{matrix}\diagup NR_3\\ \diagdown NR_3\end{matrix}$, which on the electronic theory of valency would be readily interpreted as

$$XH + 2R{:}\underset{\cdot\cdot}{\overset{\cdot\cdot}{\overset{R}{\underset{R}{N}}}}{:} = \left[R{:}\underset{\cdot\cdot}{\overset{\cdot\cdot}{\overset{R}{\underset{R}{N}}}}{:}H{:}\underset{\cdot\cdot}{\overset{\cdot\cdot}{\overset{R}{\underset{R}{N}}}}{:}R\right]^{+} X^{-}.$$

The case is in fact the parallel of the interpretation put forward for potassium hydrogen fluoride, KHF_2, where, however, co-ordinated hydrogen links the fluorine atoms in a negatively charged complex (Lewis, " Valence," 1923, 110). A difficulty, however, arises in the interpretation of the compounds $(NH_3)_4$,HCl (Joannis, *Compt. rend.*, 1902, **135**, 1106), $(NH_3)_4$,HBr (Bakhuis-Roozeboom, *Rec. trav. chim.*, 1885, **4**, 361), and $(NH_3)_4$,HNO_3 (Kuriloff, *Z. physikal. Chem.*, 1898, **25**, 108). These would indicate a co-ordination number of 4 for hydrogen or else chain formation of ammonia molecules with links of co-ordinated hydrogen.

We are indebted to Captain S. R. Douglas, F.R.S., for a determination of the effect of sodium aurothiolmethylglyoxalinecarboxylate on tubercle bacilli. It inhibits the growth of these organisms *in vitro* at a dilution of 1 in 100,000 (not tested at lower concentrations). Guinea-pigs were injected each with 0·5 mg. of a virulent culture of tubercle bacilli which had been subjected for 12 hours to a concentration of the sodium salt ranging from 1 in 1,000,000 to 1 in 1000. The time elapsing between injection and death of the animal from tuberculosis was progressively longer with increasing concentration of the salt used in the preliminary treatment of the bacilli. In no case had sterilisation been effected. Rabbits inoculated with a virulent strain were injected weekly with the sodium salt (0·01 g. per kilo.) and after four injections the lungs showed less signs of tubercular lesions than the controls, whilst the death of mice inoculated with the bacilli was distinctly delayed by one and by two injections of the sodium salt, 50 mice being used as controls, 25 mice for one dose and 25 for two doses.

To Miss Durham and Miss Marchal we are indebted for a determination of the toxicities to mice of sodium aurothiolmethylglyoxalinecarboxylate (0·05 mg. per g.) and of sodium 2-chloromercurithiolmethylglyoxalinecarboxylate (0·005 mg. per g.). The same compounds were tested for curative action on mice infected with trypanosomes, but no such action was detected.

Our thanks are also due to Professor F. L. Pyman, F.R.S., for the gift of samples of a series of thiolglyoxalines from his unique collection.

EXPERIMENTAL.

Hydrolysis of Ethyl 2-Thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylate (III).—This ester was prepared in 42% yield from ethyl acetoacetate as described by Posner and Gabriel (*Ber.*, 1894, **27**, 1141), but Wolff's method (*Annalen*, 1902, **325**, 135) was used for the preparation of oximinoacetoacetic ester. It melts at 236—237° (P. and G. give 229°) and is soluble in 64 parts of boiling water.

The ester (50 g.) was boiled for 1 hour with 100 g. of sodium carbonate (anhydrous) in 1000 c.c. of water, and the reaction then adjusted to neutrality to Congo-paper. The precipitate and the successive crops obtained by evaporation of the mother-liquors (in all, 38·3 g.) were extracted with one-half saturated sodium hydrogen carbonate solution, which removed the whole of the carboxylic acid and the major portion of the decarboxylated base, leaving behind non-hydrolysed ester mixed with a little decarboxylated base. The main alkaline extract on neutralisation to Congo-paper gave the carboxylic acid (23·35 g.), and the mother-liquors on concentration gave the thiol base (3·7 g.). The portion insoluble in sodium hydrogen carbonate solution (9·05 g.) was boiled with water (50 c.c.) and left, undissolved, almost pure ester (3·5 g.); the water-soluble fraction was made alkaline with sodium carbonate and boiled down in an open flask to hydrolyse the ester still present. From this alkaline liquor the thiol base was recovered in successive crops, 6·0 g. in all, the mother-liquors which gave the thiol base (3·7 g.) being incorporated at one stage. The final liquor was acidified to Congo-paper and gave a small crop of carboxylic acid (0·4 g.).

2-Thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylic acid (V) is soluble in 100 parts of boiling water and separates in granular crystals. It melts with loss of carbon dioxide at 240—241°, and the crystalline residue obtained, at 244—245°, the m. p. of 2-thiol-4(5)-methylglyoxaline (Found: S, 20·5; N, 17·9. $C_5H_6O_2N_2S$ requires S, 20·3; N, 17·2%). The acid gives an immediate red colour with Pauly's reagent in sodium carbonate solution.

Esterification of 2-Thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylic Acid.—The acid (5 g.) was suspended in 100 c.c. of absolute alcohol, and the liquid saturated with hydrogen chloride at 0°. The suspension was then boiled for 3 hours with further passage of the gas. After removal of alcohol and excess of acid by evaporation with water, the syrupy residue was dissolved in 20 c.c. of water and treated with saturated potassium carbonate solution so long as a crystalline precipitate separated. This amounted to 4·4 g., and

when crystallised from the minimum volume (350 c.c.) of boiling water separated in long, white, silky needles (4·05 g.), m. p. 144—145°.

Ethyl 2-*ethylthiol*-4(or 5)-*methylglyoxaline*-5(or 4)-*carboxylate* (XVII) is readily soluble in boiling organic solvents, but crystallises conveniently only from acetone, ethyl acetate, or water (Found in air-dried material: loss at 100°, 10·7. $C_7H_{10}O_2N_2S,1\frac{1}{2}H_2O$ requires H_2O, 11·2%. Found in anhydrous solid: N, 12·8. $C_7H_{10}O_2N_2S$ requires N, 13·1%). It forms very soluble salts with nitric, hydrochloric and sulphuric acids, the *hydrochloride* crystallising in needles. It forms an oily *chloroaurate*, but a *picrate* crystallising in glistening, yellow prisms, m. p. 135—136° (Found: picric acid by nitron, 52·1. $C_9H_{14}O_2N_2S,C_6H_3O_7N_3$ requires picric acid, 51·7%).

In a preliminary experiment (1·6 g. of thiol acid) where esterification was only carried out for 90 minutes, the product precipitated at neutrality (1·35 g.) gave by ether extraction 1·25 g. of *S*-ethyl ether and 0·1 g. of insoluble material which proved to be ethyl 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylate.

S-*Alkylation of Ethyl* 2-*Thiol*-4(or 5)-*methylglyoxaline*-5(or 4)-*carboxylate*.—The 2-thiolcarboxylic ester (10 g.) was suspended in 100 c.c. of absolute alcohol and submitted to the same treatment as in the foregoing esterification. The yield of crude *S*-ethyl ether was 10·8 g. It was recrystallised from 100 volumes of boiling water and gave 10·3 g. of pure material crystallising in needles, m. p. 144—145°. On prolonged standing, the mother-liquor deposited stout, triangular plates which proved to be the same substance, m. p. 143—144°.

Alkaline Hydrolysis of Ethyl 2-*Ethylthiol*-4(or 5)-*methylglyoxaline*-5(or 4)-*carboxylate*.—The ethyl ester of the *S*-ethyl ether (8·1 g.) was boiled for 4 hours with 16·2 g. of anhydrous sodium carbonate in 162 c.c. of water. The ethereal extract on evaporation gave 2·3 g. of 2-*ethylthiol*-4(or 5)-*methylglyoxaline*, m. p. 68—69°. This base was insoluble in light petroleum and very soluble in benzene, and crystallised well from ethyl ether in delicate, rectangular leaflets, m. p. 69—71°. It was converted into the *picrate* (5·5 g.), which was soluble to the extent of 2·3% in boiling water and separated on cooling in prismatic needles, m. p. 136—137° (Found: picric acid by nitron, 62·6, 62·7. $C_6H_{10}N_2S,C_6H_3O_7N_3$ requires picric acid, 61·7%). The picrate was converted into the hydrochloride, which could not be crystallised, and a portion of the latter precipitated with chloroauric acid. The *chloroaurate* separated in red plates, m. p. 130—131° without decomposition (Found: Au, 41·0. $C_6H_{10}N_2S,HAuCl_4$ requires Au, 40·9%).

The alkaline liquors after ethereal extraction were made very

faintly acid to Congo-paper and concentrated; two crops of needles, 4·05 g. in all, were then obtained. Of this, 3·3 g. were dissolved in 10 c.c. of boiling water in a covered vessel to avoid access of nuclei from the air. When the solution was cool and supersaturated, it was inoculated with nuclei of the needles. The crop of needles (2·3 g.) was collected and washed with ice-cold water [Found: Cl, 8·3; N, 13·4. $(C_7H_{10}O_2N_2S)_2,HCl$ requires Cl, 8·7; N, 13·7%]. This *semihydrochloride* of *2-ethylthiol-4*(or 5)-*methylglyoxaline-5*(or 4)-*carboxylic acid* was very readily soluble in water, with a reaction faintly acid to Congo-paper. It melted rather indefinitely with effervescence between 122° and 125°, but without loss of carbon dioxide, as the residue did not give a picrate. If a strong aqueous solution was heated, the free *carboxylic acid* (XVIII) separated in stout rhombs; on cooling, needles of the semi-hydrochloride invariably separated, but the rhombs, even on prolonged standing, remained unchanged. If alkali was added until the faint acidity to Congo-paper was completely removed and the reaction was very faintly acid to sensitive methyl-orange paper, the free carboxylic acid was precipitated. It was soluble in 10 parts of boiling water and crystallised in large, rectangular tablets, m. p. 179—180° (efferv.) (Found: N, 14·9. $C_7H_{10}O_2N_2S$ requires N, 15·0%). The decarboxylated melt solidified and melted at 67° and gave a picrate identical with 2-ethylthiol-4(or 5)-methylglyoxaline picrate.

If the semi-hydrochloride (0·2 g.) be dissolved in a few drops of hot 3*N*-hydrochloric acid it forms a syrupy solution which soon deposits large, triangular prisms of the *monohydrochloride*, m. p. 189—190° (efferv.) (Found: Loss at 100°, 7·8. $C_7H_{10}O_2N_2S,HCl,H_2O$ requires H_2O, 7·5%. Found in dried salt: Cl, 16·0. $C_7H_{10}O_2N_2S,HCl$ requires Cl, 15·9%). This salt is very soluble in water, the solution turning Congo-paper blue.

Preparation of 5(or 4)-*Carbethoxy*-4-(or 5)-*methyl*-2-*glyoxaline Disulphide* (XIII).—Ethyl 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylate (1 g.) was dissolved in 1000 c.c. of hot water, cooled to 50°, and treated with *N*/10-iodine solution until a slight excess was present as shown by the pale brown colour. Usually 55 c.c. were required instead of the theoretical 53·7 c.c. Three further batches were treated similarly. The *disulphide* (3·25 g.) which separated during the addition of iodine was collected; the mother-liquors, on being again treated with iodine until present in slight excess, and then neutralised with sodium carbonate, deposited a further 0·2 g. of disulphide. The product (yield, 86%), m. p. 220—222°, separated from boiling alcohol (120 c.c.) as a voluminous felt of pale yellow needles; after a further crystallisation, the m. p. was con-

stant at 222—223° (yield, 3·25 g.) (Found : N, 15·3. $C_{14}H_{18}O_4N_4S_2$ requires N, 15·1%). The same ester with the same m. p. was obtained by oxidation of the thiol ester in alkaline solution with potassium ferricyanide, but it was difficult to free it from Prussian blue, formed in traces. It was also obtained by dissolving the thiol ester in spirit, adding a lump of fused sodium nitrite, and running *N*-sulphuric acid on to the nitrite so that there was a vigorous evolution of gases through the liquid. The solution eventually deposited the disulphide. A modification of this method may prove to be the most accessible route to this disulphide. In sodium carbonate solution, the disulphide gives a yellow colour with Pauly's reagent. The ester is readily reduced to the thiol ester by passage of sulphur dioxide in aqueous solution.

Hydrolysis of the Disulphide.—(a) *By alkali.* The disulphide (7·4 g.) was boiled for 1 hour with 15 g. of anhydrous sodium carbonate in 150 c.c. of water. The solution, on being neutralised to Congo-paper, turned yellow, evolved sulphur dioxide, and gave a fraction (2·95 g.). On concentration, two further fractions (0·45 and 1·6 g.) were obtained. The sodium hydrogen carbonate extracts of these fractions gave, on neutralisation to Congo-paper, 2·76 g. of 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylic acid, identical in all its reactions with the product of hydrolysis of the corresponding 2-thiol ester. The portion soluble in sodium hydrogen carbonate but not precipitated on neutralisation was isolated by concentration and proved to be pure 2-thiol-4(or 5)-methylglyoxaline (0·1 g.), m. p. 244—245°. The portion of original material insoluble in sodium hydrogen carbonate, on three crystallisations from water, gave 0·4 g. of ethyl 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylate, m. p. 237°.

Quantitative determinations of the proportion of sulphur dioxide formed in the hydrolysis of the disulphide were made by hydrolysing 1·23 g. (*M*/300) with 2·46 g. of anhydrous sodium carbonate in 24·6 c.c. of water for 1 hour at 100°. The alcoholic distillate contained only a trace of reducing substance, possibly acetaldehyde. The alkaline mother-liquor was made acid by addition of 3*N*-hydrochloric acid, and the liberated sulphur dioxide absorbed by aspiration into standard *N*/10-iodine solution, any volatile iodine being caught in *N*/10-sodium thiosulphate solution. In two separate experiments, 72·4 and 73·5% of the sulphur dioxide required by the equation $2RS{\cdot}SR + 2H_2O = SO_2 + RH + 3RSH$ was found. The mother-liquors also contained appreciable amounts of sulphate. The method of estimation was controlled by experiments on standard sodium sulphite solution and found to agree within 2%.

(b) *By acid.* The disulphide (0·9 g.) was boiled for 3 hours with

10 c.c. of 16% hydrochloric acid. The solution was evaporated dry at 50°, and the residue was dissolved in a little water and made faintly alkaline to litmus; an amorphous base (0·4 g.) then separated. This was probably a mixture of bases, as it did not behave normally on reduction to the thiol base with sulphur dioxide or on oxidation to a base free from sulphur by dilute nitric acid. After removal of the amorphous substance, the mother-liquors, on concentration, gave 0·2 g. of crude 2-thiol-4(or 5)-methylglyoxaline, m. p. 239°. Recrystallised from 1·2 c.c. of hot water, it separated in the characteristic large crystals of the pure thiol base, m. p. 244°.

Preparation of Ethyl 2-Aurothiol-4(or 5)-*methylglyoxaline-5*(or 4)-*carboxylate* (IV).—Ethyl 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylate (1·86 g.; 3 mols.) in 100 c.c. of dry methyl alcohol was treated with 1 g. (1 mol.) of gold trichloride in 30 c.c. of methyl alcohol. The solution became brilliant ruby-red and after 2 hours was pale yellow. The alcohol was removed and treatment of the residue with 400 c.c. of boiling water left 0·22 g., m. p. 254° (decomp.), undissolved. On keeping, the solution deposited needles (1·35 g.), m. p. 170°, containing 30·3% of combined gold. These were extracted with a further 150 c.c. of boiling water, which left 0·35 g. of solid undissolved, m. p. 252° (decomp.). This was the required *ethyl 2-aurothiol-4*(or 5)-*methylglyoxaline-5*(or 4)-*carboxylate* (Found: Au, 50·6. $C_7H_9O_2N_2SAu$ requires Au, 51·6%). Attempts to convert this ester into the corresponding acid by hydrolysis led to decomposition with separation of gold.

Preparation of 2-*Aurothiol-4*(or 5)-*methylglyoxaline-5*(or 4)-*carboxylic Acid* (VI).—2-Thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylic acid (4·7 g.), dissolved in 435 c.c. of pure dry methyl alcohol, was treated with 3·0 g. (1/3 mol.) of gold trichloride in 10 c.c. of methyl alcohol. After 1 hour, the deep ruby-red colour which developed immediately on mixing had completely gone. The yellow solution was concentrated to about 10 c.c. and diluted with 250 c.c. of water. The solution set to a jelly which rapidly broke up with deposition of a mixture of amorphous and crystalline matter. There was no free gold present. The solid was collected, and dissolved in 100 c.c. of water with the aid of 22 c.c. of saturated sodium hydrogen carbonate solution. Addition of 30 g. of sodium chloride caused the separation of a white, amorphous precipitate of the sodium salt of the crude aurothiol acid. It was redissolved in 100 c.c. of water, by gentle warming with addition of a few drops of 2*N*-sodium hydroxide, and reprecipitated by 30 g. of sodium chloride. This process was repeated in order to eliminate the last traces of thiol acid. The amorphous sodium salt was suspended in water and treated with excess of 3*N*-hydrochloric acid, and the

amorphous aurothiol acid was centrifuged off, resuspended in water, and re-centrifuged so long as the supernatant fluid showed chloridion. The acid, after being dried in a vacuum and ground, was obtained as a pale primrose-yellow powder (yield, 2·7 g. or 77%) (Found: Loss on prolonged drying at 110°, 6·3%. Found in anhydrous solid: N, 7·6; Au, 57·8, 57·8. $C_5H_5O_2N_2SAu$ requires N, 7·9; Au, 55·6%). On ignition even with nitric and sulphuric acids, this aurothiol acid leaves a residue of gold soluble in cold aqua regia but containing a small quantity of insoluble black material. This is destroyed by digestion with hot aqua regia, and after removal of nitric acid the gold can be quantitatively precipitated by excess of ferrous chloride in acid solution. If insufficient acid be added, the gold contains a large quantity of iron (compare Treadwell, "Analytische Chemie," 1921, II, 213).

The aurothiol acid forms a clear pale yellow solution on neutralisation with sodium hydrogen carbonate and can be boiled without decomposition.

The first two sodium chloride precipitation liquors of the sodium salt, on acidification to Congo-paper, gave precipitates of 1·37 g. and 0·1 g., respectively, of crystalline 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylic acid. This was identical in all its reactions with the 2-thiol acid prepared by hydrolysis of its ethyl ester. In particular, 1·2 g. were esterified by alcoholic hydrogen chloride and gave 1·1 g. of ethyl 2-ethylthiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylate.

In some experiments, the salting-out of the amorphous sodium salt of the aurothiol acid led to simultaneous separation of flattened needles of the sodium salt of the 2-thiol acid. This could be eliminated only by increasing the number of precipitations.

Action of Mercuric Acetate on Ethyl Glyoxaline-4(or 5)-*carboxylate*.—Ethyl glyoxalinecarboxylate (0·7 g.) was dissolved in 25 c.c. of alcohol and treated with 1·6 g. (1 mol.) of mercuric acetate. The gelatinous mass immediately produced was boiled for 6 hours; it then consisted of homogeneous, microscopic, flat prisms almost insoluble in cold alcohol (yield, 2·0 g.). *Ethyl* 1-*acetoxymercuri-glyoxaline*-4(5?)-*carboxylate* (IX) is instantly soluble in dilute hydrochloric acid, and black mercuric sulphide is precipitated from the solution by hydrogen sulphide. Sodium hydroxide produces orange-yellow mercuric oxide. The ester has no definite melting point, but shrinks suddenly at about 222° and is not further changed at 300° (Found: Loss at 100°, 2·8. $C_8H_{10}O_4N_2Hg,\frac{1}{2}H_2O$ requires H_2O, 2·2%. Found in dried substance: N, 6·8; Hg, 50·8. $C_8H_{10}O_4N_2Hg$ requires N, 7·0; Hg, 50·4%).

Action of Mercuric Chloride on Ethyl 2-*Thiol*-4(or 5)-*methyl-glyoxaline*-5(or 4)-*carboxylate*.—The thiol ester (1·86 g.) was boiled

with 5·4 g. (2 mols.) of mercuric chloride in 50 c.c. of absolute alcohol for 6 hours. On standing for a few days, *ethyl 2-chloromercurithiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylate* (X), m. p. 167—168°, separated in six-sided plates (yield, 95%). It was soluble without difficulty in 3 volumes of boiling absolute alcohol (Found: N, 6·5. $C_7H_9O_2N_2ClSHg$ requires N, 6·7%). The ester does not give mercuric oxide on treatment with sodium hydroxide, but is immediately blackened by ammonium sulphide.

Action of Mercuric Chloride on 2-Thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylic Acid.—The thiol acid (1·58 g.), dissolved in 100 c.c. of pure dry methyl alcohol, was boiled for 6 hours with 5·43 g. (2 mols.) of mercuric chloride. After remaining for 12 hours at room temperature, the solution deposited 0·25 g. of substance, and on concentration a further 0·8 g. *2-Chloromercurithiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylic acid* (XI), m. p. 257° (efferv.), is readily soluble in sodium hydrogen carbonate solution and is precipitated unchanged, but microcrystalline, on addition of hydrochloric acid (Found: N, 7·1. $C_5H_5O_2N_2ClSHg$ requires N, 7·1%). Mercuric sulphide is readily precipitated when hydrogen sulphide is passed into a suspension of the acid in hot dilute mineral acid solution, or instantly by the action of ammonium sulphide. The acid does not give mercuric oxide on treatment with sodium hydroxide.

Action of Hydrogen Peroxide on 2-Thiol-4(or 5)-methylglyoxaline.—Finely powdered thiolmethylglyoxaline (1·14 g.) was added in portions to a stirred solution of 2·4 g. (2 mols.) of Merck's perhydrol in 6 c.c. of water at 0° to −5°. The thiol compound rapidly passed into solution through oxidation and yielded a clear solution which after a short time became filled with microscopic leaflets of *4(or 5)-methylglyoxaline-2-sulphinic acid* (XV). These were filtered off on an ice-jacketed funnel at 0° and washed with ice-cold water (yield, about 0·7 g.). For analysis, portions were removed, rubbed quickly on ice-cold porous plate, and rapidly weighed (Found: N, by Kjeldahl's method, 15·7; SO_2 evolved by digestion with boiling dilute sulphuric acid and absorbed by aspiration in *N*/10-iodine, 36·7; N in distillation residue, by Kjeldahl's method, 15·9—whence $SO_2 : N = 1·01 : 2$. $C_4H_6O_2N_2S,2H_2O$ requires SO_2, 35·2; N, 15·4%. Found: oxygen consumed by oxidation with *N*/10-permanganate in 2*N*-sulphuric acid at 0°, 8·1. $C_4H_6O_2N_2S,2H_2O$ requires O, 8·8%). This sulphinic acid is an unstable substance. When kept for a few hours either in a vacuum over sulphuric acid or in the air at room temperature, it passes into a clear basic liquid with loss of some sulphur dioxide. This liquid residue, when kept dry or when heated on the water-bath, partly crystallises as the normal *sulphite* of 4-methylglyoxaline. If the basic residue be

mixed with saturated potassium carbonate solution and extracted with chloroform, the latter on evaporation yields a base which readily crystallises completely as 4-methylglyoxaline. The sulphinic acid melts at 73° and effervesces at 92°. It is faintly acid to sensitive methyl-orange paper and dissolves in sodium hydrogen carbonate solution with evolution of carbon dioxide. It is not very readily soluble in ice-cold water and gives no precipitate with ferric chloride. Its ammoniacal solution gives no precipitate with calcium or barium chloride.

The mother-liquors of the oxidation were evaporated to a small volume over sulphuric acid in a desiccator and then deposited clusters of fine needles (0·1 g.) of the corresponding sulphonic acid (see below). The mother-liquor also contained sulphate and 4-methylglyoxaline, the latter being readily removed from saturated potassium carbonate solution by chloroform.

4(or 5)-*Methylglyoxaline-2-sulphonic Acid* (XVI).—2-Thiol-4(or 5)-methylglyoxaline (0·57 g.) was oxidised by hydrogen peroxide (3 mols.) in the way described in the previous section. When the sulphinic acid had crystallised from the liquor, 2*N*-sodium hydroxide (2 c.c.) was added drop by drop until an alkaline reaction was attained. The clear solution was concentrated at room temperature over sulphuric acid in a vacuum for 12 hours and had then become acid (decomposition of sulphinic acid) in reaction with deposition of a few crystals of the sulphonic acid. It was made acid to Congo-paper and gradually deposited the sulphonic acid (yield 0·55 g.). For analysis, 0·35 g. was dissolved in 0·2 c.c. of hot water and gave 0·3 g., crystallising in stout columns, m. p. about 280° (Found: Loss at 100°, 10·3. $C_4H_6O_3N_2S,H_2O$ requires H_2O, 10·0%. Found in dried substance: N, 16·9. $C_4H_6O_3N_2S$ requires N, 17·2%). This sulphonic acid is faintly acid to Congo-paper and methyl-orange paper and is stable to acid permanganate. The *calcium* and *barium* salts are very soluble in water. The *ammonium* salt is readily soluble, but crystallises well in microscopic rods.

Action of Sulphur Dioxide on 2-Thiolglyoxalines.—If 2-thiol-4(or 5)-methylglyoxaline, ethyl 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylate or 2-thiol-4(or 5)-methylglyoxaline-5(or 4)-carboxylic acid be dissolved in *N*-hydrochloric acid and subjected to a current of sulphur dioxide, the solution immediately becomes yellow. The same behaviour is shown by thiocarbamide but not by cysteine. When 2-thiol-1-phenylglyoxaline, 2-thiol-1-phenyl-4-methylglyoxaline, 2-thiol-1 : 5-dimethylglyoxaline, and 2-thiol-1 : 4-dimethylglyoxaline are dissolved in water and saturated with sulphur dioxide, yellow solutions are produced and in the case of the two 1-phenyl derivatives orange-yellow crystalline addition

products separate readily. These are stable in presence of excess of sulphur dioxide, but redissolve as the sulphur dioxide passes off. 2-Thiol-4 : 5-diphenylglyoxaline, unlike all the other 2-thiolglyoxalines examined, showed no visible change, possibly owing to its sparing solubility in water. When sulphur dioxide is passed over powdered 2-thiolglyoxalines, they become yellow to orange-yellow through absorption of the gas. Thus 2-thiol-1-phenyl-, 2-thiol-1-phenyl-4-methyl-, 2-thiol-1 : 5-dimethyl-, 2-thiol-4-methyl-, and 5-carbethoxy-2-thiol-4-methyl-glyoxalines all become yellow on exposure to sulphur dioxide. Thiocarbamide became pale yellow, but 2-thiol-1 : 4-dimethylglyoxaline and allylthiocarbamide (thiosinamine) immediately liquefied on exposure to the gas, forming orange and yellow liquids respectively. 5-Carbethoxy-4-methyl-2-glyoxaline disulphide went deeper yellow on exposure to the gas and in aqueous suspension was rapidly reduced to the corresponding thiol compound. The hydrated form of ergothioneine from blood was immediately converted into an orange-coloured, pasty product by exposure to sulphur dioxide.

Quantitative Absorption Experiments.—Finely divided 2-thiol-1-phenylglyoxaline (0·0712 g.) was submitted to a current of sulphur dioxide in a small U-tube fitted with pierced ground glass stoppers and side arms. Absorption of the gas was rapid and at the end of 2 hours 0·0249 g. had been absorbed. From this point absorption was slow and after 12 hours the total absorption was 0·0263 g., corresponding to 1·01 molecule of sulphur dioxide. When this compound was exposed to the air in an open boat, it was one-half dissociated in 10 minutes. In a similar manner, thiocarbamide (0·1211 g.) absorbed 0·74 molecule of sulphur dioxide in 15 hours, becoming pale yellow; absorption thereafter was very slow. Korczyński and Glebocka (*loc. cit.*) found absorption of 0·5 mol. and described their product as white. In the former case, after the sulphur dioxide had completely gone, the m. p. of the original substance was unchanged. In the latter case, there was a slight depression. A control experiment on ethyl 4(or 5)-glyoxaline-carboxylate showed negligible absorption of sulphur dioxide.

Colour Reactions for Thiolglyoxalines.—The colour reactions of thiolglyoxalines with sulphur dioxide and with auric chloride have been described above. Sato's reaction for thiocarbamide (*loc. cit.*) is applicable to thiolglyoxalines and is best carried out as follows : The substance is dissolved in water, treated with one drop of glacial acetic acid followed by one drop of potassium ferrocyanide solution; a yellowish-green solution is then produced which on warming rapidly becomes intense blue. Tschugaev's reaction (*Ber.*, 1902, **35**, 2483) for thiocarbamide, an intense gentian-blue on warming

with benzophenonechloride, although given by allylthiocarbamide, is not given by 2-thiolglyoxalines. Rheinboldt's reaction for thiol groups (*Ber.*, 1927, **60**, 184)—a wine-red solution—does not apply to 2-thiolglyoxalines or thiocarbamides, which all give yellow solutions. Tanret (*Compt. rend.*, 1909, **149**, 222) described a colour reaction for ergothioneine, which, on warming with chloroform and potassium hydroxide solution, gave a green solution which became blue on acidification. This reaction has been tried on a wide variety of thiolglyoxalines, glyoxalines, and thiocarbamides and is not specific for the thiol group. Thiocarbamides give nothing distinctive and in the glyoxaline group the reaction is probably of value for the diagnosis of constitution. Whilst 2-thiol-4(or 5)-methylglyoxaline gives an eosin-red solution which on careful addition of acid becomes blue, other glyoxalines, when they do give a colour, generally give a yellow or orange-yellow solution which may or may not be discharged by acids. In some cases, the yellow colouring matter is soluble in chloroform. Thus 4(or 5)-methylglyoxaline gives a bright yellow solution, 2-thiol-1 : 4-dimethylglyoxaline gives a yellow solution, whilst its isomeride, 2-thiol-1 : 5-dimethylglyoxaline, gives no colour. Again, 2-thiol-1-phenylglyoxaline gives no colour, whereas 2-thiol-1-phenyl-4-methylglyoxaline gives a bright yellow colour in the aqueous and chloroform layers. The reaction seems to be conditioned by the presence of at least one substituent in the 4- or 5-position, but both may be substituted if carboxyl or carbethoxyl is one, as these probably suffer replacement. Finally, if the hydrogen attached to nitrogen is displaced, only the 1 : 4-disubstituted derivatives produce colour. The reaction is possibly dependent on the formation of the triglyoxaline analogues of the triphenylmethane dyes.

A reaction which appears to be new for thiocarbamides and 2-thiolglyoxalines is the intense blue colour produced when an ammoniacal solution of the substance to be tested is treated with a drop of phosphomolybdic acid. This reagent shows the great ease with which 4(or 5)-carbethoxy-5(or 4)-methyl-2-glyoxaline disulphide is hydrolysed with production of the thiol group by very brief boiling in ammoniacal solution.

The thanks of the authors are due to Mr. W. K. Anslow for assistance in the preparation of initial materials and in the analyses.

CCXLI.—*Chemical Action at an Interface: The Production of Acidity in Neutral Salt Solutions.*

By N. VENKATANARASIMHA ACHAR and FRANCIS L. USHER.

THE frequently noticed development of acidity in neutral salt solutions in the presence of material from which no detectable quantity of acid can be extracted by pure water can be accounted for by assuming (1) a simple chemical interaction between the salt and a definite acid or mixture of acids, (2) a preferential absorption of the base of the salt, or (3) an exchange between the kations of the salt and hydrogen ions previously adsorbed by the material (Mukherjee, *J. Indian Chem. Soc.*, 1925, **2**, 191). The second explanation assumes the selective adsorption of hydroxyl ions from water, and can evidently be employed, alternatively with the third, to account for acidity produced by materials which are not regarded as actual or potential acids.

The first, or "chemical," theory has been objected to on the ground that, if the materials dealt with contain acids, the latter must be both insoluble, since the water extracts are neutral, and strong, in that they are able to decompose salts of the strong mineral acids; but no acids of this character are known. The purpose of this paper is to show that the effects observed with materials of complex and undetermined composition may also be observed with a simple insoluble weak acid; that these effects may properly be regarded as arising from an ordinary chemical interaction of the ionic type, qualified by the circumstance that one of the ions is non-diffusible; and that their occurrence is a logical consequence of the "surface dissociation" theory. This theory was developed by Pauli in connexion with colloidal suspensions, and advocated by McBain in the case of electrokinetic phenomena, and it does not require the assumption of selective adsorption.

If the molecules in the surface of an insoluble acid in contact with water are imagined to undergo dissociation, and if the hydrogen ions so produced are osmotically active and have a range of movement determined by the electrostatic field due to the residual acid anions on the surface, such a system is separated from the external liquid by an imaginary envelope which marks the extreme range of movement of the hydrogen ions, and is equivalent to a membrane permeable by any ions except the acid anions embedded in the surface of the insoluble acid. When the external liquid is pure water, this, on separation from the insoluble acid, should not have acquired hydrogen ions from the latter, since they are electrostatically tethered to its surface; but if a neutral salt is present in the water,

an exchange should take place between some of the hydrogen ions within the envelope and an electrically equivalent number of kations in the external liquid. On the foregoing assumptions, a solution of a neutral salt in contact with, *e.g.*, stearic acid, should become acid, and the total acid present should increase with increase of the volume of solution per unit surface of the solid, in consequence of the progressive dissociation of the molecules in the surface; or alternatively, if this ratio is kept constant, the acidity should vary directly with the concentration of the salt within the limits denoted by the principle of "membrane equilibrium." The experiments with stearic acid described below confirm these expectations, and suggest an equally simple explanation of the results obtained by Mukherjee and his co-workers (J., 1926, 3023) in the case of hydrated silica.

EXPERIMENTAL.

Some experiments were carried out with colloidal suspensions of stearic acid in water, in order to ascertain the order of magnitude of the acidity, if any, produced in neutral solutions of potassium chloride. The stearic acid used (Kahlbaum's best) was recrystallised twice from neutral methyl alcohol. It was shown that this degree of purification furnished a material the solubility of which in water ($3{\cdot}5 \times 10^{-6}$ equiv. per litre) was not further reduced by repeated recrystallisation (compare Bowden, J., 1911, **99**, 192; Bunbury and Martin, J., 1914, **105**, 418). The acid was dispersed by dropping a dilute methyl-alcoholic solution into boiling "conductivity" water contained in a large Jena-glass flask, the methyl alcohol being removed by continued boiling. To 50 c.c. of this suspension 25 c.c. of a neutral solution of potassium chloride were added, and the mixture was either filtered through an "ashless" filter, or, if coagulation was incomplete, submitted to ultrafiltration through a collodion membrane, the first portions of the filtrate being rejected. 10 C.c. of the clear liquid were then titrated against standard sodium hydroxide, and the acidity was calculated after the value obtained by titrating the ultrafiltrate from a suspension in water alone had been subtracted. The last-named ultrafiltrate was considered to be a saturated solution of stearic acid in water, but the solubility as determined from it is probably slightly in excess of the true value, because the liquid, in spite of its apparent clarity, may have contained a few ultramicronic and amicronic particles. The true values of the acidity due to the salt action should probably therefore be rather higher than those in Table I. It is also to be observed that, although atmospheric carbon dioxide was not rigidly excluded, the solubility determination itself constituted a control

experiment, so that any error due to this cause can only be a difference between two small and nearly equal errors.

The liquids, excepting the alkali contained in the microburette, were handled in vessels coated with hard, neutral paraffin wax, and the experiments were carried out at the ordinary temperature (about 23°). The results are in Table I.

TABLE I.

Normality ($\times 10^6$) of acid due to salt action	6	7	16	26	32	49

A second series of experiments had for its object the accurate determination at the ordinary temperature of the relation between acidity and salt concentration, and between acidity and the volume of salt solution per unit surface of stearic acid. The method used was the electrical measurement of the hydrogen-ion activity of mixtures of stearic acid suspensions with neutral solutions of potassium sulphate. The hydrogen-ion activity of solutions of potassium sulphate at the three dilutions employed, when containing various known quantities of sulphuric acid, was also measured separately, and curves were drawn from which the actual quantity of sulphuric acid liberated by the suspensions could be read off. Preliminary experiments with an ordinary hydrogen electrode were discontinued on account of the unsatisfactory readings obtained, due possibly to the spoiling of the platinised surface of the electrode by particles of stearic acid. A bright platinum quinhydrone electrode gave satisfactory and reproducible results.

The quinhydrone, stearic acid, and potassium sulphate were recrystallised several times, the best-quality " conductivity " water was used, and no liquid of which the hydrogen-ion activity was to be measured was ever in contact with glass other than well-steamed Jena-glass or glass coated with neutral, hard paraffin wax. The liquid was deprived of dissolved carbon dioxide, before measurements were made, by prolonged passage of carbon dioxide-free air saturated with the vapour of the liquid under examination. A " saturated " calomel electrode was used as the second pole of the combination the *E.M.F.* of which was measured, and the combination was kept on an earthed metal sheet in a large air thermostat at 29° (the room temperature during these experiments being usually 27—28°). In order to avoid contact of the liquids with soda-glass measuring vessels, the solutions were prepared in every case by weight, not volume. The solutions of known acidity were made up by adding sulphuric acid of known strength contained in a paraffined

weight-pipette to 25 g. of potassium sulphate solution of double the strength required, in a tared Jena-glass flask, the final weight being then made up to 50 g. with conductivity water. The stearic acid mixtures contained equal weights of the suspension and of the potassium sulphate solution. If coagulation occurred before dissolved carbon dioxide was removed, as it did with the $N/2$-salt solutions at all dilutions except the highest, the liquid was filtered through an " ashless " paper, and the first 10 c.c. were rejected. If coagulation occurred either not at all or only after the bubbling of air, the unfiltered liquid was used. The relative hydrogen-ion activities were calculated from the formula $\log f = (E - 0{\cdot}4536)/0{\cdot}0598$, in which E denotes the measured $E.M.F.$ of the combination. The values of the hydrogen-ion activities corresponding to various concentrations of sulphuric acid in the three solutions of potassium sulphate used are in Table II. The figures are calculated on the assumption that the potential at the K_2SO_4-saturated KCl junction is zero, an assumption which does not affect their validity for the purposes of this investigation.

TABLE II.

Table III gives the results of the measurements of acidity produced by the stearic acid suspensions. The figures headed " dilution " refer to dilutions of the stock suspension which contained 2·32 g. of stearic acid per litre. Columns A, B, and C contain, respectively, the relative hydrogen-ion activities ($\times 10^6$), the concentration of acid (g.-equivs. $\times 10^6$ per kg.), and the total acid liberated (g.-equivs. $\times 10^6$ per g. of stearic acid). The figures are calculated from the mean of two or more separate measurements in each case.

The Nature of the Reaction between an Insoluble Acid and Salt Solutions.

The application of the theory of " membrane equilibrium " to the present problem is complicated by two factors which were not included in the theory as originally formulated by Donnan, *viz.*, (1) the unknown ratio of the volumes of liquid on either side of the " membrane," and (2) incomplete dissociation of the non-diffusible substance, involving the possibility of an increase in the number of diffusible ions available for exchange. In the absence of any knowledge of the magnitude of these factors, no quantitative application of the theory is possible; but an examination of the results of the experiments just described is strongly in favour of the conclusion that the reaction under discussion (and, by implication, similar reactions in which acidity is produced in neutral salt solutions) is qualitatively accounted for by the theory.

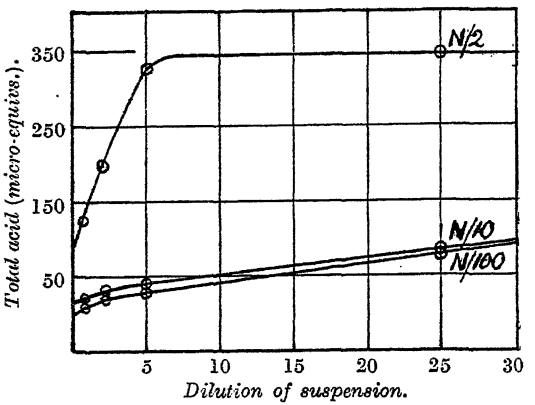

FIG. 1.

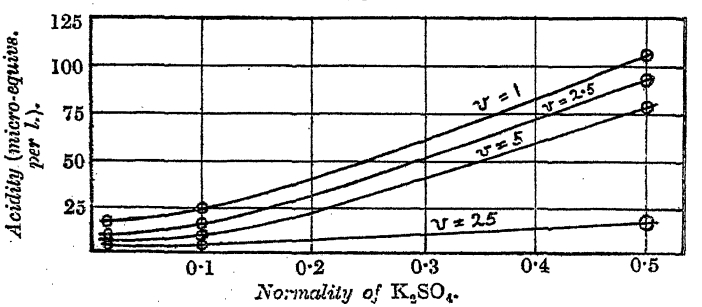
The progressive dilution of a suspension by the salt solution used is equivalent to increasing the volume of the liquid containing only diffusible ions, while maintaining constant that of the liquid containing the non-diffusible ion. If no dissociation of the surface molecules of the insoluble acid takes place, the activity of the hydrogen ions in the external liquid should decrease in an approximately linear manner with the dilution, provided that the volume of the external liquid is always a large fraction of the total volume, as it almost certainly is when the suspension is dilute. Assuming, on the other hand, that the surface molecules are initially but slightly dissociated, then if there were an unlimited supply of such molecules, which could undergo progressive dissociation, the hydrogen-ion activity in the external liquid should show little change with dilution. Under the experimental conditions the supply of surface molecules is limited, and it can be seen from Fig. 1 that, at the higher dilutions, the observations nearly correspond to these two extreme cases. Since a concentrated salt solution produces a more complete



exchange of ions than do the more dilute solutions, the reserve of undissociated molecules is in the former case nearly exhausted initially, and very little further dissociation is possible as the volume is increased; on the other hand, in the dilute solutions the acid concentration is comparatively little affected by dilution. Fig. 2,

FIG. 2.

showing the relation between dilution and total acid liberated, provides a striking clue to this behaviour: practically all the available acid is liberated by the strong salt solution during the early part of the dilution process (1 to 5), and further dilution (5 to 25)

FIG. 3.

produces no more. With the weaker solutions, the production of acid is still in evidence even at the highest dilution.

Again, the increase of acidity due to an increase in the concentration of potassium sulphate (see Fig. 3) is, at least qualitatively, predicted by the theory of membrane equilibrium. The increase is considerably greater than would be expected in a system where the number of exchangeable ions is constant, and this constitutes

additional evidence of the dissociation of the surface molecules under the experimental conditions.

The Relation between Acid Concentration and Hydrogen-ion Activity.

Donnan's theory is concerned with activities rather than concentrations, but in the present experiments the activity relationships tend to be obscured by disturbing factors incidental to the method used. In the presence of an excess of potassium sulphate, any sulphuric acid liberated is present as potassium hydrogen sulphate which, itself a strong binary electrolyte, furnishes an anion which is an acid with a dissociation constant of about 10^{-2} (Drucker, *Z. physikal. Chem.*, 1920, **96**, 382). An increase in the concentration of potassium sulphate may therefore be expected to influence the hydrogen-ion activity and the acid concentration in opposite senses, because a higher concentration of the salt, whilst effecting a more complete exchange of hydrogen ions, will at the same time cause a greater proportion of them to assume an inactive condition. This is, in fact, observed, for the activity–salt concentration curves pass through a minimum except at the highest dilution of the suspension.

Although it is chiefly a matter of terminology whether the production of acid, in circumstances similar to those considered in this paper, is to be regarded as an ionic exchange or as a chemical reaction between equivalent quantities of two molecular species, the suggestion has been put forward (Mukherjee, *loc. cit.*), in the case of hydrated silica, that the production of acid is to be attributed to an exchange of *adsorbed* ions bearing no stoicheiometric relation to the number of molecules of silica associated with them. The point of view advocated here differs radically from Mukherjee's in regarding the action as taking place between quantities of the insoluble acid and the neutral salt which are in a simple stoicheiometric proportion; in other words, one is dealing with a reversible chemical change differing from the ordinary type only in its localisation at an interface. The advantages of this point of view are that it does not need to invoke any of the various types of adsorption, and is at once in harmony with accepted chemical theory and with a theory of interfacial behaviour for which there is a rapidly increasing body of evidence (see *Trans. Faraday Soc.*, 1925, **21**, 406).

Summary.

1. The production of acidity by suspensions of stearic acid has been measured in neutral solutions of potassium chloride and potassium sulphate.

2. The variation of hydrogen-ion activity and of total acid with the salt concentration and with dilution of the suspension has been

examined, and found to be consistent with the view that the observed acidity is produced by exchange of the kations of the salt with hydrogen ions formed from dissociating molecules in the surface of the insoluble acid.

3. It is considered that the production of acidity in neutral solutions of salts of strong acids in contact with an extensive surface of a weak insoluble acid is generally to be expected on the basis of accepted theory, and is capable of a simple chemical interpretation.

CCXLII.—*Reactions of Incandescent Tungsten with Nitrogen and with Water Vapour.*

By COLIN JAMES SMITHELLS and HAROLD PERCY ROOKSBY.

(COMMUNICATION FROM THE RESEARCH STAFF OF THE GENERAL ELECTRIC COMPANY, LTD., WEMBLEY.)

1. *Reaction with Nitrogen.*

THE temperature at which a tungsten filament can be operated in a vacuum is in practice limited by the rate of evaporation of the metal, which forms a black deposit on the bulb, thereby reducing the candle power of the lamp. By surrounding the filament with an atmosphere of inert gas, the loss of metal by evaporation is reduced, and the filament can be operated at a higher temperature, and therefore at a higher efficiency, for an equal life (Brit. Pat., 10,918, 1913). In lamps of small wattage, it is customary to use as the inert gas a mixture of argon and nitrogen containing 10—20% of the latter, but lamps of 500 watts and upwards are frequently filled with pure nitrogen on grounds of economy. The filaments operate at a temperature of about 2850° K. It is found that a dark brown deposit is slowly formed on the inside of the bulb during the life of such lamps; but it forms much more slowly if an argon–nitrogen mixture is used. The cause of this coloration has now been investigated.

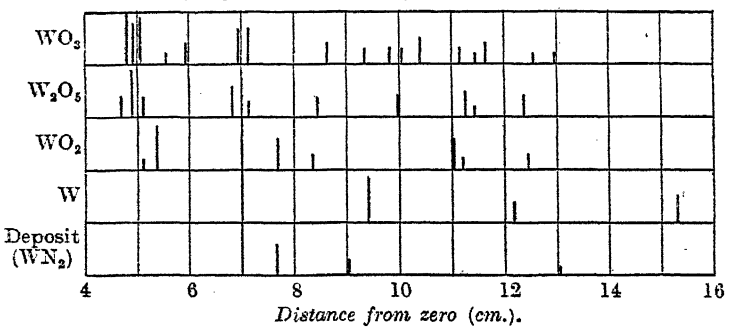
Very little information exists as to the formation, composition, or properties of the nitrides of tungsten. Henderson and Galletly (*J. Soc. Chem. Ind.*, 1908, **27**, 387) heated tungsten powder to 860° in a current of ammonia, but the product contained only a trace of nitrogen. By heating "tungsten nitramide," $W_3N_6H_4$, in ammonia, Uhrlaub ("Die Verbindungen einiger Metalle mit Stickstoff," Göttingen, 1859) obtained a substance to which he

assigned the formula W_3N_2. By heating tungsten hexachloride in ammonia, Rideal (J., 1889, **55**, 41) obtained a black, metallic-looking powder, the composition of which was represented as W_2N_3.

Langmuir (*J. Amer. Chem. Soc.*, 1913, **35**, 931) has studied the rate at which nitrogen is absorbed in a tungsten-filament vacuum lamp. He found that this was dependent on the rate of evaporation of the filament, and that one molecule of nitrogen disappeared for each atom of tungsten evaporated. He therefore assumed that nitrogen did not react with solid tungsten at temperatures in the neighbourhood of 2200° K., but that when an atom of tungsten struck a molecule of nitrogen they combined to form WN_2, which was deposited on the bulb. This nitride is described as a brown compound, readily decomposed by water to form ammonia and tungstic oxide, WO_3. No direct analyses were made.

It appeared probable that the coloration of the lamps under consideration might be due to the formation of such a nitride. Alternatively, it was possible that the deposit was evaporated tungsten from the filament, or nickel or molybdenum from the supporting and leading-in wires. The presence of traces of oxidising gases might also give rise to oxides of any of these metals. The total weight of the deposit on the inside of the largest lamps, which have a capacity of about 4 litres, is only 5—10 mg. after the lamp has been operated for 1000 hours. Special methods of analysis had, therefore, to be developed.

Preliminary Examination.—On opening the lamp a distinct odour is observed, which resembles ammonia, but is difficult to identify. The deposit can easily be rubbed off with the finger, or scraped together with a knife. After being exposed to the air for an hour, it becomes slightly sticky, more difficult to remove, and somewhat lighter in colour. After two or three days' exposure, it is again quite dry and easily rubbed off. A small quantity was ignited in air and gave a greenish-yellow residue, which resembled tungstic oxide and yielded its characteristic *X*-ray pattern, thus proving that the original material was definitely tungsten or one of its compounds.



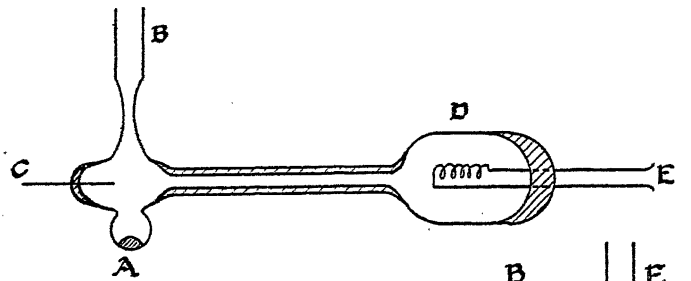
X-Ray Examination.—Tungsten forms three oxides, which are readily distinguished by their colour: WO_3, yellow; W_2O_5, deep blue; and WO_2, chocolate-brown. Pure specimens of each of these oxides were prepared, and the characteristic *X*-ray diffraction patterns obtained, together with that of the metal. These are shown in Fig. 1, where the height of the lines represents their relative intensities on the film. A little of the deposit was then smeared on a piece of tissue paper, and exposed to the *X*-ray beam. Three strongly marked but somewhat diffuse lines appeared in the

pattern. Although they were sufficiently clear for purposes of identification, it was not easy to measure their position accurately. The diffuseness was due to the extremely fine state of division of the deposit. By heating another sample at 600° in a current of pure, dry argon for 2 hours, the particles became coarser, and the lines in the diffraction pattern appeared much sharper. Their position, however, was unchanged. This pattern is also shown in Fig. 1. On comparing the positions of the lines with those in the patterns of the metal and its oxides, it is clear there is no correspondence and that the deposit must be some other compound.

Spectroscopic Examination.—The fact that the material burnt readily in air to tungstic oxide suggested a simple way of proving whether it was a nitride, for nitrogen should be formed when such a compound is oxidised.

FIG. 1.

X-Ray diffraction patterns of tungsten compounds.



A small hard-glass spectrum tube was made as shown in Fig. 2. This had a bulb, A, into which a mixture of the deposit with a little potassium permanganate was introduced through B. A plain molybdenum electrode, C, was arranged at this end, whilst at the other end of the tube a thick tungsten spiral filament, D, acted as the second electrode for the discharge. The electrodes were thoroughly freed from gas before the mixture was introduced, after which the tube was evacuated and sealed off. The whole volume of the apparatus was less than 1 c.c., and since a pressure of about 1 cm. was sufficient to obtain a satisfactory discharge, only 0·0003 g. of material was necessary.

On heating the bulb, A, a vigorous reaction occurred between the material and the permanganate. On passing a discharge, the spectrum of both nitrogen and oxygen appeared. The excess oxygen, derived from the permanganate, was then removed by heating the tungsten filament, and finally the tube contained nearly

pure nitrogen. The material was therefore most probably a nitride of tungsten having the formula WN_x.

FIG. 2.
Discharge tube.

Composition of the Nitride.—The value of x was determined by measuring (*a*) the volume of oxygen required to burn a small weight of the material, and (*b*) the volume of nitrogen evolved. From the equation

$$2WN_x + 3O_2 = 2WO_3 + xN_2,$$

it is seen that the value of x is determined from the ratio of the volumes of oxygen and nitrogen. It is not necessary to know the weight of the nitride, but, as a further check on the analysis, the material was weighed before the combustion was carried out. A special form of combustion apparatus was made (Fig. 3) which consisted of a hard-glass tube, A (volume about 3 c.c.), attached to a tap, B, and to a piece of barometer tubing, C (volume 1·5 c.c.). The lower end of the barometer tube was connected by a flexible rubber tube to a second piece of barometer tubing, D. The volume of the apparatus was carefully calibrated and a scale was attached to the tube C.

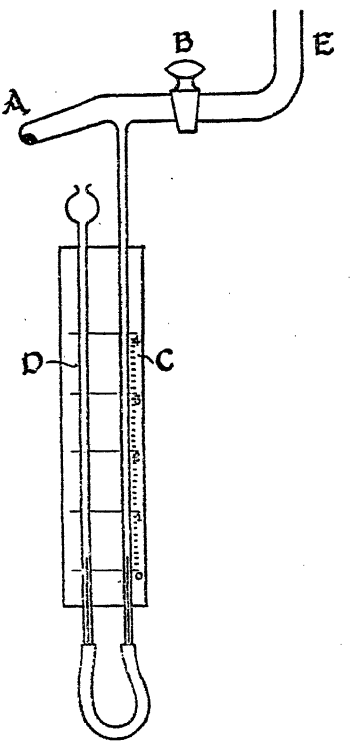


FIG. 3.
Combustion apparatus.

A weighed quantity (2—3 mg.) of the nitride was introduced into the limb A. The barometer U was filled with mercury up to about

the scale zero, and the tap closed. The whole apparatus was carefully protected from draughts and allowed to attain a steady temperature, which was read on an attached thermometer. The pressure was adjusted and the scale reading gave the volume of air in the apparatus. The nitride was then heated to about 650° by means of a blow pipe; it burnt readily to the yellow oxide, WO_3, and nitrogen was liberated. The apparatus was allowed to cool to room temperature during 5—10 hours, the pressure was adjusted, and the new volume read off. The difference between this reading and the previous one, after correction for any change of temperature, gave the volume of oxygen absorbed minus the volume of nitrogen evolved.

The external limb, E, was now filled with an alkaline solution of pyrogallol and the apparatus tilted so that when the liquid was drawn into the wide limb it would not enter the barometer tube. By lowering or raising the tube D, the solution was alternately drawn into the apparatus and expelled. The walls of the tube A were thus repeatedly wetted with fresh liquid until the remaining oxygen was absorbed. After allowing the apparatus to attain a steady temperature, a new reading of the volume was taken. This represented the known volume of nitrogen originally in the apparatus plus the nitrogen evolved.

The apparatus had been originally filled with atmospheric air, the humidity of which was determined from wet and dry bulb thermometer readings. It was found that the water-vapour pressure was, within the limits of accuracy attainable in the experiments, the same as that of the 40% caustic soda solution used for the absorption. No correction for the vapour pressure of the liquid was therefore required.

Although the formation of oxides of nitrogen during the combustion did not seem probable, caustic potash was introduced into the apparatus before the pyrogallol solution in one experiment. No absorption occurred, thus indicating that no oxides higher than nitrous oxide were present. It was thought justifiable to neglect the possibility of the presence of the latter.

From the equation we have

$$x/3 = \text{Vol. of } N_2 \text{ evolved/Vol. of } O_2 \text{ absorbed.}$$

Let c be the volume of nitrogen evolved and b the contraction on burning. Then

$$b = \text{Vol. of oxygen} - c,$$

and

$$x = 3c/(b + c).$$

After a number of preliminary trials to test the apparatus, two accurate determinations were made with weighed quantities of

materials from two different lamps. The results are given in Table I.

TABLE I.

Expt.	Weight of material (g.).	*b* (c.c.).	*c* (c.c.).	*x*.
1	0·0026	0·10	0·19	1·96
2	0·0036	0·15	0·27	1·93

These values show very good agreement and indicate that the nitride has the formula WN_2. Assuming this to be correct, it is possible to check the values obtained for *c* from the weight of material used. In both cases, the experimental value is about 70% of the theoretical value for the volume of the combined nitrogen. The difference is probably accounted for by the presence in the material of small fragments of glass and mica, with which it becomes unavoidably contaminated when the lamp is broken open.

These results confirm the conclusion reached by Langmuir as to the composition of the nitride, by an entirely different method. The formulæ assigned by earlier workers are probably in error owing to the difficulty of separating the nitride from the metal powder, and to the inherent difficulties of gravimetric methods when dealing with oxides and nitrides of tungsten, the molecular weights of which are so nearly the same.

The approximate density of the nitride was determined by weighing samples of 5—10 mg. in air and in benzene. A small pellet of the material was pressed in a steel die, and weighed in a pan made from aluminium foil which weighed only 8 mg. The pan holding the pellet was immersed in benzene in an evacuated vessel, in order to remove any occluded air, and its weight in the liquid then determined. The method was checked by determining the density of a pellet made from a thin film of tungstic oxide condensed on a glass surface; this gave a value of 6·3 g. per c.c., the density of fused crystalline tungstic oxide being 7·2 g. per c.c. Two determinations of the density of the nitride gave a mean value of 5 g. per c.c., with a maximum error of $\pm 0{\cdot}5$ unit.

2. *Reaction with Water Vapour.*

The action of water vapour on an incandescent tungsten filament has been described previously by one of us (Smithells, *Trans. Faraday Soc.*, 1921, **17**, 485). It was shown that a reversible reaction took place in which tungsten was oxidised at the hotter parts of the filament, and the oxide reduced to metal at lower temperatures and deposited on the cooler parts of the filament: $W + 2H_2O \rightleftharpoons WO_2 + 2H_2$. The reaction is accompanied by a

gradual blackening of the bulb, and it would be expected that this is due to a certain amount of both metal and oxide being carried by convection in the gas. Langmuir (*Gen. Electric Rev.*, 1926, **29**, 153) has shown, however, that atomic hydrogen, which is formed when molecular hydrogen comes in contact with incandescent tungsten, will reduce tungsten oxides at room temperature. It therefore appeared of interest to determine the nature of the deposit, which is nearly black and easily distinguishable from the nitride just described. The *X*-ray diffraction pattern was found to be identical with that obtained from pure tungsten powder, no trace of oxide being present. This can only be explained by assuming that atomic hydrogen formed during the reaction, and in contact with the incandescent filament, arrives at the surface of the glass and reduces any oxide deposited. That oxide molecules do reach the glass walls is almost certain, since the cyclic action can hardly be so complete as to prevent their escape entirely. The fact that they are subsequently reduced explains why even very minute quantities of water vapour have such a deleterious effect in gas-filled lamps. Water vapour present in the filling gas to the extent of 1 part in 10,000 parts will cause the filament to burn out in less than an hour.

WEMBLEY. [*Received, February 22nd*, 1927.]

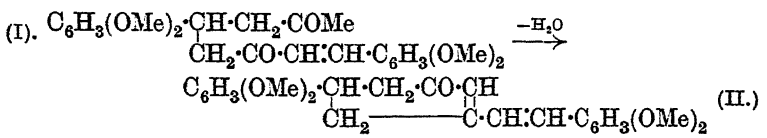
CCXLIII.—*The Intermolecular Condensation of Styryl Methyl Ketones. Part I.*

By ROBERT DICKINSON, ISIDOR MORRIS HEILBRON, and FRANCIS IRVING.

IN a previous investigation (Dickinson and Heilbron, this vol., p. 14), 3 : 4-dimethoxystyryl methyl ketone was required. Apparently three different substances, m. p.'s 168° (Francesconi and Cusmano, *Gazzetta*, 1908, **38**, ii, 70), 85—86°, and 91—92° (Ryan and Plunkett, *Proc. Roy. Irish Acad.*, 1916, **32**, *B*, 199; Kaufmann and Radosević, *Ber.*, 1916, **49**, 675), are recorded in the literature under this name, all having been prepared by the alkali condensation of veratraldehyde with acetone.

We have now investigated these compounds in detail. The second and the third are undoubtedly identical, the true melting point being 86°. This compound is definitely 3 : 4-dimethoxystyryl methyl ketone, for (1) its molecular weight, determined

ebullioscopically, is normal; (2) in the presence of hydrogen chloride, it condenses with 2-naphthol-1-aldehyde, giving 3-3′ : 4′-dimethoxystyryl-β-naphthapyrylium chloride (Dickinson and Heilbron, *loc. cit.*); (3) it may be prepared by the methylation of 3-methoxy-4-hydroxystyryl methyl ketone; (4) it absorbs one molecule of bromine (the dibromide, however, could not be isolated); and (5) it readily condenses with veratraldehyde, in the presence of alkali, giving 3 : 3′ : 4 : 4′-tetramethoxydistyryl ketone, identical with the product obtained by Stobbe and Haertel (*Annalen*, 1909, **370**, 104), the constitution of which we have now confirmed by the preparation of its tetrabromide. Guimbal (*Dipl. et Sup.*, No. 212, Paris, 1921; compare Faillebin, *Ann. Chim.*, 1925, **4**, 445) has come to the same conclusion, but only on the results of analysis and cryoscopy; he records 84° as the melting point. Lapworth and Wykes (J., 1917, **111**, 790) also must certainly have had this same ketone in their hands, as was shown by the ease with which it was oxidised to dimethylcaffeic acid. They do not, however, give the method of preparation, or record the melting point of their product, but only refer to Francesconi and Cusmano (*loc. cit.*), whose product is entirely different and cannot yield dimethylcaffeic acid.



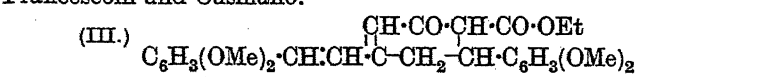
The compound described by Francesconi and Cusmano (*loc. cit.*) has also been obtained by other workers, who, beyond stating that it is not veratrylideneacetone and making suggestions as to its possible constitution, have not investigated it experimentally. It is regarded by Ryan and Plunkett (*loc. cit.*) as an isomeric form of the styryl ketone, by Kaufmann and Radosević (*loc. cit.*) as the corresponding distyryl ketone, and by Guimbal (*loc. cit.*) as a compound of 3 : 4-dimethoxystyryl methyl ketone and acetone. Francesconi and Cusmano (*loc. cit.*) do not record any analytical values for their compound, or for its alleged condensation product with cinnamaldehyde.

We have now found that in addition to its direct preparation from veratraldehyde and acetone, the 168°-compound may be obtained by treating 3 : 4-dimethoxystyryl methyl ketone with alkali, acetone being used as solvent in order to minimise the production of the distyryl ketone through scission (compare Heilbron and Buck, J., 1921, **119**, 1503). Our analyses show that the substance is formed according to the equations:

(A) $2C_6H_3(OMe)_2\cdot CHO + 2Me_2CO = C_{24}H_{26}O_5 + 3H_2O$
(B) $2C_6H_3(OMe)_2\cdot CH{:}CH\cdot CO\cdot CH_3 = C_{24}H_{26}O_5 + H_2O.$

From a knowledge of the addition reactions of unsaturated ketones, the first stage in equation (B) is undoubtedly represented by form-

ation of the compound (I) through simple addition at the αβ-ethenoid linkage.



(I.) $C_6H_3(OMe)_2\cdot CH(CH_2\cdot CO\cdot CH{:}CH\cdot C_6H_3(OMe)_2)\cdot CH_2\cdot COMe \xrightarrow{-H_2O}$ $C_6H_3(OMe)_2\cdot CH(CH_2\cdot CO\cdot C(CH_2)=C\cdot CH{:}CH\cdot C_6H_3(OMe)_2)$ (II.)

Many examples of such addition reactions are known; *e.g.*, Cornelson and Kostanecki (*Ber.*, 1896, **29**, 240) treated a mixture of 2-hydroxystyryl phenyl ketone and acetophenone with alkali and obtained 2-hydroxybenzylidenediacetophenone:

$$OH\cdot C_6H_4\cdot CH{:}CH\cdot COPh \xrightarrow{CH_3\cdot COPh} OH\cdot C_6H_4\cdot CH(CH_2\cdot COPh)_2.$$

Styryl and distyryl ketones add on acetoacetic ester and other keto-esters in precisely the same way, although secondary reactions occur afterwards (compare Heilbron and co-workers, J., 1924, **125**, 340, 2064; 1925, **127**, 2159; this vol., p. 918). The second stage of reaction (B) consists in the elimination of a molecule of water from compound (I), and this would almost certainly occur in such a manner as to yield the *cyclo*hexenone derivative (II).

The reactions of the 168°-compound are in full agreement with this formulation. We have determined its molecular weight, which is normal, and prepared its semicarbazone. It readily absorbs two molecules of bromine with exhibition of halochromy, but we have been unable to isolate the tetrabromide in a state of purity. Finally, full confirmation of formula (II) has been reached by the synthesis of the compound in the following way. 3 : 3′ : 4 : 4′-Tetramethoxydistyryl ketone was condensed with acetoacetic ester by means of sodium ethoxide (compare Heilbron and co-workers, *loc. cit.*); *ethyl* 3-mp-*dimethoxyphenyl*-5-mp-*dimethoxystyryl*-Δ^5-cyclo*hexen*-1-*one*-2-*carboxylate* (III) was then readily obtained in good yield. On treatment of this with 20% sulphuric acid, the carbethoxyl was eliminated with production of the free *cyclo*hexenone (II), which was identical in all respects with the compound described by Francesconi and Cusmano.

(III.) $C_6H_3(OMe)_2\cdot CH{:}CH\cdot C(CH\cdot CO\cdot CH\cdot CO\cdot OEt)=CH_2\cdot CH\cdot C_6H_3(OMe)_2$

We have attempted to obtain by similar means compounds analogous to (II), and for this purpose we prepared the *ethyl*, n-*propyl*, iso*propyl*, and *benzyl* ethers of 3-methoxy-4-hydroxystyryl methyl ketone. On treating these with alkali, we obtained the homologue of (II) in only one case—the *n*-propyl compound—and its reactions are in harmony with such a structure. An abnormal result was obtained with 3-*methoxy*-4-*benzyloxystyryl methyl ketone*,

treatment with alkali yielding a new substance (m. p. 174—175°) which gave analytical results for 3 : 3′-dimethoxy-4 : 4′-dibenzyloxydistyryl ketone, but was different from the distyryl ketone prepared in the usual manner (m. p. 155°). In all cases, much resinous material was formed; apparently the inter-condensation of styryl methyl ketones does not stop at the stage represented by equation (B), but continues to give a mixture of still more complex products. Such resinification of unsaturated ketones has already been considered by Borsche (*Ber.*, 1909, **42**, 4499), Giua (*Gazzetta*, 1925, **55**, 567), and especially by Herzog (*Z. angew. Chem.*, 1922, **35**, 465, 641; 1923, **36**, 471; *Chem.-Ztg.*, 1925, **49**, 119).

We next directed our attention to the action of piperidine upon styryl methyl ketones, expecting that this base would behave similarly to alkali, but would be milder in its action and possibly yield the primary additive compound (I). In all the cases we have investigated, however, much resinification took place, and we have been able to isolate solid products only in minute yields. These compounds are not true intermolecular condensation products, but dimerides of the styryl ketone, and from their saturated nature and absence of colour they must be regarded as *cyclo*butane derivatives (IV or V) analogous to that obtained by Stobbe (*J. pr. Chem.*, 1912, **86**, 248; Stobbe and Hensel, *Ber.*, 1926, **59**, 2254)

(IV.) $\begin{matrix} R\cdot CH\cdot CH\cdot COMe \\ R\cdot CH\cdot CH\cdot COMe \end{matrix}$ $\qquad$ $\begin{matrix} R\cdot CH\cdot CH\cdot COMe \\ COMe\cdot CH\cdot CHR \end{matrix}$ (V.) $\qquad [R = C_6H_3(OMe)_2]$

from phenyl 4-methoxystyryl ketone by the same method, and also to the compounds he and other workers have obtained by photopolymerisation (compare Stobbe and Hensel, *loc. cit.*).

Wieland (*Ber.*, 1904, **37**, 1145) obtained a dimeric form of phenyl styryl ketone by treating it with acetic anhydride containing a trace of sulphuric acid; but, applied to our compounds, this method yielded resinous material only, from which no pure substance has been isolated.

Experimental.

3 : 4-Dimethoxystyryl methyl ketone was prepared by Kaufmann and Radosević's method (*loc. cit.*) and found to melt at 85—86°, as given by Ryan and Plunkett (*loc. cit.*). The ketone can also be obtained in quantitative yield by the methylation of 3-methoxy-4-hydroxystyryl methyl ketone by Dickinson's method (J., 1926, 2234) for the preparation of 2-methoxystyryl benzyl ketone (Found: *M*,* 234, 207, 203. $C_{12}H_{14}O_3$ requires *M*, 206).

* The molecular weights recorded in this paper were all determined ebullioscopically in chloroform by Menzies's method (Menzies and Wright, *J. Amer. Chem. Soc.*, 1921, **43**, 2314).

The *semicarbazone*, prepared by the usual method, crystallises from alcohol in colourless needles, m. p. 205°, which exhibit phototropic properties, becoming sulphur-yellow on short exposure to light. Crystallised from 50% acetic acid, it forms canary-yellow needles melting indefinitely about 180°. This is probably an unstable acetate, for on treatment with water or on keeping over potash it loses its crystalline form and colour, becoming identical with the original semicarbazone (Found: N, 16·1. $C_{13}H_{17}O_3N_3$ requires N, 16·0%).

3 : 3′ : 4 : 4′-Tetramethoxydistyryl ketone was obtained in fair yield by the direct alkaline condensation of veratraldehyde with acetone according to Stobbe and Haertel's method (*loc. cit.*). It was also readily prepared by condensation of 3 : 4-dimethoxystyryl methyl ketone (1·3 g.) with veratraldehyde (1 g.) in alcoholic solution (20 c.c.) in presence of dilute aqueous sodium hydroxide (3 c.c. of 8%); after a few hours, the yellow precipitate was collected and crystallised from alcohol, yielding the pure product, m. p. 84°. A peculiar property of this distyryl ketone was noted: a specimen which had been kept in a sealed tube for several months changed in colour, the golden-yellow crystals becoming yellowish-brown, and crumbled to a powder. The change appeared to start at various centres and slowly spread into the surrounding material, but complete conversion was never attained. The *tetrabromide*, prepared by treating the ketone in chloroform solution with the calculated amount of bromine, crystallised from benzene in colourless needles which darkened at 145° and melted at 152° with inflation [Found: Br, 47·3 (Stepanoff). $C_{21}H_{22}O_5Br_4$ requires Br, 47·4%].

Ethyl 3-mp-*Dimethoxyphenyl*-5-mp-*dimethoxystyryl*-Δ^5-cyclo*hexen*-1-*one*-2-*carboxylate* (III).—A solution of 3 : 3′ : 4 : 4′-tetramethoxydistyryl ketone (10 g.) and ethyl acetoacetate (4 g.) in boiling alcohol (75 c.c.) was treated with sodium ethoxide (0·4 g. of sodium in 25 c.c. of alcohol) and maintained at the boiling point for 5 minutes. The crystalline solid which separated on cooling (yield, above 90%) was twice recrystallised from absolute alcohol, in which it was sparingly soluble, giving bright yellow needles, m. p. 160—161° (Found: C, 69·3; H, 6·5. $C_{27}H_{30}O_7$ requires C, 69·5; H, 6·4%).

3-mp-*Dimethoxyphenyl*-5-mp-*dimethoxystyryl*-Δ^5-cyclo*hexen*-1-*one* (II).—The above-mentioned ester (5 g.), dissolved in glacial acetic acid (75 c.c.), was boiled with 20% sulphuric acid (50 c.c.) under reflux for 4 hours. After cooling, the dark red liquid was slowly poured into ice-water (1000 c.c.). The greenish-yellow, curdy precipitate was crystallised from alcohol and then twice from ethyl acetate. The cyclo*hexenone* formed minute, pale yellow

needles, m. p. 168°, which tenaciously retained traces of ethyl acetate. For analysis, the substance was heated in a vacuum at 100° for several hours. It readily absorbed two molecules of bromine, but no pure bromo-derivative could be isolated (Found: C, 73·0; H, 6·4. $C_{24}H_{26}O_5$ requires C, 73·1; H, 6·6%).

The direct preparation of 3-*mp*-dimethoxyphenyl-5-*mp*-dimethoxystyryl-Δ^5-*cyclo*hexen-1-one was carried out by the following modification of Francesconi and Cusmano's method (*loc. cit.*). Veratraldehyde (12 g.), dissolved in aqueous acetone (70 c.c.), was treated with sodium hydroxide solution (25 c.c. of 1%). After the mixture had been kept for 2 days in the ice-chest, the solid was separated and twice recrystallised from ethyl acetate; the pure product, m. p. 168°, was then obtained (yield 20%). The filtrate gave on dilution a viscous yellow oil, from which a small quantity of the normal monostyryl ketone (m. p. 85°) was isolated. The compound, m. p. 168°, gave no depression in melting point in admixture with the *cyclo*hexenone prepared as described above, the constitution of which is definitely determined. The *cyclo*hexenone was also prepared by keeping an acetone solution of 3 : 4-dimethoxystyryl methyl ketone, mixed with a few drops of 8% sodium hydroxide solution, at room temperature for several days. The solution slowly darkened and deposited a crystalline, yellow mass which, after recrystallisation from ethyl acetate, was identical with the Francesconi compound (Found: C, 73·1; H, 6·6%; *M*, 396, 395). Both substances were mixed with the synthesised *cyclo*hexenone (II), but no depression in melting point was noted.

Preparation of the cyclo*hexenone semicarbazone.* A solution of the *cyclo*hexenone (2 g.) in glacial acetic acid was treated with semicarbazide acetate. The yellow solution slowly became red and after 3 days the separated solid was filtered off, washed with water, and dried. On boiling with alcohol part dissolved and part was converted into a golden-yellow, crystalline powder; an identical product was obtained from the alcoholic solution. The *monosemicarbazone* forms golden-yellow rhombs, m. p. 226—227° to a red liquid, and regenerates the *cyclo*hexenone on being refluxed with aqueous-alcoholic oxalic acid for several hours (Found: N, 9·2. $C_{25}H_{29}O_5N_3$ requires N, 9·3%).

Dimeride of 3 : 4-*Dimethoxystyryl Methyl Ketone.*—3 : 4-Dimethoxystyryl methyl ketone (20 g.) was heated on a steam-bath with piperidine (30 c.c.) for 24 hours. The solution was diluted with water and acidified, and the resinous precipitate obtained, on repeated treatment with boiling alcohol, yielded a white, amorphous powder. For analysis, the compound, which was obtained only

in very small yield, was precipitated from benzene solution by the gradual addition of light petroleum; m. p. 209—210° (Found: C, 70·2; H, 6·7; *M*, 418. $C_{24}H_{28}O_6$ requires C, 69·9; H, 6·8%; *M*, 412).

3-*Methoxy*-4-*ethoxystyryl Methyl Ketone*.—Ethylvanillin (5 g.), prepared according to Tiemann's method (*Ber.*, 1875, **8**, 1129), was dissolved in alcohol (5 c.c.) and acetone (15 c.c.) and treated with 1% sodium hydroxide solution (20 c.c.). After an hour, a yellow oil commenced to separate which only very slowly became solid. In subsequent experiments, seeding the mixture at this stage brought about a rapid separation of the solid ketone. Recrystallised from dilute alcohol, it formed yellow needles, m. p. 106° (yield, 83%). The ketone was also obtained in a colourless modification having the same melting point by allowing the yellow modification to stand in suspension in water or xylene for several weeks in direct sunlight. Whereas the yellow form gives an intense crimson coloration in concentrated hydrochloric acid, the colourless isomeride dissolves to a yellow solution (Found: C, 70·7; H, 7·0; *M*, 236. $C_{13}H_{16}O_3$ requires C, 70·9; H, 7·3%; *M*, 220). The *semicarbazone* separates from alcohol in pale yellow plates, m. p. 208—209° (Found: N, 15·4. $C_{14}H_{19}O_3N_3$ requires N, 15·2%).

3 : 3′-*Dimethoxy*-4 : 4′-*diethoxydistyryl Ketone*.—Ethylvanillin (5 g.) and acetone (1 c.c.) were dissolved in 50% alcohol (100 c.c.) together with 10% sodium hydroxide solution (2·5 c.c.) and the mixture was left at room temperature for 24 hours. The yellow precipitate was recrystallised from alcohol, the pure *ketone* separating in yellow needles, m. p. 123—124° (yield, 50%) (Found: C, 72·0; H, 6·8. $C_{23}H_{26}O_5$ requires C, 72·2; H, 6·8%).

Dimeride of 3-*Methoxy*-4-*ethoxystyryl Methyl Ketone*.—The styryl ketone (19 g.) was refluxed on a steam-bath with piperidine (30 c.c.) for 24 hours. The gummy precipitate formed on addition of water was repeatedly washed with alcohol, whereby resinous impurities were wholly removed. The polymeride was purified by slow precipitation from benzene solution by means of light petroleum. It formed a white, amorphous powder, m. p. 187° (yield, 5%) (Found: C, 70·9; H, 7·4; *M*, 446, 465. $C_{26}H_{32}O_6$ requires C, 70·9; H, 7·3%; *M*, 440).

Propylvanillin.—A mixture containing the potassium salt of vanillin (19 g.), propyl iodide (25 g.), and absolute alcohol (20 c.c.) was heated for 12 hours under reflux on the water-bath. After removal of part of the alcohol, the residue was poured into water; the precipitated oil rapidly solidified. This was dissolved in ether and repeatedly washed with dilute alkali solution to remove unchanged vanillin. The residue left after removal of the ether was

recrystallised from dilute alcohol, *propylvanillin* being obtained in colourless crystals, m. p. 59—60° (yield, 60%) (Found: C, 67·8; H, 7·4. $C_{11}H_{14}O_3$ requires C, 68·0; H, 7·2%). The *semicarbazone* separated from alcohol in colourless needles, m. p. 156° (Found: N, 16·9. $C_{12}H_{17}O_3N_3$ requires N, 16·7%).

3-*Methoxy*-4-*propoxystyryl Methyl Ketone*.—A solution of propylvanillin (2 g.) in acetone (8 c.c.) and alcohol (3 c.c.) was treated with 1% aqueous sodium hydroxide (8 c.c.). The product, which rapidly separated, was twice recrystallised from alcohol, the pure styryl ketone forming bright yellow rhombs, m. p. 92—93° (Found: C, 71·9; H, 7·8. $C_{14}H_{18}O_3$ requires C, 71·8; H, 7·7%).

3-m-*Methoxy*-p-*propoxyphenyl*-5-m-*methoxy*-p-*propoxystyryl*-Δ^5-cyclo*hexen*-1-*one*.—The ketone (10 g.) in acetone (75 c.c.), alcohol (50 c.c.), and water (100 c.c.) was treated with 2*N*-sodium hydroxide (10 c.c.), and the whole left at room temperature for 3 days. The small amount of yellow precipitate crystallised from ethyl acetate in pale yellow needles, m. p. 152—153°. It readily absorbed two molecules of bromine, halochromic colour effects being shown, but no solid tetrabromide could be isolated (Found: C, 74·5; H, 7·6. $C_{28}H_{34}O_5$ requires C, 74·7; H, 7·6%).

iso*Propylvanillin*, prepared in the same way as the *n*-isomeride, formed a pale yellow, viscous liquid, b. p. 150—152°/13 mm. The *semicarbazone* separated from alcohol in colourless needles, m. p. 151—152° (Found: N, 16·6. $C_{12}H_{17}O_3N_3$ requires N, 16·7%).

3-*Methoxy*-4-iso*propoxystyryl methyl ketone*, prepared by the method described for the *n*-isomeride, separated as a yellow oil which only became solid after long standing. It crystallised from aqueous alcohol in yellow flakes, m. p. 51—53°. An acetone–alcoholic solution of the ketone in presence of alkali darkened fairly rapidly, but only resinous material was isolated. The *semicarbazone* formed yellow needles, m. p. 203—204° (Found: N, 14·6. $C_{15}H_{21}O_3N_3$ requires N, 14·4%).

Benzylvanillin, previously prepared by the oxidation of benzyl-*iso*eugenol (Boehringer und Söhne, D.R.-P. 65,937, 1891), is more conveniently prepared by the following method. A thin alcoholic paste of the potassium salt of vanillin (23 g.) was heated under reflux with benzyl chloride (25 g.) for 12 hours. The excess of benzyl chloride was removed by short distillation in steam and the residual oil, which solidified on cooling, was twice recrystallised from alcohol, benzylvanillin being obtained in colourless crystals, m. p. 64—65° (yield, 70%).

3-*Methoxy*-4-*benzyloxystyryl Methyl Ketone*.—A solution of benzylvanillin (5 g.) in acetone (8 c.c.) and alcohol (20 c.c.) was treated

with sodium hydroxide solution (8 c.c. of 0·5%) and kept in the ice-chest; an oil then separated which slowly solidified. The crude product (yield, 80%) contained a small amount of the corresponding distyryl ketone, which was only separated with difficulty by fractional crystallisation either from alcohol or ethyl acetate. The *ketone* crystallised from alcohol in yellow needles, m. p. 93° (Found: C, 76·4; H, 6·4; *M*, 280, 285. $C_{18}H_{18}O_3$ requires C, 76·6; H, 6·4%; *M*, 282). The *semicarbazone* formed a yellow powder, m. p. 200—201° (Found: N, 12·4. $C_{19}H_{21}O_3N_3$ requires N, 12·4%).

3 : 3′-*Dimethoxy*-4 : 4′-*dibenzyloxydistyryl Ketone*.—A solution of benzylvanillin (2 g.) in acetone (0·5 c.c.) and alcohol (30 c.c.) was treated with 1% sodium hydroxide solution (10 c.c.). After 24 hours, the mixture was neutralised with dilute acetic acid, whereupon an oil separated which rapidly solidified. The distyryl ketone crystallised from ethyl acetate in golden-yellow needles, m. p. 155°. Alternatively, the same compound may be obtained by condensation of 3-methoxy-4-benzyloxystyryl methyl ketone with benzylvanillin (Found: C, 78·1; H, 6·0. $C_{33}H_{30}O_5$ requires C, 78·3; H, 5·9%). The *tetrabromide*, obtained by treating the ketone in chloroform solution with the calculated amount of bromine, formed minute, colourless needles, m. p. 141° (decomp.), from benzene. This compound rapidly decomposes with loss of bromine.

An apparent isomeride of this distyryl ketone was isolated in an attempt to prepare the *cyclo*hexenone from 3-methoxy-4-benzyloxystyryl methyl ketone by the action of alkali in the following manner. The monostyryl ketone (10 g.) in acetone (36 c.c.) and alcohol (36 c.c.) was treated with 8% sodium hydroxide solution (25 c.c.), and the mixture was kept at room temperature for 6 hours and in the ice-chest for 2 days. A solid separated which, after three recrystallisations from ethyl acetate, was obtained in dark orange-yellow needles, m. p. 174—175°. This substance absorbs 2 molecules of bromine, but no solid bromide could be isolated (Found: C, 78·3; H, 6·2%).

Phenyl 3 : 4-*Dimethoxystyryl Ketone*.—A solution of veratraldehyde (5·6 g.) and acetophenone (4 g.) in alcohol (30 c.c.) was treated with 10% sodium hydroxide solution (12 c.c.). After an hour, an oil separated which slowly solidified; in subsequent experiments, seeding of the oil brought about almost instantaneous solidification. The chalkone separated from aqueous alcohol in yellow needles, m. p. 88° (yield, 70%) (Found: C, 75·9; H, 6·3. $C_{17}H_{16}O_3$ requires C, 76·1; H, 6·0%). Attempts to condense this compound to a *cyclo*hexenone by means of alkali failed, only resinous material being formed.

In conclusion, we desire to express our thanks to the Council of the Department of Scientific and Industrial Research for a grant to one of us (R. D.) and also to the Cumberland County Council for the renewal of a scholarship (F. I.) which has enabled this research to be carried out.

THE UNIVERSITY, LIVERPOOL. [*Received, June 8th,* 1927.]

CCXLIV.—*The Oxidation of* n-*Triacontane.*

By FRANCIS FRANCIS and NORMAN EDWARD WOOD.

IT is now known that Scotch paraffin wax fusing between 55° and 56°, and probably all similar waxes, are composed of ten to twelve *n*-hydrocarbons (J., 1926, 1420).

The oxidation of paraffin by air or oxygen has been described in this Journal, but in 1922 (J., **121**, 501) it was shown that the synthetic hydrocarbons *n*-hexadecane and *n*-dotriacontane in the presence of 5% of turpentine suffered no change when treated with a current of air at 100° for 730 and 696 hours, respectively. Under similar conditions, paraffin wax reached a content of about 19% of oxygen. At that time, these observations led to the conclusion that the hydrocarbons present in the latter substance differed from those of the normal series.

Later it was found, however, that the presence of very small quantities of certain impurities in paraffin was capable of greatly prolonging the latent phase of the oxidation process, that characteristic period in this reaction when no change is observed.

Both of the above hydrocarbons had been synthesised from their halogen derivatives—octyl and cetyl iodide—purified by the ordinary method, and were judged from their constants and analyses to be pure. A sufficient amount of the specimen of hexadecane used in the work was available, and on being tested was found to contain traces of iodine, and there is but little doubt that the dotriacontane was contaminated in a similar manner. It was highly probable that these impurities had prolonged the latent period of the oxidation, and in order to test this view, a suitable hydrocarbon—*n*-triacontane—was synthesised by a method that did not involve the use of halogen derivatives.

Triacontane was prepared by the electrolysis of potassium palmitate (Peterson, *Z. Elektrochem.*, 1906, **12**, 141). The palmitic acid used was Kahlbaum's purest preparation, and the resulting hydrocarbon (480 g.) was purified by crystallisation from benzene, followed by fractional distillation in a vacuum. It fused at 66·5°, and boiled at 304° (corr.)/15 mm.; the analysis is given in Table I.

During this preparation, about 70 g. of a hydrocarbon were isolated, liquid at the ordinary temperature, a description of which will be given in a later communication.

When triacontane and 5% of turpentine were treated at 95° ± 2° with a current of air free from moisture and carbon dioxide, oxidation took place in a manner strikingly similar to that shown by paraffin wax or the hydrocarbons isolated from it. The analysis of the material after the passage of air for various periods is given in Table I, *a* being the duration of the air current in hours. The final product showed an acid value of 88·6.

TABLE I.

Oxidation of $C_{30}H_{62}$. $t = 95° \pm 2°$.

a.	% C.	% H.	% O by diff.	*a*.	% C.	% H.	% O by diff.
Hydrocarbon	84·9	14·9	—	506	80·5	13·6	5·9
173	82·5	14·5	3·0	577	79·1	13·0	7·9
266	82·4	14·5	3·1	748	78·0	12·8	9·2
341	82·3	14·3	3·4	865	76·1	12·6	11·3
413	81·3	14·0	4·7	1009	75·7	12·2	12·1

If the data in Table I be compared with those for paraffin wax at 100° (J., 1924, **125**, 387), it will be seen that in both cases there is a halt in the progress of the oxidation when the oxidised material contains about 3% of oxygen, and a similar but less well-marked phenomenon when the content has reached 8% of this element.

With the above hydrocarbon at the temperature mentioned, an oxygen content of 7% is reached in 550 hours; at 100°, paraffin wax requires 790 hours, the hydrocarbon $C_{22}H_{46}$ isolated from paraffin 460 hours, and $C_{29}H_{60}$ from the same source 420 hours (compare J., 1924, **125**, 383).

Products of the Oxidation.—(1) During the oxidation of paraffin wax, of the hydrocarbons isolated from it, and of triacontane itself, carbon dioxide and formic acid are formed. The amounts of these were determined by passing the gases through an excess of barium hydroxide solution. Triacontane gave 4·3 g. of carbon dioxide per 100 g. of hydrocarbon oxidised, and in the other cases the amount varied between 4·6 and 6·3 g. The amount of carbon in the form of formic acid produced from triacontane was 0·6 g. per 100 g. oxidised, and in the other cases varied between 1·0 and 1·3 g.

(2) The products of the oxidation were freed from unoxidised triacontane by several crystallisations from fifteen times the volume of acetone. The unchanged hydrocarbon, insoluble in this solvent, amounted to 21%. In the case of paraffin wax under comparable conditions, the corresponding amount lies between 25 and 30%.

(3) The oxidised triacontane, consisting of acids and inert material, was then saponified with an alcoholic solution of caustic potash, water added until 50% was present, and the inert products were extracted with large quantities of light petroleum. The acids amounted to 64%, whereas in the case of paraffin wax they lay between 58 and 69% in different experiments.

Acidic Products of the Oxidation.—(1) The acids were steam-distilled, but the amount of oily distillate was too small for identification. The water in the distilling flask, however, had dissolved a small quantity of a substance which consisted chiefly of succinic acid, although the amount isolated was insufficient for complete purification. It fused at 176°, and at 178—179° when mixed with succinic acid (m. p. 181°), and its molecular weight by titration was 119 (Found: C, 41·2; H, 4·3. Calc. for $C_4H_6O_4$: C, 40·7; H, 5·1%; *M*, 118).

(2) The cake of dry acids from the previous operation was recrystallised several times from chloroform followed by acetone, and about 9% of a mixture of white, crystalline acids was obtained. After long-continued fractional crystallisation, these were found to consist chiefly of $C_{26}H_{52}O_2$, which appeared to be identical with cerotic acid, and a small quantity of $C_{24}H_{48}O_2$. Both these acids had been previously isolated in this laboratory from products of the oxidation of paraffin wax.

The specimen of cerotic acid used for the comparison was prepared for us by the Eastman Kodak Co. It had been isolated from beeswax and purified by the fractionation of its methyl ester. Both this acid and the corresponding one mentioned above were further purified by conversion, in methyl-alcoholic solution, into the barium salt, which was extracted with ether and finally with acetone. The acids recovered from these salts by solution in hot acetic acid were repeatedly crystallised from acetone and finally from light petroleum. The full comparison is given in Table II.

The data given for the corresponding acids from paraffin wax (*a*) and (*b*) were for specimens isolated by different observers and their preparation will be described in another communication. We have to thank Mr. Piper, who is undertaking an investigation of these other acids, for the *X*-ray data. He informs us that, as regards the high values in the above table, the error is about 1%. We point out that the melting points of the above acids are about 10° lower than that of the synthetic acid of the same carbon content, which, according to Levene and Taylor, fuses at 88·5° (*J. Biol. Chem.*, 1924, **59**, 919). We leave to a later date the discussion of this acid and that melting at 74°, of acid value 152, which is probably $C_{24}H_{48}O_2$, together with a series of what are believed to be

analogous acids, which have been isolated from the oxidation products of paraffin wax.

(3) The main bulk of the acids, from which cerotic acid and the acid $C_{24}H_{48}O_2$ have been removed, is a complex mixture of monobasic and oxy-acids which cannot be separated from the small amount of inert material present by conversion into barium salts and extraction with solvents. The mixture is as difficult to deal with as that of the corresponding material from paraffin wax.

The material was converted into methyl esters, of which about 38% could be distilled without decomposition in a vacuum of 3 mm., this amount corresponding closely with that observed in the case of the similar complex obtained from paraffin wax. The distillate boiled between 140° and 205°/6 mm. and on standing in the ice-chest deposited a crystalline substance. The acids obtained from this were fractionally crystallised from acetone and finally two were isolated in small quantities: (A) M. p. 63°, acid value 188. Found: C, 76·1, 76·3; H, 12·7, 12·7%. The pressed *X*-ray spacings were Å. 52·11. Provisionally this is regarded as $C_{20}H_{40}O_2$ (Calc.: Acid value, 179; C, 76·9; H, 12·8%). (B) M. p. 53·4°. Found: C, 74·8, 75·0; H, 12·5, 12·4%. The pressed *X*-ray spacings = Å. 46·56. This is provisionally regarded as $C_{16}H_{32}O_2$ (Calc.: C, 75·0; H, 12·5%), but is probably contaminated with an acid of higher carbon content.

(4) The residue of esters which could not be distilled gave a

small quantity of an acid, fusing at 68° after repeated crystallisation from glacial acetic acid (Found : C, 76·9; H, 12·6%). It is probably an impure specimen of $C_{22}H_{44}O_2$ (Calc. : C, 77·6; H, 12·9%).

Acids similar to those just described have been isolated in larger quantities from the products of the oxidation of paraffin wax.

Inert Products of the Oxidation.—Following the method previously described (J., 1926, 2377), the non-acidic products of the oxidation were repeatedly crystallised from five times their weight of acetone, and thus separated into a relatively insoluble, white, crystalline mass, comprised chiefly of ketones and dioxy-products constituting together about 46% of the mixture, and a more soluble coloured mixture of more highly oxidised hydrocarbon, which was not further examined.

(i) The crystalline mixture fused at 58—59°. It was acetylated and the more soluble acetyl derivatives were separated by their greater solubility in acetone. The acetates were decomposed, and the resulting alcohol after purification fused at 69° (Found : C, 79·4; H, 13·5. Calc. for $C_{30}H_{60}O_2$: C, 79·6; H, 13·2%). It was either a ketonic alcohol or a dihydroxy-derivative, but the amount obtained was insufficient for further examination. The residual material, from which a certain part of the dioxy-substance had been separated, fused at 60—61° and contained C, 80·7; H, 14·2%. It was chiefly composed of ketones and dioxy-derivatives.

(ii) This mixture was treated with hydroxylamine, and the resulting oxime separated by its greater solubility in alcohol from the other substances present. The oxime itself could not be purified, but on saponification it gave a well-defined, crystalline ketone, m. p. 62·5° (Found : C, 82·0; H, 13·8. Calc. for $C_{30}H_{60}O$: C, 82·5; H, 13·7%).

Mr. Piper examined this specimen by *X*-rays and informed us that it contained 30 carbon atoms and, judging from the intensity distribution, the oxygen was situated most probably on the fourth carbon atom. (See J., 1926, 2381, for corresponding ketones with lower carbon content obtained from paraffin wax.)

Summary.

We have shown the striking similarity between the oxidation of synthetic triacontane, the mixture of solid *n*-hydrocarbons termed paraffin wax, and the pure constituents isolated from the latter. This similarity extends, not only to the velocity of oxidation, but to the nature and amounts of the products formed.

The highest acid present among the acidic products of the oxidation of triacontane has a carbon content of 26 atoms and appears to be identical with cerotic acid obtained from beeswax. This

acid fuses 10° lower than the corresponding synthetic acid, a phenomenon noticed with other acids obtained from paraffin wax, which will be discussed at a later date.

Support has been obtained for the view expressed previously (J., 1926, 2383) that in the oxidation of hydrocarbons such as triacontane the first product is a secondary alcohol, which then passes to a ketone. The latter has been isolated and found to have a carbon content of 30 atoms. *X*-Ray analysis indicates that the oxygen is situated on the fourth carbon atom; on further oxidation, the chain breaks, and the fact that a C_{26} acid results leads to the conclusion that the ketone has the structure

$$CH_3 \cdot [CH_2]_{24} \cdot CH_2 \cdot CO \cdot CH_2 \cdot CH_2 \cdot CH_3.$$

This view is also supported by the presence of succinic acid among the products of the reaction.

The amount of acids with high carbon content resulting from the oxidation of such long-chain hydrocarbons is always very small. Probably, simultaneously with the formation of the secondary alcohol followed by that of the ketone and their breakdown into acids, there occurs the further oxidation of the mono-oxy-derivative first formed to polyhydroxy-derivatives, which on further oxidation pass to ketones and then break down to acids and oxy-acids of still smaller carbon content.

Our thanks are due to the Colston Research Society for grants towards the expenses of this work.

UNIVERSITY OF BRISTOL. [*Received, June 1st,* 1927.]

CCXLV.—*The Isomeric Hydroxybenzyldimethylamines.*

By EDGAR STEDMAN.

A SEPARATE problem necessitated the synthesis of the isomeric hydroxybenzyldimethylamines, which was effected by treating the methoxybenzyl bromides with dimethylamine and hydrolysing the methoxybenzyldimethylamines so prepared with hydrobromic acid —a method similar to that employed by Tiffeneau (*Bull. Soc. chim.*, 1911, **9**, 825) for the preparation of the *p*-isomeride. Previous unsuccessful attempts had been made to prepare these phenols from the nitrobenzyl chlorides. Dimethylamine converted the latter into the nitrobenzyldimethylamines, which, on reduction, gave the aminobenzyldimethylamines. These underwent smooth diazotisation, but no phenol could be isolated from the tarry product obtained by decomposing the diazo-compound in hot aqueous solution.

In the interaction between *p*-nitrobenzyl chloride and dimethylamine, a considerable quantity of di-*p*-nitrobenzyldimethylammonium chloride was produced, whilst only insignificant amounts (if any) of such quaternary salts were formed from the *o*- and *m*-isomerides. Although the reactions were not carried out under the same conditions of concentration, this result agrees with the recent experiments of McCombie, Scarborough, and Smith (this vol., p. 802), who have shown that the velocity coefficient for the formation of quaternary salts from trimethylamine and the nitrobenzyl chlorides is greater in the case of the *p*- than of the *o*- and *m*-isomerides.

EXPERIMENTAL.

o-, m-, *and* p-*Hydroxybenzyldimethylamine.*—A solution of the methoxybenzylbromide in benzene was prepared by saturating a benzene solution of the methoxybenzyl alcohol with dry hydrogen bromide, drying it over anhydrous calcium bromide, and distilling off benzene until most of the excess hydrobromic acid had been removed (compare Lapworth and Shoesmith, J., 1922, **121**, 1391). Excess of a solution of dimethylamine in benzene was then added and after 24 hours the dimethylamine bromide which had separated was removed by filtration and the methoxybenzyldimethylamine extracted from the benzene solution with hydrochloric acid. Traces of benzene were removed from the acid solution by extraction with ether, and the base was liberated with sodium hydroxide and extracted with ether. Evaporation of the dried ethereal extract gave the methoxybenzyldimethylamine, which, after being distilled under diminished pressure, was converted into the hydroxybenzyldimethylamine by boiling with constant-boiling hydrobromic acid. In the case of the *m*-compound, 4 hours sufficed completely to hydrolyse the methoxy-group. The hydrobromic acid was removed by distillation under diminished pressure, the residue dissolved in water and made alkaline with sodium carbonate, and the phenol shaken out with ether. The product obtained on evaporation of the dried ethereal extract rapidly crystallised. In the case of the *o*- and *p*- compounds, the treatment with hydrobromic acid was continued for 10 hours. Nevertheless, hydrolysis was incomplete and considerable decomposition occurred with the *p*-isomeride. In both cases, the product left after removal of the hydrobromic acid was dissolved in water, and the solution was extracted with ether before and after being made alkaline with sodium hydroxide in order to remove impurities and unchanged methoxy-compound. It was then made slightly acid and the phenol was precipitated with sodium carbonate and shaken out with ether. Evaporation of the dried ethereal extract gave the phenols in fairly pure form.

m-*Methoxybenzyldimethylamine* is a colourless oil, b. p. 105°/13 mm. The *hydrochloride* crystallises from acetone–alcohol in tablets, m. p. 173° (Found: Cl, 17·6. $C_{10}H_{15}ON,HCl$ requires Cl, 17·6%).

m-*Hydroxybenzyldimethylamine* crystallises from benzene in prisms, m. p. 108°. The *hydrochloride* crystallises from alcohol in flat prisms, m. p. 173° (Found: Cl, 18·9. $C_9H_{13}ON,HCl$ requires Cl, 18·9%).

p-Methoxybenzyldimethylamine has b. p. 109°/13 mm. (compare Tiffeneau, *loc. cit.*). The *hydrochloride* crystallises from acetone in prisms, m. p. 152° (Found: Cl, 17·6%).

p-Hydroxybenzyldimethylamine (compare Tiffeneau) has m. p. 106°. The *hydrochloride* separates from alcohol in macroscopic prisms, m. p. 185° (Found: Cl, 18·7%).

o-*Methoxybenzyldimethylamine* is a colourless oil, b. p. 113°/20 mm. The *hydrochloride* is hygroscopic. After crystallisation from acetone, it has m. p. 149° (Found: Cl, 17·7%).

o-*Hydroxybenzyldimethylamine* is a colourless oil, b. p. 99—100°/12 mm. The *methiodide* crystallises from alcohol in prisms, m. p. 169° (Found: I, 43·1. $C_9H_{13}ON,CH_3I$ requires I, 43·35%).

o-*Nitrobenzyldimethylamine.*—An alcoholic solution of 30 g. of *o*-nitrobenzyl chloride was treated with dimethylamine (slightly more than 2 mols.) dissolved in the same solvent. After 3 days, the alcohol was evaporated, and the residue treated with water and sufficient hydrochloric acid to produce a clear solution. After extraction with ether to remove any unchanged nitrobenzyl chloride, the solution was made alkaline with sodium carbonate and the oil thus precipitated shaken out with ether. Evaporation of the dried ethereal extract left 29·1 g. of an oil. This was converted directly into the hydrochloride (yield 33 g.). When recrystallised from alcohol–acetone, the *hydrochloride* of o-*nitrobenzyldimethylamine* forms long, almost colourless prisms, m. p. about 221° (Found: Cl, 16·4. $C_9H_{12}O_2N_2,HCl$ requires Cl, 16·4%).

o-*Aminobenzyldimethylamine.*—The hydrochloride (10 g.) of *o*-nitrobenzyldimethylamine was mixed with 17 g. of granulated tin, and 70 g. of concentrated hydrochloric acid were added slowly in small portions, with efficient cooling. The solution was finally heated on the water-bath for 30 minutes and then cooled. The crystalline stannichloride which had separated was filtered off and decomposed in aqueous solution by hydrogen sulphide, the filtrate from the tin sulphide was boiled to expel the excess of hydrogen sulphide and made alkaline with sodium carbonate, and the oil thus precipitated was extracted with ether. Evaporation of the dried ethereal extract left 4 g. of a somewhat brown oil which slowly crystallised. (A further 1·6 g. was obtained by working up

the filtrate from the stannichloride in a similar manner.) This was distilled under diminished pressure; o-*aminobenzyldimethylamine*, b. p. 107°/14 mm., then passed over as a colourless oil which crystallised completely on cooling. The crystals had m. p. 36—37°. The *dihydrochloride* separates from alcohol in blunt prisms, m. p. 205° after sintering at 193° (Found: Cl, 31·7. $C_9H_{14}N_2,2HCl$ requires Cl, 31·8%).

Action of Dimethylamine on p-*Nitrobenzyl Chloride.*—A mixture of dimethylamine (slightly more than 2 mols.) and *p*-nitrobenzyl chloride (30 g.) in alcoholic solution was kept for 3 days. The alcohol was then evaporated, and the residual brown oil treated with water and sufficient hydrochloric acid to produce a clear solution. Ether extracted from this a small quantity of a red oil. Addition of sodium carbonate to the aqueous solution precipitated an oil which partly solidified. Extraction with ether removed the oil, but not the solid. On evaporation of the dried ethereal extract, an orange oil (20·8 g.) was obtained. This was converted directly into the hydrochloride, but only 14 g. could be obtained in solid form. The *hydrochloride* of *p*-nitrobenzyldimethylamine thus prepared crystallised from acetone–alcohol in faintly yellow plates, m. p. 188° (Found: Cl, 16·3. $C_9H_{12}O_2N_2,HCl$ requires Cl, 16·4%). The base was recovered from the oily residue from the preparation of the hydrochloride and divided into two portions, one of which was treated with methyl iodide. This yielded p-*nitrobenzyltrimethylammonium iodide*, which crystallised from alcohol in yellow, wedge-shaped prisms, m. p. 198° (Found: I, 39·1. $C_9H_{12}O_2N_2,CH_3I$ requires I, 39·4%). The second portion of the recovered base was treated with an alcoholic solution of oxalic acid; the *oxalate* of *p*-nitrobenzyldimethylamine was thus obtained, which separated from alcohol in lustrous, yellow plates, m. p. 155°. The identities of the oxalate and methiodide were established by recovering the base from the oxalate and converting separate portions into its methiodide and hydrochloride. The salts obtained were identical with those described above.

The above-mentioned solid which was not extractable with ether was filtered off (yield 8·8 g.) and recrystallised from alcohol; it then formed stout prisms, m. p. about 176°. Its behaviour was that of a quaternary chloride, for it was soluble in water and its aqueous solution contained ionic chlorine, but gave no precipitate on addition of alkalis. Analysis indicated that it was *di*-p-*nitrobenzyldimethylammonium chloride* (Found: Cl, 10·1. $C_{16}H_{18}O_4N_3Cl$ requires Cl, 9·8%).

p-Aminobenzyldimethylamine, prepared as in the case of the *m*-isomeride, has b. p. 133°/16 mm. (compare Friedländer and

Moszyc, *Ber.*, 1895, **28**, 1141). The *dihydrochloride* separates from alcohol in needles, m. p. 216° (Found: Cl, 31·7. $C_9H_{14}N_2,2HCl$ requires Cl, 31·8%).

m-*Nitrobenzyldimethylamine* was prepared from *m*-nitrobenzyl chloride (20 g.) and dimethylamine as in the case of the *o*-isomeride, 19·1 g. of a yellow oil being obtained. This was converted directly into the hydrochloride (yield 23 g.). When recrystallised from alcohol, the *hydrochloride* of *m*-nitrobenzyldimethylamine forms practically colourless, stout prisms, m. p. 230° (Found: Cl, 16·3. $C_9H_{12}O_2N_2,HCl$ requires Cl, 16·4%).

m-*Aminobenzyldimethylamine* was prepared by the method employed for the *o*-isomeride. 10 G. of the hydrochloride of the nitro-compound yielded a crystalline stannichloride which, on decomposition with hydrogen sulphide, gave 3 g. of the base. On distillation, it was obtained as a colourless oil, b. p. 129°/13 mm., which rapidly crystallised. The crystals had m. p. 46°. The *dihydrochloride* crystallised from alcohol in prisms, m. p. 225° after sintering at 210° (Found: Cl, 31·7. $C_9H_{14}N_2,2HCl$ requires Cl, 31·8%).

The expenses of this work, which was carried out during the tenure of a Carnegie Teaching Fellowship, have been met by grants from the Earl of Moray Research Fund of this University.

DEPARTMENT OF MEDICAL CHEMISTRY,
UNIVERSITY OF EDINBURGH. [*Received, June 1st*, 1927.]

CCXLVI.—*The Effect of Hydrochloric Acid on the Electrode Potential between Mercury and Mercurous Chloride.*

By SYDNEY RAYMOND CARTER, FREDERICK MEASHAM LEA, and ROBERT ANTHONY ROBINSON.

THE effect of hydrochloric acid on the electrode potential between mercury and calomel has been investigated by Sauer (*Z. physikal. Chem.*, 1904, **47**, 146), who worked with 0·1*N*- and 1·0*N*-solutions of hydrochloric acid. Measurements have also been made by Tolman and Ferguson (*J. Amer. Chem. Soc.*, 1912, **34**, 232), Ellis (*ibid.*, 1916, **38**, 737), and Linhart (*ibid.*, 1917, **39**, 2601), on cells of the type:

$$H_2|xN\text{-HCl, solid } Hg_2Cl_2|Hg$$

combined with a similar cell using *N*-hydrochloric acid, the whole forming a concentration cell without transport, reversible with respect to both the chlorine and the hydrogen ions.

Direct measurements of cells of the type :

$$Hg|Hg_2Cl_2,xN\text{-}HCl|N\text{-}HCl|N\text{-}KCl|N\text{-}KCl,Hg_2Cl_2|Hg$$

have now been carried out, a correction being applied for the diffusion potential across the boundary xN-HCl|N-HCl on the basis of some earlier results (Carter and Lea, J., 1925, **127**, 487). Measurements of this type have been employed to elucidate certain results which are described in the succeeding communication.

Construction of Cells.—Mercurous chloride was obtained in a state of purity, containing no mercuric chloride and only a trace of free mercury. The mercury used was purified both by electrolytic methods and by distillation. Cell solutions were prepared by grinding calomel, together with a little free mercury, into a paste with hydrochloric acid of a known concentration. The supernatant liquid was decanted repeatedly as in the construction of the normal calomel electrode. The electrode was of mercury, and upon this was placed a thin layer of calomel paste, the vessel being filled with hydrochloric acid solution saturated with calomel. The following chain of solutions was constructed :

$$\underset{\leftarrow E}{Hg|Hg_2Cl_2,xN\text{-}HCl}\,|\,\underset{\rightarrow \pi}{xN\text{-}HCl}\,|\,\underset{\rightarrow 0\cdot0288}{N\text{-}HCl}\,|\,N\text{-}KCl\,|\,N\text{-}KCl,\underset{\rightarrow 0\cdot560}{Hg_2Cl_2|Hg}$$

$$\leftarrow E_c$$

Special experiments were made in order to ascertain that the diffusion potentials were constant over a considerable period of time and were also reproducible. Several arrangements were tried, but the above was found to be the most satisfactory. Connexion between the solutions at A and B was made by means of inverted U-tubes filled with N-solutions of hydrochloric acid and potassium chloride, respectively, and plugged at both ends with wads of filter paper. The diffusion potential at B can be calculated on the basis of Henderson's formula (*Z. physikal. Chem.*, 1907, **59**, 118) to be 0·0288 volt. That at A has been measured (Carter and Lea, *loc. cit.*) for values of x greater than unity ; for values less than unity it may be calculated from the usual formula. Thus if E is the potential of the half-element, $Hg|Hg_2Cl_2,xN$-HCl, and E_c is the potential of the whole cell, then

$$E = E_c + \pi + 0{\cdot}0288 + 0{\cdot}560 \text{ volt.}$$

All measurements were made at 18°, and the observed *E.M.F.* is regarded as positive if the current flows through the cell from the normal calomel electrode towards the acid solution. An inert atmosphere of nitrogen was maintained in the cells during the experiments.

Results.

The results are given in Table I. The values given under the heading E (obs.) were obtained from the above equation by using the mean of the values given under E_c.

The potential between mercury and any solution in equilibrium with it is given by the equation:

$$E = E_0 + 0{\cdot}029 \log [Hg_2^{\cdot\cdot}] \quad . \quad . \quad . \quad . \quad (1)$$

Since the solution is saturated with respect to calomel, if the solubility product $[Hg_2^{\cdot\cdot}]\,[Cl']^2 = k_1$, then

$$E = E_0 + 0{\cdot}029 \log k_1/[Cl']^2 =$$

$$E_0 + 0{\cdot}029 \log k_1 - 0{\cdot}058 \log [Cl'] \quad . \quad . \quad (2)$$

or

$$E = E_0' - 0{\cdot}058 \log [Cl'] \quad . \quad . \quad . \quad . \quad (3)$$

The calculated values in the last two columns have been obtained from equation (3) by taking the observed value of $E = 0{\cdot}6687$ volt for $[HCl] = 0{\cdot}0106N$. In column 5, the chlorine-ion concentration has been deduced from conductivity–viscosity data for concentrations up to N-hydrochloric acid, whilst in column 6 it has been obtained from activity data (Lewis and Randall, "Thermodynamics," 1923, p. 336).

The agreement with the observed *E.M.F.* is satisfactory, but it should be pointed out that the agreement in the case of the activities cannot be regarded as an entirely independent proof, since the activity values have been derived primarily from potential measurements of cells which are virtually the same as those under consideration.

Effect of Mercuric Chloride on the Electrode Potential.—It was thought possible that mercuric chloride in presence of mercury might register a measurable potential. When such a cell was constructed from $0{\cdot}05N$-mercuric chloride in $3{\cdot}0N$-hydrochloric acid,

the usual grey film appeared on the surface of the mercury, and the *E.M.F.* measured showed wide fluctuations over several days, but tended towards the same value as the potential of the same cell containing calomel in 3·0*N*-hydrochloric acid. It was therefore concluded that the Hg–Hg$^{\cdot\cdot}$ potential is inaccessible.

The reduction of mercuric chloride by mercury is by no means rapid. Thus two solutions, each containing 13·576 g. of mercuric chloride per litre in 10*N*-hydrochloric acid, were found after 10 days' contact with mercury electrodes to contain 5·648 and 6·558 g. of mercuric chloride per litre, respectively. In more dilute solutions, the reduction is even slower; for instance, a solution of 0·05*M*-mercuric chloride in 7·6*N*-hydrochloric acid contained 12·90 and 12·32 g. of mercuric chloride per litre after 5 and 7 days' contact with mercury, respectively.

It is thus possible to have a considerable quantity of mercuric chloride in contact with mercury and calomel for a long time before equilibrium is reached, and it should therefore be possible to determine the effect of mercuric chloride on the electrode potential 2Hg–$Hg_2^{\cdot\cdot}$.

Cells were constructed containing 0·05*M*-mercuric chloride, in varying concentrations of hydrochloric acid saturated with calomel, in contact with mercury. In Table II E_c' is the *E.M.F.* of the cell

TABLE II.

containing 0·05*M*-mercuric chloride, and E_c that of the cell free from mercuric chloride. Both potentials represent that of the whole cell, including that of the normal calomel electrode. It will be seen that the effect of 0·05*M*-mercuric chloride on the *E.M.F.* is always small and is least in the higher concentrations of acid. The effect of mercuric chloride is to decrease the chlorine-ion concentration owing to the formation of complex ions, and from equation (2) it may be seen that this results in an increase in the *E.M.F.*

Potentials registered at an Inert Electrode.—Richards and Archibald (*Z. physikal. Chem.*, 1902, 40, 385) have shown that a definite equilibrium exists between the components of the system

$$Hg–Hg_2Cl_2–HgCl_2,$$

provided that the three are present together; the active masses of the first two are definite but beyond analytical detection, whilst the concentration of mercuric chloride in contact with mercury and

calomel has been determined and found to be dependent on the acid concentration. If, therefore, pure mercurous chloride is brought into contact with hydrochloric acid solution, it will not be in a state of equilibrium, but will tend to decompose with separation of metallic mercury and mercuric chloride, the process going on until the equilibrium concentration of mercuric chloride is reached. At this point, as the three components are in equilibrium, the three potentials $E_{2Hg\text{-}Hg_2^{\cdot\cdot}}$, $E_{Hg_2^{\cdot\cdot}\text{-}2Hg}$, and $E_{Hg\text{-}Hg^{\cdot\cdot}}$ will be equal, hence the electrode potential between a mercury electrode and the mercurous ions measured in the above series should be equal to the oxidation potential between mercurous and mercuric ions measured at an inert platinum electrode. Measurements of this nature have been carried out. By the use of hydrochloric acid solutions of 4·6*N*, 7·2*N*, and 10·0*N*, it was found that the potentials at a platinum electrode in a solution saturated with calomel and containing concentrations of mercuric chloride less than the equilibrium concentration were identical with the electrode potentials registered above. Moreover, the mercuric chloride concentration increased until it reached the equilibrium concentration. If, however, the initial mercuric chloride concentration was greater than this, then no further increase occurred, and, moreover, the potential registered —presumably the oxidation potential—was greater than the corresponding electrode potential. Since the oxidation potential is proportional to log [$HgCl_2$], any further increase in the mercuric chloride concentration beyond the equilibrium point will result in a continuous increase in the potential. Thus it was found (compare Fig. 1, following paper) that if the potential were plotted against log [$HgCl_2$], the curve obtained was a straight line parallel to the log [$HgCl_2$] axis for low values of [$HgCl_2$], but it exhibited a definite break at the [$HgCl_2$] value corresponding to the equilibrium point, and then rose sharply.

Table III gives a comparison between the values of the equilibrium concentrations of mercuric chloride which we observed (C., L., and R.) and the values found by Richards and Archibald (R. and A.).

TABLE III.

[HCl]	4·60	5·48	7·20	7·30	10·0*N*
[$HgCl_2$] (R. and A.)	—	0·0020	—	0·0025	0·0025*M*
[$HgCl_2$] (C., L., and R.).	0·0021	—	0·0021	—	0·0019*M*

Thus for [$HgCl_2$] values less than the equilibrium concentration the oxidation potential is less than the electrode potential and the latter is registered both at a mercury electrode and at an inert electrode. At the equilibrium point, they are equal to one another, and for higher concentrations of mercuric chloride the electrode

potential is registered at a mercury electrode and the higher oxidation potential at an inert platinum electrode.

In lower acid concentrations (0·01*N*—2·7*N*), this agreement could not be obtained. Richards and Archibald found that the equilibrium concentration of mercuric chloride in 1·0*N*- and 2·7*N*-hydrochloric acid was 0·00017*M* and 0·00076*M*, respectively. Cells constructed containing these concentrations of mercuric chloride were found to yield potentials against platinum electrodes which were, respectively, higher than the corresponding electrode potentials by 0·071 and 0·023 volt. It is probable, therefore, that in solutions which are dilute with respect to both the acid and the mercuric chloride the potential registered at the platinum electrode does not represent the true reversible oxidation potential. It was found that the same potential was registered whether the electrodes were platinised or not. Moreover, the presence of a single platinum electrode did not alter the equilibrium concentration of mercuric chloride which at 18° in *N*-hydrochloric acid was at 0·00022*M*-mercuric chloride. If, however, several electrodes (*e.g.*, four) were placed in the mixture of solution and calomel, an increase in the mercuric chloride concentration to 0·00050*M* occurred, together with the corresponding increase in potential. These phenomena are somewhat obscure and render the measurement of oxidation potentials in very dilute mercuric chloride and hydrochloric acid solutions somewhat uncertain and difficult to interpret.

Summary.

The effect of hydrochloric acid on the electrode potential between mercury and mercurous chloride in hydrochloric acid solution has been investigated over a range of acid concentration from 0·0027*N* to 10·0*N*.

Under the conditions of these experiments, the potential Hg–$Hg^{\cdot\cdot}$ was inaccessible, and the effect of mercuric chloride on the above electrode potential was small.

The equilibrium of the system Hg–Hg_2Cl_2–$HgCl_2$ has been studied in relation to the work of Richards and Archibald, and the potentials registered by this system of platinum electrodes have been described.

The authors desire to express their thanks to the Advisory Council of the Department of Scientific and Industrial Research for grants to two of them (F. M. L. and R. A. R.) which have enabled this research to be carried out.

[*Received, April 2nd*, 1927.]

CCXLVII.—*The Oxidation-Reduction Potentials of Mercurous and Mercuric Chlorides in Hydrochloric Acid Solution.*

By SYDNEY RAYMOND CARTER and ROBERT ANTHONY ROBINSON.

LITTLE attention has hitherto been devoted to the oxidation-reduction potentials of the chlorides of mercury. Although Drucker (*Z. physikal. Chem.*, 1901, **36**, 195; *Z. Elektrochem.*, 1912, **18**, 236) and Baur (*Z. physikal. Chem.*, 1908, **63**, 687) have made a few measurements in potassium chloride solution, a further investigation of the potentials in hydrochloric acid solution is desirable in view of the complicated behaviour of mercury halides in the presence of halogen acids, and also of the recent investigations of Stewart and Wardlaw (J., 1922, **121**, 1481) on the action of sulphur dioxide on these two chlorides which can be correlated with the electrochemical properties of these systems.

EXPERIMENTAL.

Preliminary experiments indicated that it would be a matter of considerable difficulty to obtain steady reproducible potentials corresponding with the oxidation process $Hg_2^{\cdot\cdot} \longrightarrow 2Hg^{\cdot\cdot}$. In the first place, it was found that a 0·1*M*-solution of mercuric chloride saturated with calomel and containing no acid had so low a conductivity that potential measurements were impossible. Secondly, in solutions of 0·1*N*-hydrochloric acid saturated with calomel and containing mercuric chloride, it was found that no agreement could be obtained between the potentials registered at platinised platinum electrodes; moreover, the potential varied widely with time. In a similar solution containing 0·0005*M*-mercuric chloride, a large fall in potential was observed over several days, but after this a reading was obtained which was fairly constant and almost equal to the electrode potential of mercury and calomel in 0·1*N*-hydrochloric acid. Since the electrodes had become covered with a grey deposit of mercury, it was concluded that an electrode and not an oxidation potential was being measured.

A number of similar experiments were performed with the same result. Shaking the calomel with the solution of hydrochloric acid and mercuric chloride for 12 hours did not give a more constant potential reading. It was noticed, however, that if the electrodes were completely buried to a considerable depth in a paste of calomel instead of being suspended in the solution, and if the dissolved air in the solution were removed by means of a current of purified nitrogen, it was possible to obtain potentials which gave good

agreement between different electrodes over considerable periods of time and were reproducible. Moreover, they were distinct from the electrode potentials described in the preceding paper. The necessity for the complete immersion of the electrodes is probably due to the low concentration of mercurous ions, the passage of a very small current in the course of potential measurements being sufficient to exhaust the supply of mercurous ions in the vicinity of the electrode if this is simply suspended in the solution. Complete immersion of the electrode in the paste ensures full saturation in its vicinity.

Cells of the following type were constructed:

$$\mathrm{Pt}\left|\begin{matrix}\mathrm{Hg_2Cl_2}\\ x\mathit{M}\text{-}\mathrm{HgCl_2}\\ y\mathit{N}\text{-HCl}\end{matrix}\right|y\mathit{N}\text{-HCl}\left|\mathit{N}\text{-HCl}\right|\mathit{N}\text{-KCl}\left|\mathit{N}\text{-KCl},\mathrm{Hg_2Cl_2}\right|\mathrm{Hg}.$$

The chain of intermediate solutions has been shown to be sufficient to maintain constant reproducible diffusion junctions (Carter and Lea, J., 1925, **127**, 487; Carter, Lea, and Robinson, preceding paper), and possesses the advantage that the potential at each junction can be determined with the necessary degree of accuracy. The system differs from the previously investigated systems of iron and copper salts (Carter and Clews, J., 1924, **125**, 1880; Carter and Lea, J., 1925, **127**, 499) in that only the mercuric chloride and the hydrochloric acid concentrations in the oxidation cell can be subjected to variation, since the calomel cannot be varied in concentration owing to its low solubility. It is essential, however, to maintain the solution saturated with respect to the calomel in order to obtain a defined system.

The oxidation cell consisted of a glass vessel containing a solution of mercuric chloride and hydrochloric acid in the requisite proportion and saturated with respect to calomel. Experiments showed that platinisation of the electrodes did not increase their sensitivity, nor was the shape or form of the electrodes a factor influencing the potential readings. Three electrodes of polished platinum foil (about 1 sq. cm. in area) were actually employed.

Measurements of each of the cells were carried out, in general, over a period of a week, a lapse of 12—24 hours after construction being necessary before a constant potential was registered. Renewal of the liquid boundaries during this period showed that no appreciable change had occurred in the diffusion potentials. All potentials are referred to the absolute scale. A positive sign indicates that the current flows through the cell from the calomel electrode to the oxidation element. All measurements were made at 18°. Concentrations of mercuric chloride are given as g.-mols. per litre.

Potential Measurements.—If E is the potential of the oxidation element, π the diffusion potential between xN- and N-hydrochloric acid (Carter and Lea, *loc. cit.*), 0·0288 volt the diffusion potential between N-hydrochloric acid and N-potassium chloride (calculated on the basis of Henderson's formula, *Z. physikal. Chem.*, 1907, **59**, 118), and E_c the potential of the whole cell, then:

$$E = E_c + \pi + 0{\cdot}0288 + 0{\cdot}560 \text{ volt.}$$

The values for one experiment given in Table I are typical of the degree of accuracy attained.

TABLE I.

Cell made up as: $[HCl] = 1{\cdot}00N$, $[HgCl_2] = 0{\cdot}75M$.
Final composition by analysis: $[HCl] = 0{\cdot}96N$, $[HgCl_2] = 0{\cdot}735M$.

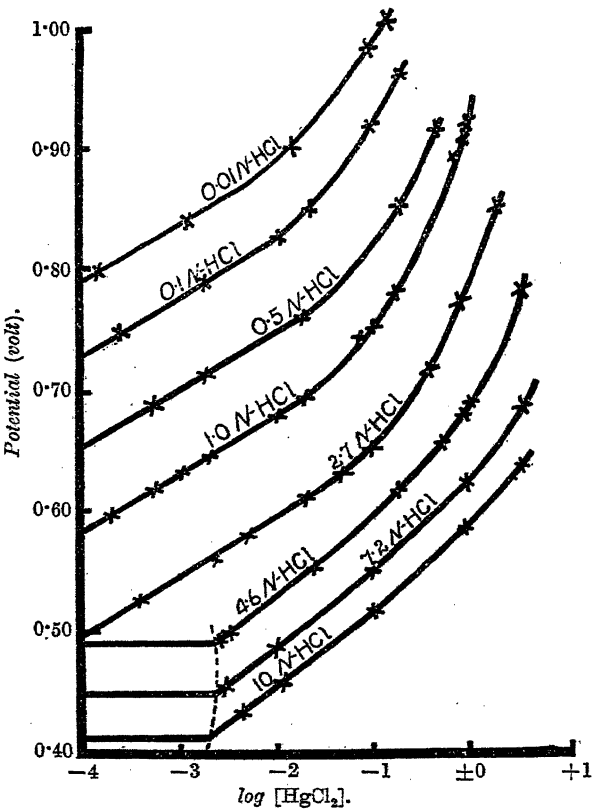
* Cell No. 19 contained four electrodes, two of polished platinum foil and two of platinised platinum foil. They all gave identical results.

Variation of Potential with Concentration of Mercuric Chloride.—In Fig. 1 the potential of the oxidation element is plotted against the

logarithm of the mercuric chloride concentration, for each acid concentration. According to the equation:



$$E = E_0 + 0{\cdot}029 \log [Hg^{\cdot\cdot}]^2/[Hg_2^{\cdot\cdot}] \quad . \quad . \quad . \quad (1)$$

since $$[Hg^{\cdot\cdot}] = k_2[HgCl_2]/[Cl']^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

and $$[Hg_2^{\cdot\cdot}] = k_1/[Cl']^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

therefore $$E = E_0 + 0{\cdot}029 \log k_2^2[HgCl_2]^2/k_1[Cl']^2 \quad . \quad . \quad (4)$$

FIG. 1.

It follows that for a given acid concentration, the mercurous-ion concentration is constant, whilst the mercuric-ion concentration will be proportional to $[HgCl_2]$ since the feeble ionisation of mercuric chloride renders its contribution to the chlorine-ion concentration negligible.

Hence $$E = E_0' + 0{\cdot}058 \log [HgCl_2] \quad . \quad . \quad . \quad . \quad (5)$$

or the *E.M.F.* is a linear function of the logarithm of the mercuric chloride concentration.

From the graph, it will be seen that the logarithmic law holds in the more dilute solutions of mercuric chloride, but breaks down when the concentrations of mercuric chloride and hydrochloric acid are of the same order. It is noteworthy that in place of the theoretical slope of 0·058 volt for a ten-fold dilution, we obtained slopes of 0·060 volt in the 4·6*N*-, 7·2*N*-, and 10·0*N*-hydrochloric acid solutions, and of 0·047 volt in the lower acid concentrations. The discrepancy in the former case is not serious, but in the latter case is beyond the range of experimental error, and up to the present we have not been able to account for it.

To explain the deviations from the logarithmic law in the more concentrated mercuric chloride solutions, complex-ion formation may be assumed. Complex-ion formation between calomel and hydrochloric acid is unlikely, as calomel is known to form only a few double salts. Sherrill (*Z. physikal. Chem.*, 1903, **43**, 705; 1904, **47**, 103) and Noyes and Le Blanc (*Z. physikal. Chem.*, 1890, **6**, 389) have brought forward evidence in favour of the existence of the ion $HgCl_4''$, whilst Sand and Breest (*Z. physikal. Chem.*, 1907, **59**, 424) and Drucker (*Z. Elektrochem.*, 1912, **18**, 236) consider that the ion has the formula $HgCl_3'$. As the percentage of mercuric chloride in the form of complex ions is high, it may be seen from the equations $HgCl_2 + 2Cl' = HgCl_4''$ and $HgCl_2 + Cl' = HgCl_3'$ that when the mercuric chloride is present in the same concentration as the acid, a considerable decrease in the acid concentration must occur in order to allow the formation of these complex ions, and hence, according to equation (4), the potential of the cell will be increased. Quantitatively the behaviour of the system is given by equation (4) and an equation determining the equilibrium of the complex ion. According to Sherrill,

$$[HgCl_4'']/[HgCl_2][Cl']^2 = 70 \quad . \quad . \quad . \quad . \quad (6)$$

whilst according to Sand and Breest (if the value of the constant as recalculated by Drucker be used),

$$[HgCl_3']/[HgCl_2][Cl'] = 11{\cdot}5 \quad . \quad . \quad . \quad . \quad (7)$$

These two views have been reconciled by Linhart (*J. Amer. Chem. Soc.*, 1915, **37**, 258; 1916, **38**, 1272) who considers that both the ions $HgCl_3'$ and $HgCl_4''$ are present in solution [together with small quantities of polymerised mercuric chloride, $(HgCl_2)_2$, and the complex ions Hg_2Cl_5 and Hg_2Cl_6''], the equilibrium conditions being given by the equations:

$$[HgCl_3']/[HgCl_2][Cl'] = 9{\cdot}8 \quad . \quad . \quad . \quad . \quad (8)$$

$$[HgCl_4'']/[HgCl_3'][Cl'] = 4{\cdot}9 \quad . \quad . \quad . \quad . \quad (9)$$

and therefore $$[HgCl_4'']/[HgCl_2][Cl']^2 = 48 \quad . \quad . \quad . \quad . \quad (10)$$

From equation (9) it follows that in N-hydrochloric acid solution the complex ion $HgCl_4''$ is predominant, but in 0·01 N-acid solution the $HgCl_3'$ ion is the main constituent, whilst in 0·1N- and 0·5N-acid both ions are present in comparable amounts. We may therefore, as an approximation, apply equation (10) to solutions of mercuric chloride in N-hydrochloric acid. It is difficult to solve this equation to give the amounts of free unbound mercuric chloride in equilibrium with free acid and complex ion, but it is easy to proceed in the reverse manner. Thus, for any given total acid concentration [HCl], if an arbitrary value of the concentration of complex ion $[HgCl_4'']$ be assumed, it follows that the concentration of the free acid is $\{[HCl]-2[HgCl_4'']\}$, and hence the concentration of chlorine ion is $\{[HCl]-2[HgCl_4'']\}\gamma$, where γ is the activity coefficient corresponding with the concentration of the free hydrochloric acid. Hence by substitution in equation (6) we can determine the concentration of free mercuric chloride. The sum of free and combined mercuric chloride gives the total concentration of mercuric chloride, since that of the $Hg^{\cdot\cdot}$ and $HgCl^{\cdot}$ ions is negligible. The concentrations of free mercuric chloride and of chlorine ions may now be substituted in equation (4), together with the values of the constants $E = 1{\cdot}190$ volt, $k_1 = 3{\cdot}5 \times 10^{-18}$, and $k_2 = 10^{-14}$, to give a calculated value of the $E.M.F.$ corresponding with given values of [HCl] and total mercuric chloride.

Hence we obtain Table III, which gives the calculated values of the potential corresponding to different total concentrations of mercuric chloride in N-hydrochloric acid on the assumption that $HgCl_4''$ ions are formed.

TABLE III.

$[HCl] = 1{\cdot}0N$.

$[HgCl_4'']$.	Free [HCl].	γ.	[Cl'].	Free $[HgCl_2]$.	Total $[HgCl_2]$.	E (calc.).	E (obs.).
0·40	0·2	0·783	0·157	0·338	0·738	0·903	0·883
0·30	0·4	0·763	0·305	0·0672	0·367	0·846	0·825
0·10	0·8	0·796	0·637	0·00513	0·105	0·763	0·752
0·05	0·9	0·811	0·730	0·00195	0·0520	0·735	0·722
0·01	0·98	0·821	0·805	0·000322	0·0103	0·687	0·680

It will be seen that the considerable deviations from the logarithmic law that occur in concentrated solutions of mercuric chloride can be accounted for by assuming the existence of the ion $HgCl_4''$. If it is borne in mind that the values of k_1 and k_2 given above are strictly applicable only at 25° and not at 18°, that there are polymerised molecules $(HgCl_2)_2$, which give rise to Hg_2Cl_5' and Hg_2Cl_6'' ions, also present in solution, and moreover, that the formation of the complex ion $HgCl_4''$ causes a considerable reduction in the chlorine-ion concentration in the more concentrated mercuric chloride solutions,

which in turn favours the formation of $HgCl_3'$ ions, it will be seen that the method can only be expected to yield an approximation to the observed values of the potentials. However, the agreement is sufficient to show that the observed potentials can be accounted for on the basis of complex-ion formation.

Since in 0·1*N*- and 0·5*N*-hydrochloric acid both $HgCl_3'$ and $HgCl_4''$ ions are present to about the same extent, it is difficult to calculate the distribution of mercuric chloride between the various complex ions and to obtain calculated values of the potentials in these dilute acid solutions.

In the case of the three highest concentrations of acid, the portions of the curves parallel to the log $[HgCl_2]$ axis represent the potentials registered in solutions in which the mercuric chloride concentration is not high enough for equilibrium between Hg–Hg_2Cl_2–$HgCl_2$ to obtain. Under these conditions it was found that an oxidation potential was not registered, since it was independent of the mercuric chloride concentration, but a potential identical with the electrode potential of mercury and calomel described in the previous paper, and the data for the latter were used for plotting the horizontal portions of the curves. Such systems were found to be unstable since mercurous chloride decomposed into mercury and mercuric chloride until the concentration of the latter corresponded with the equilibrium value for the acid concentration under consideration.

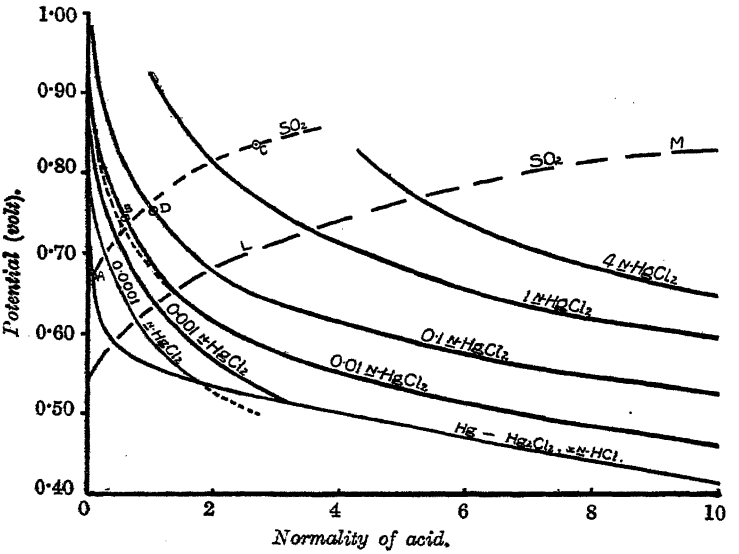
Variation of Potential with Acid Concentration.—By drawing a line perpendicular to the abscissa and cutting it at the desired value of the mercuric chloride concentrations, we have read off from the curves in Fig. 1 the values of the potential of a cell in which the mercuric chloride concentration is constant and the hydrochloric acid concentration is varied between 0·01*N* and 10*N*. This has been done for five values of the former, namely, 1·0, 0·1, 0·01, 0·001, and 0·0001*N*. The results are in Table IV.

TABLE IV.

	$[HgCl_2]$, *M*.					
[HCl].	0·0001	0·001	0·01	0·1	1·0	4·0.
	Potential (volt).					
0·01	0·7910	0·8375	0·8885	0·9820	—	—
0·10	0·7295	0·7775	0·8260	0·9130	—	—
0·5	0·6530	0·7005	0·7475	0·8155	—	—
1·0	0·5840	0·6325	0·6795	0·7500	0·9110	—
2·7	0·4960	0·5455	0·5960	0·6550	0·7850	—
4·6	—	—	0·5305	0·5945	0·6860	0·7960
7·2	—	—	0·4890	0·5500	0·6240	0·6925
10·0	—	—	0·4560	0·5180	0·5875	0·6400

These results have been plotted in Fig. 2, which shows the relation between potential and hydrochloric acid concentration. This graph

also contains the curve of the electrode potential $2Hg$–$Hg_2^{\cdot\cdot}$ against acid concentration, based upon data given in the preceding paper.



On the assumption that the ions $HgCl_3'$ and $HgCl_4''$ are formed according to equations (8) and (10), and since

$$[HgCl_4''] + [HgCl_3'] + [HgCl_2] = [HgCl_2]_{total}$$

then $$[HgCl_2]_{total} = [HgCl_2]\{1 + 9{\cdot}8[Cl'] + 48[Cl']^2\}$$

or $$[HgCl_2] = [HgCl_2]_{total}/\{1 + 9{\cdot}8[Cl'] + 48[Cl']^2\}.$$

FIG. 2.

Hence from equation (4)

$$E = E_0 + 0{\cdot}029 \log k_2^2/k_1 + 0{\cdot}058 \log [HgCl_2]_{total} / [Cl']\{1 + 9{\cdot}8[Cl'] + 48[Cl']^2\}$$

or $$E = E_0 + 0{\cdot}029 \log k_2^2/k_1 + 0{\cdot}058 \log [HgCl_2]_{total} - 0{\cdot}058 \log [Cl']\{1 + 9{\cdot}8[Cl'] + 48[Cl']^2\}.$$

In 0·01*M*-mercuric chloride, as the concentration of this salt is so low that the formation of these complex ions does not affect the concentration of acid appreciably, then for a constant value of $[HgCl_2]_{total}$ values of E corresponding to different concentrations of hydrochloric acid may be calculated.

In Fig. 2, the dotted curve indicates the potentials calculated in this manner, compared with the observed potentials, which are indicated by a continuous line. It is evident that good agreement has been obtained for concentrations of hydrochloric acid between 0·01*N* and 1·0*N*; for higher concentrations, however, the calculated

potentials decrease much more rapidly than the observed. It is difficult to account for this behaviour, partly because the activities of the different complex ions may vary in an unknown manner in concentrated acid solution, partly because the actual nature of these ions is unknown, and partly because the complex acids may not be completely dissociated. It may be pointed out, however, that in the most concentrated acid solutions the oxidation potential varies in the same way as the $Hg|Hg_2Cl_2,xN\text{-}HCl$ potential, *i.e.*, it is proportional to $-0{\cdot}058 \log [Cl']$, the chlorine-ion concentration being calculated on the basis of activity data. This indicates that the system is behaving as if complex-ion formation ceased in the high acid concentrations and as if it conformed to its normal behaviour according to equation (4). Although there is no theoretical reason for this supposition, it is interesting to notice that Richards and Archibald (*Z. physikal. Chem.*, 1902, **40**, 385; compare preceding paper) found that the amount of mercuric chloride in equilibrium with mercury and calomel was independent of the acid concentration provided this was above $5N$. As almost all the mercuric chloride is present as complex ion, this is equivalent to saying that above $5N$-hydrochloric acid complex-ion formation is not increased by increasing the acid concentration.

The Action of Sulphur Dioxide on the Chlorides of Mercury.—In Fig. 2, we have indicated the variation of the oxidation–reduction potential of sulphur dioxide by the curve LM (Carter and James, J., 1924, **125**, 2234). Stewart and Wardlaw (*loc. cit.*) have studied the action of sulphur dioxide on the two chlorides of mercury, and in considering their results we have been guided by the principle that the system possessing the higher potential will oxidise the other system, being itself reduced.

The various reactions between mercury salts, hydrochloric acid, and sulphur dioxide were found to be extremely sensitive to small changes in acid concentration, and this is in agreement with the steepness of the potential curves, particularly in the region of low acid concentration.

(a) *Action of sulphur dioxide on calomel.* At 95°, Stewart and Wardlaw found that sulphur dioxide acted on calomel suspended in hydrochloric acid, in four ways, depending on the concentration of acid:

(1) $8N$- to $2N$-acid. Oxidation of calomel to mercuric chloride occurs, being complete only in the most concentrated acid and slight in $2N$-acid.

(2) $2N$- to $0{\cdot}16N$-acid. Decomposition of calomel and darkening of the solution, according to the equation: $Hg_2Cl_2 \longrightarrow Hg + HgCl_2$. We have confirmed the fact that this reaction is independent of the

sulphur dioxide; moreover, it ceases at approximately 0·16*N*-acid, because calomel could be boiled for several hours in 0·10*N*-acid without the slightest darkening.

(3) 0·16*N*- to 0·07*N*-acid. Inert region—calomel unaffected.

(4) 0·02*N*- to zero acid. Calomel is reduced to mercury by sulphur dioxide.

According to our graph, for acid concentrations between zero and 0·2*N*, the sulphur dioxide potential is lower than the $Hg–Hg_2Cl_2$ potential and hence reduction of the calomel is to be expected corresponding to (4).

Between 0·2*N*- and *N*-hydrochloric acid, it is to be expected that the oxidising action of sulphur dioxide on calomel will be slight, because the amount of mercuric chloride that must be formed to raise the oxidation potential as high as the sulphur dioxide potential is very small. Observation in this region is hindered by the fact that simultaneous decomposition of the calomel occurs into mercury and mercuric chloride. Above 2*N*-acid the oxidation of calomel becomes considerable and, according to our graph, should proceed almost to completion. It seems probable that equilibrium was not attained in all the experiments of Stewart and Wardlaw.

The point A on Fig. 2 represents the point on the $Hg–Hg_2Cl_2$ electrode potential curve (at 0·02*N*-HCl) where it intersects the sulphur dioxide curve.

(b) *Action of sulphur dioxide on mercuric chloride.* Stewart and Wardlaw found that if sulphur dioxide was passed for 12 hours through a solution of mercuric chloride in 0·48*N*-hydrochloric acid at 95°, calomel was formed, the amount decreasing with lowering of the mercuric chloride concentration, so that when $[HgCl_2] = 0·0094M$ the amount of calomel formed by reduction was very small. It therefore follows that the oxidation potential of sulphur dioxide in acid of this concentration is less than the oxidation of the mercury system when $[HgCl_2]$ is greater than 0·0094*M*, and greater than the oxidation potential when $[HgCl_2]$ is less than 0·0094*M*. This gives the point B in Fig. 2.

In 2·64*N*-hydrochloric acid, Stewart and Wardlaw found that mercuric chloride was not reduced until its concentration reached 1·92*M*. This gives the point C. In 1·0*N*-acid, the extent of reduction was very small when $[HgCl_2] = 0·1M$. This is the point D.

It will be seen that the line AC drawn through these four points gives a curve for the oxidation potential of sulphur dioxide which is similar in form to the curve LM based on direct potential measurements, but it is displaced upwards by about 0·2 volt. The discrepancy may be partly attributed to the different temperatures at

which our experiments and those of Stewart and Wardlaw were carried out, *viz.*, 18° and 95°, respectively.

Summary.

The conditions necessary for obtaining reproducible oxidation potentials of mercurous and mercuric chlorides in hydrochloric acid solution at 18° have been examined. The influence on potential of various concentrations of both the mercuric chloride and the hydrochloric acid has been determined over a wide range.

The departures from the logarithmic law that have been observed have been attributed to a large extent to the formation of complex ions.

Evidence has been adduced in favour of the existence of complex ions, especially $HgCl_4''$, in hydrochloric acid solutions of mercuric chloride.

The abnormal effect of hydrochloric acid stronger than 5*N* on the complex-ion formation, noticed by Richards and Archibald, has been confirmed.

The reactions of sulphur dioxide on the chlorides of mercury have been studied in the light of the electrochemistry of these systems.

The authors desire to express their thanks to the Advisory Council of the Department of Scientific and Industrial Research for a grant to one of them (R. A. R.) which has enabled this research to be carried out.

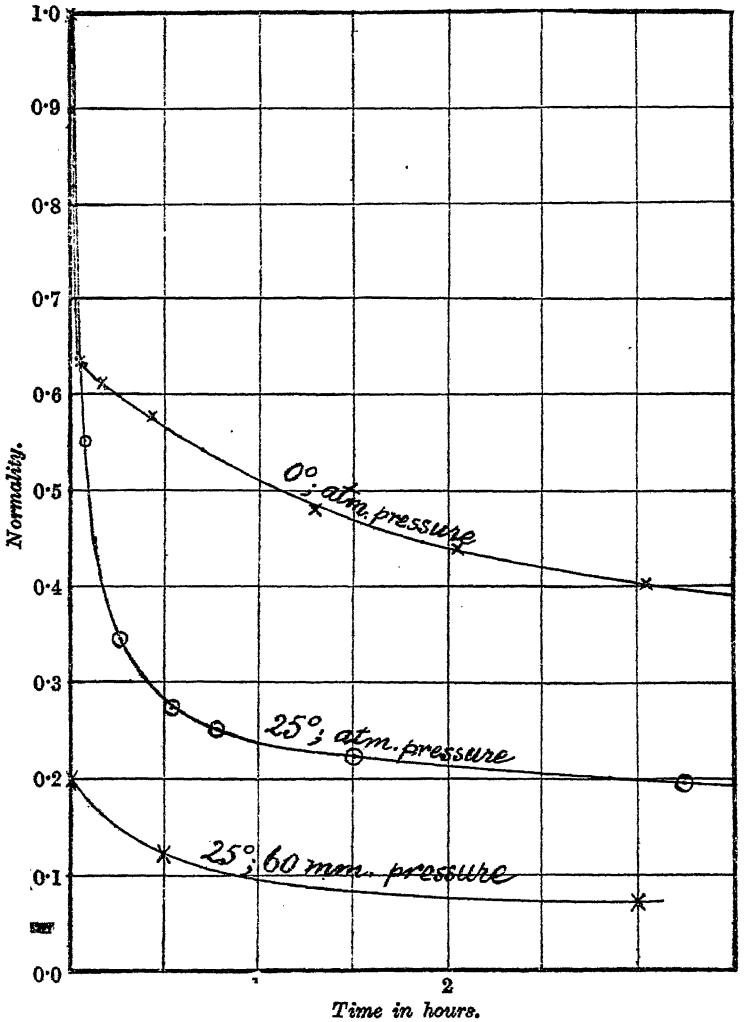
CCXLVIII.—*The Decomposition of Nitrous Acid in Aqueous Solution.*

By THOMAS WESTON JOHNS TAYLOR, ERNEST WILLIAM WIGNALL, and JOHN FREDERICK COWLEY.

THE decomposition of nitrous acid in aqueous solution is a complex phenomenon. The more important facts already known can be summarised as follows: (1) In contact with air, there is a certain amount of oxidation; if an inert gas replaces air, the reaction $3HNO_2 \longrightarrow HNO_3 + 2NO + H_2O$ takes place (Montemartini, *Atti R. Accad. Lincei*, Rendiconti, 1890, **6**, ii, 263). (2) The rate of decomposition follows approximately a unimolecular law, in contact either with air (Ray, Dey, and Ghosh, J., 1917, **111**, 413) or with carbon dioxide (Montemartini, *loc. cit.*). (3) The rate is reduced by adding nitric oxide to the gas above the solution, and is slower

the greater the pressure of nitric oxide (Montemartini, *loc. cit.*; Klemenc and Pollak, *Z. physikal. Chem.*, 1922, **101**, 150). (4) The rate is much increased by bubbling an inert gas through the solution (Knox and Reid, *J. Soc. Chem. Ind.*, 1919, **38**, 105T) and apparently reaches no limit as the speed of bubbling is increased (Klemenc and Pollak, *loc. cit.*). (5) The reaction is reversible (Veley, *Chem. News*, 1892, **66**, 175), but the reverse reaction proceeds extremely slowly with dilute solutions of nitric acid (Saposhnikov, *J. Russ. Phys. Chem. Soc.*, 1900, **32**, 375; 1901, **33**, 306).



In an attempt to find conditions under which solutions of nitrous acid would be sufficiently stable for investigation of its reactions, the effect of reducing the area of surface of the solution in contact with the gas phase was tried. This can be done most simply by floating a layer of an immiscible liquid on the top of the solution; most liquids which might be used, however, such as benzene or ligroin, dissolve nitrogen trioxide from fairly strong solutions of nitrous acid, but the solubility of the trioxide is smaller in the mixture of higher paraffins sold as "medicinal paraffin," and this liquid has the added advantage that its high viscosity makes it possible to stir the lower aqueous layer without breaking up the paraffin layer.

Dilute solutions of nitrous acid prepared beneath a layer of this paraffin from a solution of pure barium nitrite (Witt and Ludwig, *Ber.*, 1903, **36**, 4384) and the equivalent of dilute sulphuric acid, and thus containing barium sulphate in suspension, are considerably more stable than similar solutions under nitrogen and very much more stable than those in contact with air. For example, equal volumes of a solution in identical vessels were kept at 25°, the one under paraffin and the other in contact with air; after 3 hours, the first showed 5% decomposition and the second 53%. Quite dilute solutions, *i.e.*, 0·1*N* and less, could be kept at 0° for 5 hours without the decomposition exceeding 4%. The solutions were stirred during these experiments by a small stirrer passing through the paraffin, but not at such a rate as to draw gas bubbles into the solution; the concentration of acid was determined by Veley's method (*Proc. Roy. Soc.*, 1893, *A*, **52**, 28).

When stronger solutions were investigated under paraffin, it was found that critical concentrations existed above which the rate of decomposition was very rapid and below which it was much slower. The critical concentration depends on the temperature, being higher the lower the temperature, and on the pressure of air above the paraffin, increasing with the pressure. Fig. 1 shows the rate of decomposition in two solutions, originally of *N* concentration, at 25° and at 0°, and also the effect at 25° of reducing to 60 mm. the pressure above a 0·2*N*-solution, *i.e.*, one which at atmospheric

pressure would decompose but slowly. Ray, Dey, and Ghosh (*loc. cit.*) noted this critical phenomenon and could not obtain a solution stronger than 0·185*N* which did not evolve nitric oxide rapidly when at 0° and in contact with air.

FIG. 1.

The velocity of the "slow" reaction at 25° was measured, and the results of any one experiment roughly agreed with the unimolecular law, although the velocity coefficient slowly decreased as the reaction proceeded; but the reaction is in no sense truly uni-

molecular—even well below the critical concentration the value of the velocity coefficient depends on the initial concentration and on the shape of the vessel in which the solution is kept, and thus has no absolute significance.

The velocity of the reaction under paraffin is also influenced by the presence of other substances in the solution; in 5*N*-sulphuric acid it is markedly smaller, and in 7*N*-acid smaller still. This result disagrees with that found by Klemenc and Pollak, who used solutions through which nitrogen was bubbling, but agrees with that of Knox and Reid (*loc. cit.*), whose solutions were in contact with air. The velocity is also much reduced by the presence of sodium sulphate, which at 0·65*M* concentration has an effect equivalent to 5*N*-sulphuric acid.

The presence of barium sulphate in suspension during these experiments had no appreciable influence on the stability of the acid, since similar experiments were carried out using nitrous acid prepared from pure sodium nitrite (Divers, J., 1899, **75**, 80) and sulphuric acid, and the rates of decomposition were those to be expected from the previous experiments, account being taken of the effect of the sodium sulphate.

These results show that, by using paraffin and sodium sulphate, solutions of nitrous acid the strengths of which do not exceed certain maximum values (0·4*N* at 0° and 0·2*N* at 25°, at atmospheric pressure) can be conveniently stabilised to a considerable extent. The complicated character of the decomposition has, however, not yet been satisfactorily explained. Klemenc and Pollak advance the improbable hypothesis that nitrous acid spontaneously breaks up into nitric oxide and the hydroxyl radical, and attribute its existence in solution to mutual action between molecules of the acid and of the solvent; they suggest that the rate of decomposition depends upon the rate of escape of nitric oxide from the solution. This, although accounting for the sensitiveness of a solution to its method of treatment, scarcely accounts for the sudden change in rate of decomposition shown in the figure.

The fact that the reaction is reversible does not come into play, because of the extremely slow rate of the reverse reaction at the dilutions investigated [see (5), p. 1924]. The critical phenomenon and its dependence on temperature and pressure must arise from the existence of some kind of equilibrium in which one of the substances involved is a gas of limited solubility in water; this equilibrium must be established with great rapidity to account for the observations of Klemenc and Pollak [(4), p. 1924].

The view advanced here is that in a solution of nitrous acid the equilibrium $2HNO_2 \rightleftharpoons N_2O_3 + H_2O$ is set up, and that the com-

plicated nature of the decomposition arises from the behaviour of the anhydride; that this latter exists in solution is supported by the observations of Saposhnikov (*loc. cit.*) on the ease with which organic solvents will dissolve it from solutions of the acid. It is not the anhydride itself which escapes as gas from the solution, for, if this were so, the solution would contain eventually less nitric acid than the quantity corresponding to the equation of decomposition [(1), p. 1923], and experiment showed that in every case under paraffin the theoretical amount of nitric acid remained. If, however, the further equilibrium $N_2O_3 \rightleftharpoons NO + NO_2$ tends to be set up in solution, the facts receive an intelligible explanation. In a completely stable solution, the concentration of water being assumed to be constant, the function $[NO][NO_2]/[HNO_2]^2$ would have a fixed value at any one temperature; but the concentration of nitric oxide cannot exceed a certain limit because of its slight solubility, and the limit will depend on the pressure. The existence of the "rapid" decomposition is accounted for. No completely stable solution, however, can exist, even in a sealed bulb where the pressure of nitric oxide can become high (Montemartini, *loc. cit.*), since the nitrogen peroxide is continually hydrated and removed from the equilibrium. During the "slow" decomposition two factors come into play: the rate of escape of nitric oxide and the rate of hydration of the peroxide. The concentration of the latter is probably extremely small and thus the quantity hydrated in unit time is small, and consequently the second factor under normal conditions is of less importance. Any factor tending to facilitate the escape of the nitric oxide, such as increased area of contact with the gas phase, addition of sand or charcoal (Frémy, *Compt. rend.*, 1870, **70**, 63), or reduction of pressure, will increase the rate of decomposition. The escape of a gas from solution has a rapid stage, followed by a slower stage (Perman, J., 1895, **67**, 868; Bohr, *Ann. Physik*, 1899, **68**, 507; Findlay and King, J., 1913, **103**, 1170) which follows a logarithmic law, thus agreeing with the behaviour of nitrous acid. The effect of added substances in reducing the rate of decomposition can be compared with the result found by Bohr that carbon dioxide escapes less rapidly from a solution of sodium chloride than from pure water.

Work is in progress on various reactions of nitrous acid stabilised in the manner described in this paper.

Our thanks are due to Dr. W. H. Mills for his helpful criticism and to Messrs. Brunner Mond & Co., Ltd., for their generosity in making a grant which has covered part of the expenses of this work.

OXFORD. [*Received, May 9th*, 1927.]

CCXLIX.—*The Action of the Metallic Derivatives of Ethyl Dehydroundecenoate upon Alkyl Halides.*

By WILLIAM WHALLEY MYDDLETON and RUDOLPH G. BERCHEM.

AN attempt to synthesise Δ^{10}-stearolic acid by acting upon the silver derivative of ethyl dehydroundecenoate with heptyl bromide in alcoholic solution resulted in the formation of silver bromide, ethyl heptyl ether, and free ethyl dehydroundecenoate. With the silver derivative in absence of alcohol, an excess of heptyl bromide gave silver bromide, heptene, and ethyl dehydroundecenoate. In each case, the yields of silver bromide and ethyl ester were practically quantitative.

n-Propyl, *iso*butyl and ethyl bromides and ethyl iodide were used in succession, and in each case quantitative yields of silver halide and ethyl dehydroundecenoate were obtained. Other products in these reactions were not investigated. The silver derivative obviously reacts with halogen acid derived from the alkyl halide.

During the preparation of the silver derivative by the action of alcoholic silver nitrate upon the ester, we followed the reaction more closely than Krafft (*Ber.*, 1896, **29**, 2232) and found the yields of silver derivative and free nitric acid required for the equation:

$$CH{:}C\cdot[CH_2]_8\cdot CO_2Et + 2AgNO_3 = AgNO_3,CAg{:}C\cdot[CH_2]_8\cdot CO_2Et + HNO_3.$$

We add to Krafft's observations that the silver derivative is soluble in hot alcohol and is stable in bright sunlight. The presence of a little free dehydroundecenoic acid in the ester results in the formation of a grey silver derivative which rapidly darkens in daylight.

Sodium derivatives of acetylenic compounds are not so readily prepared as the silver derivatives, but by the action of finely powdered sodamide upon ethyl dehydroundecenoate in toluene we obtained the sodium derivative of dehydroundecenoamide. The action of this compound upon alkyl halides was similar to that of the silver derivative.

EXPERIMENTAL.

Bromination of Undecenoic Acid.—Light petroleum (b. p. 60—80°) was treated with a slight excess of bromine, washed after some time with sodium bisulphite solution and with water, dried, and distilled. To a solution of 170 g. of undecenoic acid (m. p.

24·5°; b. p. 168·3°/15 mm.) in 500 c.c. of the solvent, cooled in a freezing mixture, 150 g. of bromine were added during 1½ hours with efficient stirring. After 1 hour the precipitate was filtered off, washed with 100 c.c. of cold solvent, and dried (250 g.; m. p. 38·5°). The remainder of the dibromo-acid was obtained as an oil after washing the filtrate with a solution of sodium bisulphite and then with water and drying and evaporating the solvent. The yield of oil was practically the same in a number of brominations (Found: Br, 46·2; equiv., by titration with alkali, 345·1. Calc. for $C_{11}H_{20}O_2Br_2$: Br, 46·5%; equiv., 344·0).

Preparation of Ethyl Dehydroundecenoate and its Silver Derivative.—Dehydroundecenoic acid was prepared from the dibromo-acid by Krafft's method (*loc. cit.*) and esterified with lime-dried alcohol and concentrated sulphuric acid. The ester had b. p. 145°/15 mm.

(*a*) A solution of 2 g. of the ethyl ester in 5 c.c. of absolute alcohol was added to 3·24 g. of silver nitrate in 105 c.c. of alcohol; 4·7 g. of the silver derivative were obtained. The filtrate and washings (10 c.c.) were shaken with solid potassium chloride and filtered. The filtrate required for neutralisation 9·0 c.c. of *N*-sodium hydroxide.

(*b*) 17·5 G. of the ester, 28·4 g. of silver nitrate, and 1 l. of alcohol gave 38·5 g. of the silver derivative, and the filtrate required 82·1 c.c. of *N*-alkali (Found: Ag, 44·5. Calc. for $C_{13}H_{21}O_2Ag,AgNO_3$: Ag, 44·3%).

Action of the Silver Derivative upon Heptyl Bromide in Alcohol.—The silver derivative precipitated from 17·5 g. of the ester was washed and dissolved in 300 c.c. of warm alcohol, 30 g. of heptyl bromide were added, and the solution was warmed under reflux on the water-bath; 30 g. of silver bromide separated during 3 hours. Alcohol was distilled from the filtered solution, and the residue fractionated.

Fraction (*a*), boiling below 140°/15 mm., was redistilled and collected up to 168°/760 mm. After it had been warmed with aqueous caustic potash to hydrolyse heptyl bromide and extracted with ether, an oil was obtained. Heptyl alcohol was removed from this by treatment with successive quantities of sodium. The remaining liquid was distilled and collected at 165—166°/760 mm. (3·5 g.) (Found: C, 74·65; H, 13·7. Calc. for $C_7H_{15}\cdot O\cdot C_2H_5$: C, 74·9; H, 14·0%).

Fraction (*b*) (16 g.), collected at 145°/15 mm., was ethyl dehydroundecenoate, since it gave after hydrolysis an acid of m. p. 43—44° (Found: C, 72·3; H, 10·2; equiv., by titration, 185·2. Calc. for $C_{11}H_{18}O_2$: C, 72·5; H, 10·0%; equiv., 182·1).

Action of the Silver Derivative upon Heptyl Bromide in Absence of Alcohol.—The silver derivative from 15 g. of the ester was dried in a

vacuum desiccator during 2 days and then warmed with 50 g. of heptyl bromide on the water-bath, the flask being shaded. The cooled solution was filtered after dilution with ether. The filtrate gave a fraction, b. p. 95—100°/760 mm. On redistilling this, 4·5 g. were collected at 96—98°. Bromine in the cold converted this into an oil, b. p. 105—107°/15 mm. αβ-Dibromoheptane has b. p. 105—107°/15 mm. (Found: Br, 61·5. Calc. for $C_7H_{14}Br_2$: Br, 62·0%).

Formation of the Sodium Derivative.—Ethyl dehydroundecenoate was heated under reflux for about 2 days with toluene in which a 5% excess of finely powdered sodamide was suspended; ammonia was slowly evolved. The flocculent precipitate of the sodium derivative of dehydroundecenoamide was treated with excess of heptyl bromide. Sodium bromide was slowly formed and the filtered solution gave practically the whole of the ethyl dehydroundecenoate.

The authors are indebted to the Research Fund Committee of the Chemical Society for a grant which defrayed part of the cost of the investigation.

UNIVERSITY OF LONDON. [*Received, April 10th,* 1927.]

CCL.—*Besson's Supposed Phosphorus Suboxide,* P_2O.

By LESLIE JAMES CHALK and JAMES RIDDICK PARTINGTON.

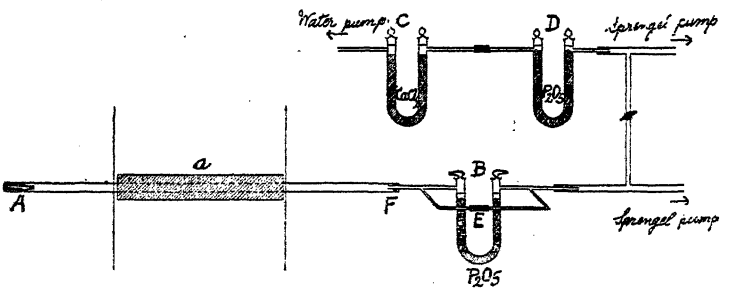
BESSON describes (*Compt. rend.*, 1897, **124**, 763; 1897, **125**, 1032; 1901, **132**, 1556; compare *Bull. Soc. chim.*, 1900, **23**, 582) the preparation of an oxide, P_2O, (i) by heating phosphoryl chloride with phosphonium bromide, (ii) by the action of a slow stream of air on a solution of phosphorus in carbon tetrachloride, and (iii) by heating a concentrated solution of phosphorous acid with phosphorus trichloride. The identical products are stated to be yellowish-red and stable at 100°, but decomposed in a vacuum at 135° with the evolution of oxygen. Analysis gave about 79% of phosphorus (P_2O requires 79·49%). The substances obtained by Michaelis and Pitsch (*Ber.*, 1899, **32**, 337; *Annalen*, 1900, **310**, 45) by the action of hydrochloric acid on a solution of yellow phosphorus in aqueous-alcoholic potassium hydroxide, and by the action of acetic anhydride on a solution of hypophosphorous acid in glacial acetic acid, were considered by Besson to be largely P_2O contaminated by phosphorus and solid hydrogen phosphide.

Preparation of Besson's Oxide.—10 G. of Kahlbaum's phosphorous

acid were dissolved in 8 g. of water in a flask under a reflux condenser and 50 g. of phosphorus trichloride were added. Hydrogen chloride was steadily evolved and crystals were formed. These consisted of phosphorous acid, and not phosphorus trioxide, as required by the equations given by Besson, *viz.*, $PCl_3 + H_3PO_3 = 3HCl + P_2O_3$, followed by $2P_2O_3 = P_2O + P_2O_5$. On heating for about 15 minutes on a water-bath with shaking, the crystals disappeared and a yellow solid began to separate. On further heating, red particles appeared. A viscous layer settled out which contained most of the deposit, the upper layer being unchanged phosphorus trichloride. Reaction is complete in 6 hours. Besson states that a substance with the appearance of phosphorus pentoxide is formed in the reaction, but this could not be confirmed, neither was a hissing noise observed on adding water to the residue, although heat was evolved by the action of water on unchanged trichloride—if the upper layer is poured off before the addition of water there is practically no evolution of heat.

The product was filtered, washed with cold water according to the directions of Besson, and dried in a vacuum over phosphorus pentoxide for 3 weeks. The filtrate contained phosphorous, phosphoric, and hydrochloric acids, most of the phosphorus being in the form of phosphorous acid. The dry powder was yellowish-red, but contained darker red particles, and was free from chlorine. The yield from 10 g. of phosphorous acid was 0·7 g. In this way, the preparations numbered I, II, III, and VII in the tables were obtained.

Action of Phosphorus Trichloride on Crystalline Phosphorous Acid.—Although the preceding experiment was performed exactly as specified by Besson, it was clear that it would be better to use crystalline phosphorous acid instead of the solution. 50 G. of phosphorus trichloride and 10 g. of solid phosphorous acid did not react until the mixture was warmed; the acid then dissolved completely and a yellow solid soon appeared. This turned redder on further heating for 5 or 6 hours, and the product was then isolated and dried as before. It was exactly similar in appearance to the previous product. The liquid poured off from the solid was mainly unchanged trichloride (43 g.). The yield of "oxide" was about the same as in the first method. The preparations numbered IV, V, VI, and VIII were obtained by this method. Preparation V, containing 86·7% of phosphorus, was not further examined.



The Action of Phosphorus Trichloride on Phosphorous Acid below 70°.—50 G. of phosphorus trichloride and 10 g. of phosphorous acid were heated so that the temperature never rose beyond 70°. The action was slow, but no further yield appeared after 20 hours. Only 0·15 g. of product resulted, which was pure yellow without any tinge

of orange, and appeared homogeneous under the microscope. The washings contained phosphorous acid and a small amount of phosphoric acid, but no hypophosphorous acid. The upper layer yielded 33·5 g. of unchanged trichloride. The dry powder, specimen IX, had a stronger odour of phosphine than that prepared at 100°.

Analysis of the Products.—The preparations were analysed by the method described by Chapman and Lidbury (J., 1899, **75**, 973), except that phosphoric acid was estimated by the method described by Treadwell (" Quantitative Analysis," p. 437).

The water and hydrogen contents of the preparations were determined by a modification of the apparatus described by Burgess and Chapman (J., 1901, **79**, 1235), which is shown in Fig. 1. The aluminium foil used by these experimenters was omitted. The substance was weighed into a small tube, A, which was introduced

FIG. 1.

into the Bohemian-glass tube, F, 9 mm. in diameter and 120 cm. long. The part inside the resistance furnace, *a*, contained a roll of bright copper gauze. The whole apparatus was first thoroughly cleaned and dried by prolonged heating in a vacuum. The junction with the phosphorus pentoxide absorption tube, B, was made with sealing wax, since this part remained quite cool, so that the tube B could be removed easily for weighing. A screw-clip on the pressure tubing, E, enabled the tube B to be evacuated independently of the tube AF. The substance in A darkened on heating and evolved gas, which was collected in the receiver of the Sprengel pump exhausting the apparatus. When no further gas collected and a vacuum was re-established, the apparatus was allowed to cool and disconnected, and the tubes A and B were weighed. The tube A contained a dark grey residue, sometimes containing white, opaque specks, which were not glassy. Practically the whole of the phosphorus content of this residue could be extracted by boiling water, but the undissolved residue was in every case analysed for phosphorus.

When the preparations were heated with water in a sealed tube for 8 hours at 100°, and the tube was opened under mercury, only a very small diminution in volume was noticed, and the solution was found to contain phosphorous, but not hypophosphorous, acid. Besson attributed the production of phosphorous acid in this experiment to oxidation of P_2O: $P_2O + O_2 + 3H_2O = 2H_3PO_3$, the absorption of oxygen being inferred from a diminution of pressure; he also noticed a smell of phosphine. We find no such diminution of pressure, and there can be no doubt from this and from the quantitative experiments described below that the phosphorous acid is present as such in the original preparations. On further heating the residue from this experiment with water, more phosphorous acid was obtained, but in diminished amount, and an adsorption phenomenon is indicated. The presence of uncombined water in the preparations is considered improbable, since a portion of preparation III, on being kept in a vacuum over phosphorus pentoxide for 2 months, gave practically the same results for water and hydrogen on distillation (0·1 g. gave 0·0142 g. of residue with 43% P, 2·2 c.c. of hydrogen and 0·0056 g. of H_2O) as the freshly dried preparation. The probable constituents of the preparations are therefore: free phosphorus, phosphorous acid, and solid hydrogen phosphides. The preparation made below 70° may be expected to contain more solid phosphides, since a slow reaction between phosphorus trichloride and phosphorous acid in the cold is said to give these substances, whilst at higher temperatures (170°) red phosphorus is said to be the only product.

We assume that the only primary constituents of the preparations are phosphorous acid and phosphorus, the amount of the former being directly estimated from the phosphoric acid in the residue left after distillation in a vacuum. The weight of water and the volume of hydrogen obtained on distillation in vacuum can then be compared with those calculated from the equation: $8H_3PO_3 = 3P_2O_5 + 9H_2O + 2P + 3H_2$. The phosphorus content of the residue was generally above 40%, whereas that of metaphosphoric acid is 38·8% and that of phosphorus pentoxide 43·7%. That the residue should consist mainly of phosphorus pentoxide rather than metaphosphoric acid might appear improbable, but the pentoxide may be produced by the prolonged heating in vacuum of free phosphorus and metaphosphoric acid: $10HPO_3 + 2P = 6P_2O_5 + 5H_2$. The results of the distillation experiments, as is seen from Table I, are in agreement with this hypothesis, except that the hydrogen obtained from the oxide prepared below 70° was greater than the calculated amount, a result which would be expected if solid hydrogen phosphides are present. In other cases, the hydrogen calculated is only slightly

lower than the experimental value, which may indicate the presence of a little solid hydrogen phosphide (compare Burgess and Chapman, *loc. cit.*). The dark colour of the residue obtained on heating in a vacuum is probably due to a trace of free carbon derived from organic matter introduced from the cork of the flask in the preparation of the "oxide." This was estimated by difference on the assumption that the remainder of the residue was phosphorus pentoxide, and it was always very small.

In all cases the gas collected from 0·1 g. of preparation was 2—4 c.c. It was shown to be hydrogen by explosion with oxygen. No contraction was observed with the gas, before or after explosion, in contact with dilute acid or alkali. The contraction on explosion was slightly less than the calculated, although no gas except hydrogen could be detected by qualitative tests. The alleged evolution of oxygen on heating the substance was negatived by experiments in which the copper gauze was omitted. The gas collected in this case was phosphine; it suffered no contraction in contact with alkaline pyrogallol, and on explosion with oxygen gave white fumes of phosphoric acid. The phosphorus contents of the various preparations were as follows :

Preparation.	I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.
%P.	85·1	86·0	86·8	81·1	86·7	86·2	88·8	88·2	87·6

These results definitely exclude the composition P_2O.

In Table I, column 2 gives the actual amount of oxide used in the analysis. The figures in the remaining columns, however, have been calculated to 0·1 g. of oxide for the purpose of comparison. This applies also to all the figures in Tables II and III.

TABLE I.

Effect of distillation of the preparations.

Prep. No.	Weight (g.).	Residue (g.).	H_2O (g.).	Gas (c.c.).	H_2 (c.c.).	H_2O (calc.) (g.).	H_2 (calc.) (c.c.).
I	0·0950	0·0160	0·0059	2·8	2·6	0·0054	2·2
II	0·1081	0·0155	0·0065	3·0	2·9	0·0057	2·4
III	0·1060	0·0135	0·0051	2·2	2·0	0·0050	2·1
IV	0·0987	0·0176	0·0074	3·5	3·2	0·0064	2·7
VI	0·0945	0·0149	0·0063	2·5	2·5	0·0054	2·3
VII	0·0993	0·0121	0·0050	1·7	1·5	0·0044	1·8
VIII	0·1058	0·0128	0·0055	2·1	1·9	0·0047	2·0
IX	0·0595	0·0116	0·0044	4·6	4·4	0·0034	1·4

Specimen IV still contained phosphorous acid which could be extracted by washing. Specimens VII and VIII were washed for a longer time than the others and the phosphorus content is higher, indicating a more complete removal of phosphorous acid. Only 0·0595 g. of Specimen IX was available for distillation.

Table II contains the analyses of the residues left after distillation. Except in the cases of Preparations I and IX, all the phosphorus (as phosphoric acid) was extracted by boiling water. In these two cases, the residues after extraction contained 0·0010 g. and 0·0008 g. of free phosphorus, respectively (compare Burgess and Chapman, *loc. cit.*). The fifth column gives the amount of phosphorous acid equivalent to the phosphorus contained in the residue as P_2O_5, the sixth the amounts of hydrogen and oxygen equivalent to this, *viz.*, $(H_3PO_3)\times(51/82)$. The last column contains the sum of the weights of phosphorus, hydrogen, carbon, and oxygen in 0·1 g. of preparation, *i.e.*, the sum of the figures in columns 4, 6, and 7, and is equal to 0·1 to within 2%. This supports the hypothesis that the supposed oxide P_2O contains free phosphorus and phosphorous acid only.

TABLE II.

Composition of residue after distillation.

Prep. No.	Weight g.	% P in residue.	C. (calc.).	H_3PO_3 equiv. to P extracted.	H and O as H_3PO_3.	P in 0·1 g. "oxide."	Total.
I	0·0160	38·4	0·0009	0·0217	0·0135	0·0851	0·0995
II	0·0155	42·0	0·0005	0·0230	0·0143	0·0860	0·1008
III	0·0135	42·2	0·0006	0·0201	0·0125	0·0868	0·0999
IV	0·0176	42·0	0·0007	0·0261	0·0162	0·0811	0·0980
VI	0·0149	42·2	0·0005	0·0222	0·0138	0·0862	0·1005
VII	0·0121	41·5	0·0006	0·0177	0·0110	0·0888	0·1004
VIII	0·0128	42·5	0·0004	0·0192	0·0119	0·0882	0·1005
IX	0·0116	37·2	0·0009	0·0139	0·0086	0·0876	0·0971

The percentage of phosphorus in Preparations VII and VIII corresponds very nearly with that in the supposed suboxide P_4O, but the behaviour on distillation in a vacuum is different. Burgess and Chapman (*loc. cit.*) found that 0·1 g. of the supposed P_4O gave on distillation about 10 c.c. of hydrogen and left practically no residue, whereas these preparations give only 1—3 c.c. of hydrogen and leave 12% of residue. Burgess and Chapman, however, decomposed the water vapour by heated aluminium.

From the experimentally determined values of phosphorus, oxygen, and hydrogen in the supposed oxide, a formula for the latter may be calculated. This is done in Table III, in which the total should be 0·1 g. This is seen to be the case within 2%. The oxygen is calculated on the assumption that the phosphorus extracted by hot water from the residue after distillation existed as pentoxide.

The properties of the supposed oxide are similar to those of scarlet amorphous phosphorus and of the supposed solid hydrogen phosphides. It is insoluble in water, alcohol, benzene, chloroform, or ether. Dilute nitric acid dissolves it at 40°, whilst concentrated nitric acid causes inflammation. Hydrogen peroxide and sodium

hypochlorite solution oxidise it to colourless solutions containing phosphoric acid. Concentrated ammonia turns it slightly darker in colour, the original colour being restored by exposure to air or by the action of acids. Alcoholic potassium hydroxide forms a dark red solution with evolution of phosphine, the solution being similar to that formed by the supposed suboxide P_4O (as was found by trial).

The mechanism of the formation of Besson's substance (which is really of variable composition) is probably as follows. The phosphorous acid may be decomposed with evolution of phosphine. The latter is known to react with phosphorus trichloride giving, according to the conditions, solid hydrogen phosphide or phosphorus. When prepared at lower temperatures, the product may contain appreciable amounts of solid hydrogen phosphide. It is also possible that phosphorus trioxide may be formed by the action of the trichloride on phosphorous acid (Abegg, "Handbuch," III, iii, 420; the reference to Krafft and Neumann, *Ber.*, 1901, **34**, 566, there given does not appear to be relevant). The trioxide might then decompose, either alone or by interaction with phosphorus trichloride, to form phosphorus or solid hydrogen phosphides.

Summary.

The supposed oxide of phosphorus, P_2O, formed by the action of phosphorus trichloride on phosphorous acid under the conditions described by Besson has neither the composition nor properties attributed to it by that investigator. It is somewhat variable in composition and appears to be a mixture of finely divided amorphous phosphorus with strongly adsorbed phosphorous acid, although, especially when prepared at lower temperatures, solid hydrogen phosphides may be present. The amount of oxygen present is always much less than is required by the formula P_2O, and hydrogen also is always present, even after prolonged drying over phosphorus pentoxide.

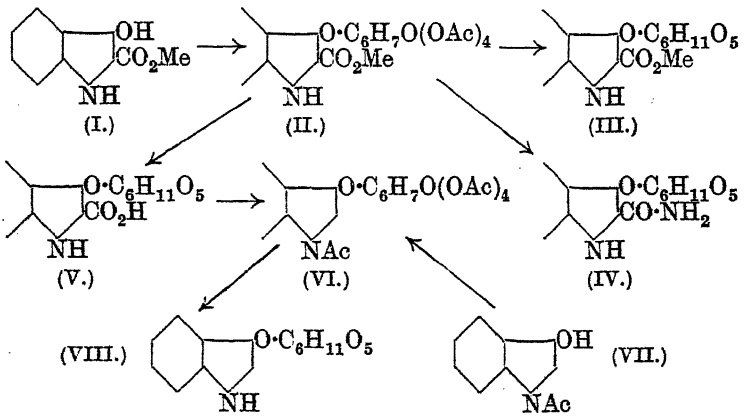
UNIVERSITY OF LONDON.

[*Received, May 24th,* 1927.]

CCLI.—*Syntheses of Glucosides. Part I. The Synthesis of Indican.*

By ALEXANDER ROBERTSON.



THE glucoside indican, 3-β-glucosidoxyindole, was first isolated by Schunk (*Phil. Mag.*, 1855, **10**, 74; 1858, **15**, 127) from *Polygonum tinctorium*, who stated that the indigotin-yielding substance in *Isatis tinctoria*, "woad," was the same. It was, however, not until many years afterwards that its correct formula was indicated by Marchlewski and Radcliffe (*J. Soc. Chem. Ind.*, 1898, **17**, 434), who suggested that the glucoside had possibly the formula $C_{14}H_{17}O_6N$, and that, on hydrolysis, glucose and indoxyl were formed, the latter on oxidation being converted into indigotin. The proof that indican is an indoxyl glucoside, and that the sugar obtained from it is glucose, was supplied by Hazewinkel (*Proc. K. Akad. Wetensch. Amsterdam*, 1900, **2**, 512). About the same time, Hoogenwerff and ter Meulen (*ibid.*, p. 520) isolated the glucoside in a crystalline condition from *Polygonum tinctorium* and *Indigofera leptostachya*. They showed that it had the formula $C_{14}H_{17}O_6N$ and when crystallised from water contained $3H_2O$. By hydrolysis of the glucoside in the presence of air, they obtained slightly impure indigotin; and later the identity of the sugar with *d*-glucose was indicated by ter Meulen (*Rec. trav. chim.*, 1905, **24**, 444). Beyerinck (*Proc. K. Akad. Wetensch. Amsterdam*, 1900, **3**, 101) showed that the glucoside in *Polygonum tinctorium* is not the same as the indigo-yielding substance in *Isatis tinctoria* as claimed by Schunk, and also that indican was slowly hydrolysed by emulsin, as well as by its specific enzyme, indemulsin.

Perkin and Bloxam (J., 1907, **91**, 1715), Perkin and Thomas (J., 1909, **95**, 793), and Thomas, Bloxam, and Perkin (J., 1909, **95**, 824), working with improved methods, isolated the crystalline glucoside from *Indigofera leptostachya*, *I. sumatrana*, *I. arrecta*, and *Polygonum tinctorium*, and confirmed in detail the work of Hoogenwerff and ter Meulen, Hazewinkel, and Beyerinck. In addition, these workers obtained the glucoside in the anhydrous state. From a study of the hydrolysis of methylated indican, Macbeth and Pryde (J., 1922, **121**, 1660) showed that the glucoside is in all probability a normal β-derivative. This is in agreement with the conclusions arrived at by ter Meulen (*loc. cit.*) as a result of a study of the hydrolysis of the glucoside by enzymes.

In attempting the synthesis of indican, the most obvious method was to obtain the penta-acetyl derivative by the interaction of 1-acetyl-3-hydroxyindole and tetra-acetyl-α-glucosidyl bromide in

acetone solution in the presence of aqueous alkali. Reference to the literature indicated the difficulty of preparing a sufficient quantity of the acetylhydroxyindole, and the instability of the latter in the presence of alkali. Accordingly, another method for the synthesis of the glucoside was devised.

Methyl 3-O-*tetra-acetyl*-β-*glucosidoxyindole*-2-*carboxylate* (II) was obtained in good yield by the interaction of methyl 3-hydroxyindole-2-carboxylate (I) and tetra-acetyl-α-glucosidyl bromide in acetone solution in the presence of potassium hydroxide.

This penta-acetyl glucoside on hydrolysis with methyl-alcoholic potash yielded 3-β-*glucosidoxyindole*-2-*carboxylic acid* (V), which was conveniently isolated from the reaction mixture as the potassium salt. The latter, when treated with fused sodium acetate and acetic anhydride, first on the water-bath and then at 160°, was acetylated and the carboxyl group simultaneously eliminated with the formation of 1-*acetyl*-3-O-*tetra-acetyl*-β-*glucosidoxyindole* (VI). In order to verify the constitution of this substance, a small quantity of it was prepared directly by the interaction of 1-acetyl-3-hydroxyindole (VII) (D.R.-P. 108761) and tetra-acetyl-α-glucosidyl bromide in a cooled acetone solution in the presence of potassium hydroxide. The specimens of *penta-acetylindican* thus obtained were identical. The penta-acetyl glucoside was deacetylated with methyl-alcoholic ammonia, and 3-β-*glucosidoxyindole*, indican (VIII), obtained in good yield. The properties of the synthetic glucoside were identical with those of the natural product described in detail by Perkin and his collaborators (*loc. cit.*).

Hydrolysis of the synthetic indican under various conditions gave the same products as those obtained by these authors, by Hazewinkel (*loc. cit.*) and by Beyerinck (*loc. cit.*).

On deacetylation of the glucoside (II), a mixture of *methyl* 3-β-*glucosidoxyindole*-2-*carboxylate* (III) and 3-β-*glucosidoxyindole*-2-*carboxylamide* (IV) was obtained, but the latter could not be isolated in a crystalline condition. Hydrolysis and acetylation, however, established the nature of the uncrystallised syrup.

The preparation of methyl 3-hydroxyindole-2-carboxylate (Vorländer, *Annalen*, 1898, **301**, 349) was carried out by the method described for the preparation of the corresponding ethyl ester (D.R.-P. 105495). This methyl ester on acetylation yielded an O-*acetyl* derivative.

EXPERIMENTAL.

Methyl 3-*Hydroxyindole*-2-*carboxylate* (I). — To pulverised sodium (2·7 g.) and methyl phenylglycine-*o*-carboxylate (25 g.) in benzene (100 c.c.), one drop of anhydrous methyl alcohol was added and the mixture was gently warmed on the steam-bath until a vigorous reaction set in; the sodium derivative of methyl 3-hydroxyindole-2-carboxylate was then deposited as a solid. When this reaction had almost ceased, the mixture was heated under reflux for 30 minutes and then cooled. The sodium derivative was collected, washed with benzene, dried, and dissolved in ice-water (250 c.c.), and the solution was filtered after treatment with charcoal and acidified with acetic acid (50%). The indoxylic ester thus precipitated crystallised from methyl alcohol (70%) (charcoal) in elongated, glistening needles, m. p. 157—158°. Yield, 15 g.

Methyl 3-*acetoxyindole*-2-*carboxylate* was obtained in almost theoretical yield when methyl 3-hydroxyindole-2-carboxylate (2 g.), fused sodium acetate (2 g.), and acetic anhydride (10 c.c.) were heated under reflux for 1 hour. Water was added to the cooled mixture, and the *acetyl* derivative gradually crystallised. After recrystallisation from methyl alcohol (50%) and then from benzene–ligroin (1 : 9), it was obtained in glistening, elongated prisms, m. p. 145° (Found: C, 62·1; H, 4·7. $C_{12}H_{11}O_4N$ requires C, 61·8; H, 4·7%). It is insoluble in dilute alkali solution. Attempts to obtain a diacetyl derivative were unsuccessful.

Methyl 3-*Tetra-acetyl*-β-*glucosidoxyindole*-2-*carboxylate* (II).—A cooled solution of potassium hydroxide (2·8 g.) in water (20 c.c.) was gradually added to one of methyl 3-hydroxyindole-2-carboxylate (9·3 g.) and tetra-acetyl-α-glucosidyl bromide (20·5 g.) in pure acetone (90 c.c.) cooled to 10°; the acetyl glucoside soon began to crystallise. After remaining at room temperature for 4 hours, the mixture was diluted with water (50 c.c.) and cooled in ice, and the solid was collected and recrystallised from hot methyl alcohol (charcoal). The *acetyl glucoside* was thus obtained in colourless

prisms with blunt ends, m. p. 229—230° (Found: C, 55·5; H, 5·2. $C_{24}H_{27}O_{12}N$ requires C, 55·5; H, 5·2%). Yield, 16·5 g.

This glucoside is sparingly soluble in ether and in cold alcohol, and moderately easily soluble in hot alcohol. A penta-acetyl derivative could not be obtained.

3-β-*Glucosidoxyindole-2-carboxylamide* (IV).—Dry methyl alcohol (200 c.c.) containing finely powdered methyl 3-tetra-acetyl-β-glucosidoxyindole-2-carboxylate (3 g.) in suspension was saturated at 0° with dry ammonia gas. The glucoside gradually dissolved and the solution was allowed to remain at 0° for 14 hours. After removal of the ammonia and methyl alcohol in a vacuum at 18°, the residual oil was freed from acetamide by distillation of the latter at 100°/1—2 mm. The straw-coloured syrup which remained was dissolved in water, and the solution on evaporation in a vacuum desiccator deposited the *amide* as a white solid. This crystallised from water in colourless, rectangular plates, which decomposed at 254—256° to a black mass after darkening at 245° (Found: C, 50·7; H, 5·6; N, 7·5. $C_{15}H_{18}O_7N_2$ requires C, 50·8; H, 5·6; N, 7·8%). Yield, 0·3 g. The amide is fairly soluble in alcohol and in hot water.

The filtrate after the separation of the amide was evaporated to small bulk, and a straw-coloured syrup obtained which could not be induced to crystallise. This undoubtedly consisted of impure *methyl* 3-β-*glucosidoxyindole-2-carboxylate* (III). When this syrup was heated to boiling with 6% hydrochloric acid for 1 minute, methyl 3-hydroxyindole-2-carboxylate (I) crystallised, m. p. 157—158° after recrystallisation from 70% methyl alcohol. The acetyl derivative, m. p. 145°, was identical with that described above. The syrup (1 part) was acetylated by heating it under reflux for 1 hour with fused sodium acetate (1 part) and acetic anhydride (10 parts). Water was added to the cooled mixture to decompose the excess of acetic anhydride, and methyl 3-tetra-acetyl-β-glucosidoxyindole-2-carboxylate separated, m. p. 229—230° after recrystallisation from methyl alcohol. A mixture of the latter with an authentic specimen of the acetylated glucoside showed no depression of the melting point.

3-β-*Glucosidoxyindole-2-carboxylic Acid* (V).—A solution of potassium hydroxide (4 g.) in 80% methyl alcohol (25 c.c.) was gradually added to a suspension of methyl 3-tetra-acetyl-β-glucosidoxyindole-2-carboxylate in methyl alcohol (50 c.c.). After the solid had dissolved, the solution was kept at room temperature for 12 hours, methyl alcohol (20 c.c.) was then added, and the mixture heated under reflux on the water-bath for 2 hours, during which time the potassium salt of 3-β-glucosidoxyindole-2-carboxylic acid crystallised

out. When cold, the colourless potassium salt was collected, washed with dry methyl alcohol, and dried. The salt (yield, 3·5 g.) was sufficiently pure for use in the next stage of the synthesis.

A solution of the potassium salt (1 g.) in water (4 c.c.) was acidified with a slight excess of 2% hydrochloric acid. The pale blue, crystalline precipitate of the *glucoside* which separated was collected and recrystallised from warm water (charcoal), from which it separated in almost colourless, rod-like prisms, which turned brown at 215—220° and decomposed to a dark liquid at 230—231° (Found: C, 53·1; H, 5·1; N, 4·0. $C_{15}H_{17}O_8N$ requires C, 53·1; H, 5·0; N, 4·1%).

A solution of this glucoside in dilute hydrochloric acid, containing ferric chloride, on boiling is quickly decomposed with the formation of indigotin. An aqueous solution when heated to boiling quickly assumes a blue colour, due to slight hydrolysis and the formation of a trace of indigotin.

1-*Acetyl*-3-*tetra-acetyl*-β-*glucosidoxyindole* (*Penta-acetylindican*) (VI).—(*A.*) Potassium 3-β-glucosidoxyindole-2-carboxylate (3·5 g.), fused sodium acetate (3·5 g.), and acetic anhydride (45 c.c.) were heated on the steam-bath for 2 hours, and then at 160—162° for 1 hour. Water (200 c.c.) was added to the cooled mixture; the penta-acetylindican then separated as an oil which gradually solidified. The solid was repeatedly crystallised from methyl alcohol (charcoal) to free it from coloured impurities, and finally from ethyl alcohol, from which it separated in glistening, colourless, elongated, rectangular prisms, m. p. 148° (yield, 4·0 g.) (Found: C, 57·2; H, 5·4. $C_{24}H_{27}O_{11}N$ requires C, 57·0; H, 5·3%). Penta-acetylindican is slightly soluble in cold and easily soluble in hot alcohol, and readily soluble in cold chloroform.

(*B.*) A suspension of methyl 3-tetra-acetyl-β-glucosidoxyindole-2-carboxylate (6 g.) in 5% baryta water (200 c.c.), maintained at 40—45°, was vigorously agitated for 24 hours; the solid gradually dissolved. The excess of barium hydroxide was precipitated by carbon dioxide, the barium carbonate removed, and the filtrate evaporated to dryness. The residue was acetylated and *penta-acetylindican* isolated, m. p. 148°, as described above. Yield, 0·8 g.

(*C.*) A solution of potassium hydroxide (0·84 g.) in water (10 c.c.) was gradually added to one of 1-acetyl-3-hydroxyindole (VI) (*loc. cit.*) (2·1 g.) and tetra-acetyl-α-glucosidyl bromide (6·2 g.) in 100 c.c. of acetone maintained below 5° in an atmosphere of nitrogen. The mixture was kept in the ice-chest for 5 hours and then acidified with dilute acetic acid, and the acetone was removed in a vacuum at room temperature. The dark brown residual oil was dissolved in warm methyl alcohol (20 c.c.), and the solution

poured into cold water (300 c.c.); impure penta-acetylindican was then precipitated in a semi-solid condition. The glucoside crystallised from ethyl alcohol (charcoal) in glistening, colourless, elongated, rectangular prisms, m. p. 148° (yield, 0·7 g.) (Found: C, 56·8; H, 5·3; N, 2·8. $C_{24}H_{27}O_{11}N$ requires C, 57·0; H, 5·3; N, 2·6%). A mixture of the penta-acetylindican prepared in this way with that described above showed no depression of the melting point.

3-β-*Glucosidoxyindole* (*Indican*) (VIII).—1-Acetyl-3-tetra-acetyl-β-glucosidoxyindole (8 g.) quickly dissolved in absolute methyl alcohol (300 c.c.) saturated at room temperature with dry ammonia. After 24 hours, the solution was cooled to 0°, saturated with ammonia, and kept for 12 hours. The ammonia and methyl alcohol were then removed under diminished pressure at 20—25°, and the residual syrup was freed from acetamide by exposure to a high vacuum (1—2 mm.) for 1 hour at 100°. A solution of the green residue in warm water (30 c.c.) was filtered after treatment with charcoal, and exposed to a vacuum over soda-lime and calcium chloride. An almost colourless mass of crystalline indican gradually filled the liquid. Yield, 4·2 g.

The glucoside, after being twice recrystallised from water, was obtained as a mass of colourless, silky needles, m. p. 57—58°. When dried in a vacuum over sulphuric acid for 48 hours, indican lost part of its water of crystallisation; it then melted at 100—101°, became crystalline at 160°, and finally melted at 176—178°. It was obtained anhydrous, m. p. 176—178°, by heating it in the steam-oven for 3 hours, at 110° for 1 hour, and finally at 160° for 5 minutes (Found in a specimen crystallised from water and air-dried: C, 48·2; H, 6·5; N, 4·4; H_2O, 15·8. Calc. for $C_{14}H_{17}O_6N,3H_2O$: C, 48·1; H, 6·6; N, 4·0; H_2O, 15·5%. Found in an anhydrous specimen: C, 56·6; H, 6·0; N, 5·0. Calc. for $C_{14}H_{17}O_6N$: C, 56·9; H, 5·8; N, 4·8%). Anhydrous indican was also obtained from the hydrated variety in colourless prisms, m. p. 176—178°, by crystallisation from warm absolute ethyl alcohol–benzene as described by Perkin and Bloxam (*loc. cit.*).

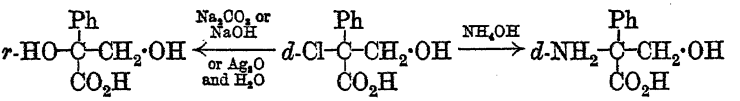
Synthetic indican is rapidly hydrolysed in warm 3% hydrochloric acid with the liberation of glucose and indoxyl, which in the presence of acid forms "indoxyl brown." If, however, a little ferric chloride is added as an oxygen carrier and air is bubbled through the solution, the liberated indoxyl is instantaneously oxidised to almost pure indigotin. When a drop of concentrated hydrochloric acid is added to a solution of the glucoside in warm glacial acetic acid containing a little *p*-nitrosodimethylaniline as an oxidising agent, glistening leaflets of indigotin, which have a bronze reflex, quickly separate. Hydrolysis of the glucoside in warm 3%

hydrochloric acid in the presence of isatin gives a quantitative yield of indirubin, which separates in microscopic red prisms, whilst, with *p*-nitrobenzaldehyde, the liberated indoxyl forms *p*-nitrobenzaldehydeindogenide, which crystallises from acetone in red, prismatic needles, m. p. 273—274°.

The author wishes to express his thanks to the Chemical Society for a grant which has partly defrayed the cost of this investigation.

THE UNIVERSITY, MANCHESTER. [*Received, June 16th*, 1927.]

CCLII.—*Reactions of Displacement in the Tropic Acid Group. Part II.*



BY CARL ALOYSIUS KERR.

IN Part I, the action of sodium carbonate and of concentrated aqueous ammonia on *l*-β-chlorohydratropic acid, $CH_2Cl{\cdot}CHPh{\cdot}CO_2H$, was examined by McKenzie and Strathern (J., 1925, **127**, 82), and it now seemed of interest to prepare the optically active chlorotropic acid, $OH{\cdot}CH_2{\cdot}CPhCl{\cdot}CO_2H$, and to effect the displacement of the chlorine atom in this acid by other groups. The actions of alkali, moist silver oxide, ammonia, and reducing agents on both the active and the inactive acid were marked out for study. Moreover, the displacement of chlorine by hydrogen obviously called for inquiry, since such a change has been investigated only rarely in connexion with the Walden inversion, for example, in the reduction of *l*-chloromalic acid to *d*-malic acid (Kuhn and Zell, *Ber.*, 1926, **59**, 2514).

The preparation of *r*-chlorotropic acid is described by Ladenburg and Rügheimer (*Ber.*, 1880, **13**, 373), who acted on atropic acid with a dilute solution of hypochlorous acid, prepared by passing chlorine into a suspension in water of freshly precipitated, yellow mercuric oxide. The author has found that this acid can be more conveniently prepared by the action of monochlorourea on atropic acid, according to the equation $CH_2{:}CPh{\cdot}CO_2H + NH_2{\cdot}CO{\cdot}NHCl + H_2O = OH{\cdot}CH_2{\cdot}CPhCl{\cdot}CO_2H + CO(NH_2)_2$. Monochlorourea has been successfully used by Detœuf (*Bull. Soc. chim.*, 1922, **102**, 176) in the preparation of the chlorohydrins of unsaturated substances, and was found in the present case to give nearly 80% yields of chlorotropic acid. The resolution of chlorotropic acid into its active components can be accomplished by means of morphine, with methyl alcohol as solvent. *d*-Chlorotropic acid has $[\alpha]_D^{18°} = +12{\cdot}6°$ for $c = 3{\cdot}025$ in methyl alcohol, and melts at

123—124°, whereas the *r*-acid has m. p. 129—130°. The rotations of chlorotropic acid in acetone and in water were considerably lower than in methyl alcohol. The first mother-liquor in the resolution contained an excess of the morphine salt of *l*-chlorotropic acid, and by five recrystallisations of this salt from methyl alcohol a morphine salt resulted which gave *l*-chlorotropic acid with $[\alpha]_D^{15°} = -12{\cdot}4°$ in methyl alcohol ($c = 3{\cdot}586$).

The action of sodium carbonate or caustic soda on *r*-chlorotropic acid gave as a main product atroglyceric acid, $OH{\cdot}CH_2{\cdot}CPh(OH){\cdot}CO_2H$, m. p. 144—145°, as well as a small quantity of a neutral oil which corresponded with the formula $C_8H_8O_2$ but could not be identified with the amount in hand. Aqueous ammonia with chlorotropic acid gave, as was expected, a chlorine-free nitrogenous substance, proved to be α-amino-β-hydroxy-α-phenylpropionic acid. *d*-Chlorotropic acid (1 mol.) when treated with moist silver oxide (2 mols.) gave *r*-atroglyceric acid, with only slight formation of the yellow neutral oil noticed in the case of alkali. The following changes can be brought about:

The action of sodium carbonate solution and of moist silver oxide on *d*-chlorotropic acid led to the formation, in both cases, of optically inactive atroglyceric acid. Such complete racemisation was not to be expected, especially in the case of silver oxide, but a similar case of complete racemisation is to be found in the action of water on *l*-α-chloro-α-phenylpropionic acid and of nitrous acid on *l*-α-amino-α-phenylpropionic acid (McKenzie and Clough, J., 1910, **97**, 1016; 1912, **101**, 390), which compounds are closely allied in structure to chlorotropic acid.

The action of concentrated ammonia on *d*-chlorotropic acid gave, on the other hand, a dextrorotatory α-amino-β-hydroxy-α-phenylpropionic acid with $[\alpha]_D^{16°} = +40{\cdot}6°$ ($c = 6{\cdot}208$) in hydrochloric acid solution. The optical purity of the amino-acid was considered to be high, but the complete proof that the optically pure acid was actually isolated was lacking owing to the difficulty of finding a suitable solvent for it. In the displacement of chlorine by the amino-group, no such extensive racemisation took place as in the formation of *r*-atroglyceric acid from *d*-chlorotropic acid. Explanation of the latter racemisation cannot be traced to the rotatory power of atroglyceric acid being low, as this acid is at present being resolved and is known to have a fairly high specific rotation.

The conversion of *r*-chlorotropic acid into tropic acid by means

of reducing agents was not accomplished, and this is in agreement with the work of McKenzie and Wood (J., 1919, **115**, 828), who found that this conversion could not be effected in the manner described by Ladenburg and Rügheimer (*loc. cit*).

EXPERIMENTAL.

Chlorotropic Acid.—Atropic acid, prepared from tropic acid by Raper's method (J., 1923, **123**, 2558), had m. p. 107—108° when recrystallised from methyl alcohol. Monochlorourea was prepared by Detœuf's method (*loc. cit.*) and its strength estimated by titration with potassium iodide and thiosulphate. Atropic acid (27 g.; 1 mol.) was mixed with 135 c.c. of water, containing 2 c.c. of glacial acetic acid, and monochlorourea solution (1½ mols.) was added. With continuous stirring for 24 hours, most of the atropic acid went into solution, the remainder going pasty. The pasty atropic acid was filtered off, washed free from chlorotropic acid with water, and recrystallised from rectified spirit; 8 g. of atropic acid were recovered. The filtrate and washings were acidified with dilute sulphuric acid and sulphurous acid was added until no reaction with starch–iodide paper was shown. The excess of sulphur dioxide was removed by boiling and the solution extracted seven times with ether. Yield, 18 g. of crude chlorotropic acid. In previous work (Ladenburg and Rügheimer, *loc. cit.*; McKenzie and Wood, *loc. cit.*), chlorotropic acid was purified by washing with cold benzene, but it was found better to recrystallise it from chloroform. Yield, 16 g. of chlorotropic acid, m. p. 129—130°.

Attempted Conversion of Chlorotropic Acid into Tropic Acid.—Ladenburg and Rügheimer (*loc. cit.*) record the reduction of chlorotropic acid with zinc and iron filings in concentrated alkali, but McKenzie and Wood (*loc. cit.*) failed to effect the reduction either by this means or by means of sodium amalgam, zinc and hydrochloric acid, or caustic soda and aluminium. 3 G. of chlorotropic acid, made into a paste with 20 g. of moist copper–zinc couple, were treated with concentrated hydrochloric acid and the mixture was heated on a water-bath for 4 hours. The sludge was separated by decanting off the liquid, and then washed with hot water. Four ether extractions of the acid liquor and washings gave a yellow oil which crystallised on standing. After two recrystallisations from hot chloroform, the crystals melted at 117—122°, but a mixture with pure tropic acid (m. p. 117—118°) had a m. p. 90—93°. After heating 3 g. of chlorotropic acid, 10 g. of copper–zinc, and 100 c.c. of hydrochloric acid (4*N*) for 23 hours, and isolating the product as before, 2 g. of white solid, containing chlorine, and of m. p. 114—116°, were isolated from the ethereal extracts. A fractional

crystallisation of this substance from water gave 0·7 g. of chlorotropic acid (m. p. 128—130°). 3 G. of chlorotropic acid, 50 c.c. of water, and an excess of zinc foil were kept in a platinum basin for two months and then treated with an excess of dilute sulphuric acid. The yellow oil obtained by extraction with ether crystallised to give a solid, m. p. 105—117°, which contained chlorine.

Action of Sodium Hydroxide on r-*Chlorotropic Acid.*—3 G. of chlorotropic acid were neutralised with 155 c.c. of caustic soda (*N*/10), and 154 c.c. of caustic soda further added with a drop of phenolphthalein. After 1 hour's heating on the water-bath the colour of the indicator faded. The cooled mixture was made alkaline, and the neutral oil removed by extraction with ether four times. Yield, 0·5 g. The alkaline solution was made acid with dilute sulphuric acid and extracted five times with ether. From the dried ethereal extracts, 1·1 g. of crystalline acid were obtained, which furnished 0·7 g. of an acid, m. p. 141—145°, when recrystallised from hot ethyl acetate. A second recrystallisation from the same solvent gave 0·5 g. of atroglyceric acid, m. p. 145—147°, (Fittig and Kast, *Annalen*, 1881, **206**, 32, give m. p. 146°) (Found: C, 59·3; H, 5·6. Calc., C, 59·3; H, 5·5%).

Action of Sodium Carbonate on r-*Chlorotropic Acid.*—2 G. of chlorotropic acid were neutralised with approximately *N*-sodium carbonate (9 c.c.), a drop of phenolphthalein was added, and a further 8·5 c.c. of sodium carbonate were run in. After 10 minutes on the water-bath, the colour of the indicator was discharged, and boiling was continued for 20 minutes. The cooled mixture, made alkaline, was extracted with ether to remove a small quantity of neutral oil. Five ether extractions of the acidified liquor gave 1 g. of solid, m. p. 130—138°, which, after recrystallisation from water, had m. p. 144—145°. It was chlorine-free and identified as atroglyceric acid.

α-*Amino*-β-*hydroxy*-α-*phenylpropionic Acid.*—A solution of 3 g. of chlorotropic acid in 50 c.c. of concentrated ammonia, saturated at 0°, was kept in a stoppered bottle for 7 days at the ordinary temperature, and then transferred to a crystallising dish. After 16 hours' standing, 2·2 g. of an acid, washed free from ammonium chloride by water, were separated. The acid was chlorine-free, gave no ammonia with caustic alkali, and behaved as an amino-acid, being soluble in acid and in alkali. It was purified by dissolving it in caustic soda and making the solution exactly neutral with hydrochloric acid. A yield of 1·3 g. of pure acid was obtained from 1·4 g. of crude acid. α-*Amino*-β-*hydroxy*-α-*phenylpropionic acid* has m. p. 285—288° (decomp.) and is insoluble in the commoner organic solvents and in water (Found: C, 59·8; H, 6·0. $C_9H_{11}O_3N$

requires C, 59·7; H, 6·1%). Its *hydrochloride* separates in rhombic prisms, m. p. 225° (decomp.).

Preparation of Optically Active Chlorotropic Acid.—A solution of 30 g. of chlorotropic acid in 300 c.c. of hot methyl alcohol was added to a solution of 45 g. of morphine in 3400 c.c. of methyl alcohol, and the mixture heated just to boiling. On cooling, crystallisation began, and after 18 hours the resulting 45 g. of very fine needles were dissolved by heating in 3750 c.c. of methyl alcohol. On concentration to 1850 c.c., the solution, after 48 hours, gave 24 g. of crystals which were dissolved by heating with 2500 c.c. of methyl alcohol. The solution was concentrated to 1250 c.c. and after 24 hours 15 g. of morphine chlorotropate, crystallising in fine needles, were separated. The acid was obtained by acidification with dilute sulphuric acid and extraction with ether. Yield, 5·8 g. with $[\alpha]_D^{18°} = +11·2°$ ($c = 3·5565$) in methyl alcohol. Three successive crystallisations of this dextro-acid from chloroform gave acids with the following rotations in methyl alcohol: $[\alpha]_D^{17°} = +12·0°$ ($c = 3·052$), $[\alpha]_D^{18°} = +12·5°$ ($c = 3·1245$), $[\alpha]_D^{18°} = +12·6°$ ($c = 3·025$). The pure d-*chlorotropic acid* has therefore $[\alpha]_D^{18°} = +12·6°$ ($c = 3·025$) in methyl alcohol. It melts at 123—124° (Found: C, 53·8; H, 4·5. $C_9H_9O_3Cl$ requires C, 53·8; H, 4·5%). The first mother-liquor in the resolution was evaporated to small bulk, and 29 g. of morphine salt were separated. This was recrystallised five times from methyl alcohol, and the resulting salt on decomposition gave l-*chlorotropic acid* with $[\alpha]_D^{15°} = -12·4°$ ($c = 3·586$) in methyl alcohol.

Action of Sodium Carbonate on d-*Chlorotropic Acid.*—1 G. of dextrorotatory chlorotropic acid, with $[\alpha]_D^{16°} = +10·3°$ in methyl alcohol, was neutralised with 7·4 c.c. of sodium carbonate (0·5745*N*) and 7·2 c.c. of the alkali were further added, with a drop of phenolphthalein. After heating for 10 minutes on the water-bath, the solution became colourless; it was made alkaline, and the neutral oil removed by extraction with ether. The solution was acidified with dilute sulphuric acid, and the acid extracted with ether. 0·3 G. of chlorine-free solid was obtained. This was atroglyceric acid and it was quite inactive ($c = 2·618$) in methyl alcohol.

Action of Silver Oxide on d-*Chlorotropic Acid.*—1 G. (1 mol.) of dextrorotatory chlorotropic acid with $[\alpha]_D^{16°} = +10·3$ in methyl alcohol, and the silver oxide obtained from 1·7 g. (2 mols.) of silver nitrate by precipitation with caustic soda, were mixed with 50 c.c. of water and stirred mechanically for 2 hours. After 60 hours at the ordinary temperature, the mixture was heated for ½ hour, and the silver chloride removed by precipitation with hydrochloric acid. By extraction of the filtrate with ether 0·2 g. of solid, m. p. 143—

146°, was obtained. A mixture of this with atroglyceric acid had m. p. 143—145°, and therefore the substance was atroglyceric acid. It was completely inactive ($c = 1{\cdot}764$) in methyl alcohol.

Action of Aqueous Ammonia on d-*Chlorotropic Acid.*—A solution of 1 g. of *d*-chlorotropic acid with $[\alpha]_D^{18^\circ} = +12{\cdot}6^\circ$ in methyl alcohol, in 10 c.c. of concentrated ammonia, saturated at 0°, was kept in a stoppered bottle for 10 days and then transferred to a crystallising dish. After 3 days, all the solvent had evaporated and the remaining solid was washed free from ammonium chloride and dried. Yield, 0·6 g. of α-amino-β-hydroxy-α-phenylpropionic acid. The rotation of the amino-acid was $[\alpha]_D^{16^\circ} = +40{\cdot}6^\circ$ in *N*-hydrochloric acid ($c = 6{\cdot}208$). Failure attended the attempts to raise the rotation of this acid, either by repeated precipitation from its solution in caustic soda by means of hydrochloric acid, or by recrystallisation from concentrated aqueous ammonia. A saturated solution of ammonia in *sec.*-octyl alcohol does not convert chlorotropic acid into the corresponding amino-acid.

The author desires to thank the Carnegie Trust for a grant which defrayed part of the cost of the material used, and to acknowledge the helpful interest shown by Professor A. McKenzie, F.R.S.

UNIVERSITY COLLEGE, DUNDEE,
UNIVERSITY OF ST. ANDREWS. [*Received, June 17th,* 1927.]

CCLIII.—*Methylmercuric Halides and Hydroxide.*

By LEONARD ERIC HINKEL and THOMAS HUBER ANGEL.

AN attempt to repeat Marvel and Gould's preparation of methylmercuric iodide by the action of magnesium methyl iodide upon an excess of mercuric chloride suspended in ether (*J. Amer. Chem. Soc.*, 1922, **44**, 153) resulted only in the production of the double compound $CH_3{\cdot}HgCl,2CH_3{\cdot}HgI$ and a small quantity of methylmercuric chloride. If the Grignard reagent was added very slowly to the suspension of mercuric chloride, a copious precipitate of mercuric iodide soon formed, which readily dissolved on further addition of the reagent. The formation of mercuric iodide can be explained by assuming that the methylmercuric iodide produced by reaction (1) reacts with the excess of mercuric chloride in accordance with equation (2).

$$CH_3{\cdot}MgI + HgCl_2 = CH_3{\cdot}HgI + MgCl_2 \quad . \quad . \quad . \quad (1)$$

$$2CH_3{\cdot}HgI + HgCl_2 = 2CH_3{\cdot}HgCl + HgI_2. \quad . \quad . \quad (2)$$

In support of this assumption, it was found that the latter reaction occurs readily in alcoholic or ethereal solution. The subsequent

solution of mercuric iodide on further addition of the Grignard reagent is explained by their interaction as represented by the equation (3).

$$CH_3{\cdot}MgI + HgI_2 = CH_3{\cdot}HgI + MgI_2 \quad . \quad . \quad . \quad (3)$$

This reaction proceeds smoothly and serves as a convenient method for the preparation of methylmercuric iodide in quantity. The fact that the double compound $CH_3{\cdot}HgCl,2CH_3{\cdot}HgI$ was obtained instead of methylmercuric iodide in the repetition of Marvel and Gould's experiment adds further support to the above assumption, since it was observed that from a hot alcoholic solution of methylmercuric chloride and iodide the stable double compound crystallised on cooling. The double compound is converted by mercuric chloride into methylmercuric chloride, and it is probable that the small amount of the latter which was found associated with the double compound in the original reaction product owed its origin to this cause, since the amount formed increased with the excess of mercuric chloride originally employed. From a consideration of these facts, it would appear impossible to obtain methylmercuric iodide under the conditions of Marvel and Gould.

Methylmercuric hydroxide has long been known in solution (Frankland, *Annalen*, 1853, **85**, 368; Dunhaupt, *ibid.*, 1854, **92**, 381; *J. pr. Chem.*, 1854, **61**, 399; Crymble, J., 1914, **105**, 666), but it was first isolated in the solid form by Sneed and Maynard (*J. Amer. Chem. Soc.*, 1922, **44**, 2946) from methylmercuric iodide and moist silver oxide in the presence of a small amount of alcohol.

Sneed and Maynard's method of purification of the base—precipitation from saturated alcoholic solution with a large excess of dry ether—is very wasteful, for large quantities of ether are necessary, the base undergoes much decomposition in its presence, and five repetitions of the process do not effect complete purification (m. p. 104°). A method is now described whereby the purification can be efficiently and rapidly achieved without loss of material. The pure base so obtained differs from that prepared by Sneed and Maynard both in melting point and in solubility.

Experimental.

Action of Magnesium Methyl Iodide on Mercuric Chloride.—The Grignard reagent prepared from 2·4 g. of magnesium was added to 30 g. of finely powdered mercuric chloride suspended in 250 c.c. of dry ether under the conditions described by Marvel and Gould (*loc. cit.*). The crude product was crystallised from hot thiophen-free benzene and then fractionally from methyl alcohol, the less soluble mercuric iodide and methylmercuric chloride being thereby removed; the final product was obtained in small, pearly leaflets, m. p. 129°

(Found: Cl, 4·0; I, 27·1. $C_3H_9ClI_2Hg_3$ requires Cl, 3·8; I, 27·0%). The double compound differs from methylmercuric chloride in having a much more intense and unpleasant odour.

Methylmercuric iodide was prepared under the conditions previously described, mercuric chloride being replaced by the equivalent amount of mercuric iodide. The product crystallised from methyl alcohol in transparent, rectangular plates melting at 145° and not 143° as stated in the literature (Found: I, 36·9. Calc.: I, 37·05%).

Methylmercuric Hydroxide.—Methylmercuric iodide (10 g.) in 50 c.c. of methyl alcohol and 2 c.c. of water was mechanically agitated for 3 hours with 7 g. of moist silver oxide containing 34% of water. The filtered solution was evaporated to dryness in a vacuum at 40°, the white residue warmed to 30° with 20 c.c. of chlorobenzene, in which it was very sparingly soluble, and alcohol added until solution was just effected, the temperature being kept at 30°; the alcohol was then removed in a vacuum over sulphuric acid, and the base, which separated in small crystals, was drained from the chlorobenzene and washed with light petroleum (previously treated with alcoholic potassium hydroxide to remove sulphur compounds, since these react readily with methylmercuric hydroxide). This process of purification was repeated several times; the base then obtained, after drying in a vacuum, melted at 106° (Found, by Rupp and Nöll's method, Meyer's "Lehrbuch der Organisch-Chemischen Methodik," 1922, p. 359: Hg, 86·0. Calc. for CH_4OHg: Hg, 86·2%). The pure base forms white crystals with a pearly lustre having a faint, unpleasant odour. It decomposes slowly on standing, more rapidly in presence of ether. When heated above its melting point, it partly decomposes and then detonates violently. Contrary to the statements of Sneed and Maynard, it is very sparingly soluble in cold benzene, toluene, carbon tetrachloride, and light petroleum.

The authors desire to thank Professor J. E. Coates for his constant help and interest in this investigation.

UNIVERSITY COLLEGE, SWANSEA. [*Received, June 1st*, 1927.]

CCLIV.—*The Alkaloids of* Picralima Klaineana.

By THOMAS ANDERSON HENRY and THOMAS MARVEL SHARP.

IN December, 1923, we received from the Imperial Institute a supply of "Akuamma" seeds which had been forwarded by the Department of Agriculture in the Gold Coast Colony, accompanied by herbarium specimens of the plant, which had been identified

by the Director of the Royal Botanic Gardens, Kew, as those of *Picralima Klaineana*, Pierre. A full account of the botany of the plant and of the use of the seeds as a febrifuge in native medicine has been published by Holmes (*Pharm. J.*, 1915, **41**, 758; 1922, **55**, 478). Last year Frère Just Gillet, Curator of the Botanical Gardens at Kisantu, Belgian Congo, sent us a small supply (300 g.) of seeds which also were identified at Kew as derived from a species of Picralima, probably *P. Klaineana*. In spite of its reputation as the source of a useful drug, at least among African natives, *P. Klaineana* does not seem to be widely distributed and Frère Gillet reports that he had to make a tedious journey of some 30 leagues to collect his small sample. We are therefore the more indebted to the authorities of the Imperial Institute and in particular to the officers of the Department of Agriculture in the Gold Coast Colony, for the supplies of seed we have examined.

Beyond the preliminary work referred to in the articles by Holmes (*loc. cit.*), there appeared, when we began this work, to be no record of the chemical examination of any species of *Picralima*, but two papers have been published recently by Clinquart (*Bull. Acad. Roy. Med. Belge*, 1926, 492; *J. Pharm. Belg.*, 1927, **9**, 187) giving results of a preliminary examination of the seeds, bark and leaves also supplied by Frère Gillet. Clinquart obtained a few centigrams of a crystalline alkaloid, m. p. 242—243°, and a large amount of an amorphous alkaloid. The behaviour of these two alkaloids with the usual precipitants and colour-producing reagents is described, but no attempt is made to characterise either alkaloid or its salts in detail. In view of the publication of these two papers it has been considered desirable to place on record the data now presented. The seeds of *P. Klaineana* contain at least four alkaloids, two of which have been crystallised. Only one of these has so far been obtained in sufficient quantity for characterisation and this, which is no doubt identical with Clinquart's crystalline base, it is proposed to call *akuammine* from "akuamma," one of the native names of *P. Klaineana* in the Gold Coast. Akuammine has the formula $C_{22}H_{28}O_4N_2$, yields a series of well-crystallised salts, gives a number of characteristic colour reactions with aromatic aldehydes in presence of hydrochloric acid, and contains one methoxyl, one hydroxyl, and one methylimino-group. The last probably represents a tertiary nitrogen atom, since akuammine furnishes a well-crystallised *monomethiodide*, which decomposes on heating, evolving a fishy odour, doubtless due to dimethylamine. The alkaloid does not react with semicarbazide or other reagents for carbonyl groups and no evidence of a methylenedioxy-group is afforded with Gaebel's reagent. The state of the remaining nitrogen has not been ascer-

tained; on treatment in hydrochloric acid solution with sodium nitrite, a scarlet hydrochloride is formed, which does not give Liebermann's nitrosoamine reaction and appears to be a nitro-derivative of akuammine. Akuammine is converted by alkalis under certain conditions into a *monohydrate*, which crystallises with some difficulty. The latter is also formed on hydrolysis of acetylakuammine by alkali, and an O-*methyl* derivative of the monohydrate appears to be produced when akuammine is treated with methyl iodide in presence of alkali. One or both of the remaining oxygen atoms are no doubt involved in these changes.

The other three alkaloids, referred to subsequently as A, B, and D, we propose to examine fully as soon as material is available. Names are not suggested for them, as they may prove to be related to akuammine, in which case it may not be necessary to add to the already large trivial nomenclature of alkaloids. Alkaloid D is remarkable in having a specific rotation of $-737°$ in alcohol or chloroform. Neither A nor B has yet been obtained crystalline.

Both the Congo and the Gold Coast seeds yield akuammine and alkaloids A and B, but only one sample of Gold Coast seeds has so far yielded alkaloid D.

EXPERIMENTAL.

The finely ground seeds were extracted in a copper Soxhlet apparatus first with petroleum, b. p. 60—80°, to remove fat and then with 96% alcohol. The alcoholic extract was taken to dryness under reduced pressure, and the residue treated with successive quantities of 2% hydrochloric acid until alkaloid was no longer removed. The mixed acid liquors were shaken out with ether to remove resinous and waxy impurities and then diluted with water until no further precipitation took place. The precipitate at this stage consists of a weakly basic alkaloid or mixture of alkaloids (A), from which no crystalline material has so far been obtained. The filtrate from this was digested with charcoal for 1 hour on a water-bath, filtered, allowed to cool, and then treated with saturated sodium carbonate solution in excess; this precipitated a mixture of alkaloids as a brown powder, which was collected, washed with hot water, and dried in a vacuous desiccator. The dry mixture was then extracted with ether in a Soxhlet apparatus and so separated into a further quantity of material apparently identical with (A), which remained undissolved in the extractor, and a partly crystalline powder, which gradually accumulated in the extraction flask. When the ether ceased to extract alkaloid, the solvent was distilled off and the dry residue macerated with twice its weight of alcohol, which dissolved a second amorphous alkaloid (B), and left a partly

crystalline residue of crude akuammine (alkaloid C). The latter was collected, washed with a little alcohol, allowed to dry in the air, and then treated with a slight excess of *N*-sulphuric acid (2·8 c.c. approx. per gram) and sufficient water to dissolve it on boiling. The hot solution was treated with charcoal and filtered. On cooling, thin, colourless needles (m. p. 214—218°) of crude akuammine sulphate separated. The mother-liquor on concentration in a vacuous desiccator deposited more of the same sulphate, but finally dried up to a brown varnish. From this, by solution in dry alcohol, a further crop of akuammine sulphate can be obtained, but eventually an amorphous residue of the sulphate of alkaloid B is left. If ammonia solution is used in place of sodium carbonate for precipitation, the residue left after the removal of most of the akuammine sulphate sets to a jelly due to the presence of the sulphate of a hydrate of akuammine formed by the action of ammonia on this alkaloid as described later (p. 1958).

The cold alcoholic extract of the ether-soluble portion of the precipitated alkaloids was taken to dryness under reduced pressure, dissolved in sufficient *N*-sulphuric acid to form a faintly acid solution, and to this was added a saturated aqueous solution of sodium iodide in water until no further precipitation occurred. After standing for a week, the clear liquor was poured off and the mixture of tar and crystalline matter that had separated was triturated with a little cold absolute alcohol, which dissolved the tar and left a small quantity of akuammine hydriodide. The alcoholic washings were added to the mother-liquors, and the whole was fractionally precipitated with sodium carbonate solution, the first few drops of precipitant serving to remove a dark brown, sticky base, from which a clear pale yellow mother-liquor was poured off. This on further addition of sodium carbonate solution yielded the crude alkaloid (B) as a pale yellow powder, m. p. 104° (air-dry) or 167° (dried in a vacuum).

The seeds received from the Imperial Institute consisted of several samples collected at different times, and from one of these, on recrystallisation of the crude akuammine sulphate as described above, the first fraction consisted of the well-crystallised sulphate of alkaloid (D) (p. 1958). As only 2 g. of this alkaloid have been obtained, it has been considered advisable to conserve it for the present and only to make such observations upon it as would not entail the loss of material. It is therefore only possible to put its chief characteristics on record.

The quantity of alkaloids present in *P. Klaineana* seeds is more than 5%, but the exact amount cannot be determined by any of the ordinary methods of estimation, because the alkaloids cannot

be precipitated completely from solution in acids by alkalis, nor can the alkaloid left in such alkaline filtrate be completely removed by any of the ordinary immiscible solvents. The yield of crude akuammine is about 0·6%. The four alkaloids are readily differentiated by their physical properties and colour reactions. Alkaloid A is insoluble in all ordinary solvents except acids and alkalis, and from these it is precipitated on dilution with water. Alkaloid B is readily soluble in all ordinary solvents except water, and solutions of its salts, unlike those of any of the other three, give an intense indigo-blue colour with ferric chloride. Akuammine (alkaloid C) dissolves in concentrated sulphuric acid without coloration, but gives an intense blood-red colour, stable for several days, with nitric acid. The second crystalline alkaloid (D) gives no colour with sulphuric acid but a vivid green, fading to yellow in a few hours, with nitric acid.

In the following descriptions, the " melting points " are corrected; in each case, except for akuammine hydrate, they are points at which the substance froths up the tube. The temperature at which this occurs varies with the rate of heating, *e.g.*, pure akuammine hydrochloride can be made to melt and decompose at any temperature from 215° to 227°. The melting points recorded for the base and its salts were taken alongside the pure hydrochloride, melting at 227°, so that they are comparable among themselves. The optical rotations are for the dried substance in each case.

Akuammine (Alkaloid C).

The base is prepared by adding excess of sodium carbonate solution to a warm, aqueous solution of a purified salt. It is sparingly soluble in cold alcohol, but once dissolved in boiling alcohol it crystallises from the latter only by spontaneous evaporation in minute, colourless needles, m. p. 255°, $[\alpha]_D^{20°}$ −66·7° (in alcohol; c = 0·504) or −73·4° (in chloroform; c = 0·8716). It is rather more soluble in chloroform and sparingly soluble in acetone or ether (Found: C, 69·0, 69·1; H, 7·2, 7·0; N, 7·5. $C_{22}H_{28}O_4N_2$ requires C, 68·7; H, 7·3; N, 7·3%).

Akuammine hydrobromide, prepared like the sulphate (see above), separates from dilute hot aqueous or alcoholic solutions in faintly grey, long, slender prisms, or from concentrated solutions in the same solvents in small needles, m. p. 228°, $[\alpha]_D^{20°}$ −26·05° (in water; c = 0·6076). The air-dry salt loses in a vacuous desiccator 3·61% and no further loss takes place in a vacuum at 100°. (Calc. for $C_{22}H_{28}O_4N_2,HBr,H_2O$: H_2O, 3·7%. Found for dry salt: C, 56·1, 56·3; H, 6·0, 6·1; Br, 16·6. $C_{22}H_{28}O_4N_2,HBr$ requires C, 56·7; H, 6·3; Br, 17·1%). The *hydrochloride* closely resembles the

hydrobromide in appearance, but is of paler colour and rather more soluble in water or alcohol. It has m. p. 227° and $[\alpha]_D^{20°}$ −26·6° (in water; $c = 0{\cdot}8769$) or −32·8° (in alcohol; $c = 1{\cdot}716$) and crystallises with one molecule of water (Found: loss in a vacuum at 120°, 4·0. $C_{22}H_{28}O_4N_2,HCl,H_2O$ requires H_2O, 4·1%. Found for dry salt: C, 62·5, 62·6; H, 6·9, 6·7; N, 7·1; Cl, 8·5, 8·4. $C_{22}H_{28}O_4N_2,HCl$ requires C, 62·7; H, 7·0; N, 6·6; Cl, 8·4%). The *sulphate*, prepared as described above, crystallises from hot water or hot alcohol in rosettes of flattened needles, which rapidly become red on exposure to light. It melts at 221° and has $[\alpha]_D^{19°}$ −40·3° (in water; $c = 2{\cdot}0868$). The salt is abnormal in composition, crystallises with 10 molecules of water of crystallisation, of which 9 are lost at atmospheric temperature in a vacuous desiccator over calcium chloride. Loss (*a*) from air-dry salt at 100° in a vacuum, 11·5; (*b*) from salt previously dried to constant weight in a vacuous desiccator, 1·8. $(C_{22}H_{28}O_4N_2)_3,2H_2SO_4$, for $10H_2O$, requires H_2O 11·8%, and for $1H_2O$ 1·3% [Found for dry salt: C, 58·8; H, 6·7; S, 4·45. $(C_{22}H_{28}O_4N_2)_3,2H_2SO_4$ requires C, 58·7; H, 6·5; S, 4·7%]. This may be a double compound consisting of one molecule of the acid salt with one molecule of the normal salt (B,H_2SO_4; B_2,H_2SO_4). In this connexion, it may be noted that another dibasic acid, *viz.*, oxalic acid, yields at least three salts, which, however, have not been satisfactorily separated.

The *hydriodide* is precipitated as a crystalline powder on adding potassium iodide to even a dilute solution in water of any soluble salt of akuammine. It cannot be crystallised from hot water without decomposition, but separates from hot alcohol in anhydrous, minute, pale grey needles, m. p. 226° (Found: C, 52·0; H, 6·0. $C_{22}H_{28}O_4N_2,HI$ requires C, 51·5; H, 5·7%).

The *nitrate*, also prepared by precipitation, crystallises from boiling alcohol in pale cream-coloured needles, m. p. 224°. The *thiocyanate*, similarly prepared, crystallises from alcohol in pale greyish needles, m. p. 218°. The *perchlorate*, precipitated by addition of sodium perchlorate to a solution of the hydrochloride in water, crystallises from hot alcohol in colourless, spheroidal granules, m. p. 215°, if the solution is concentrated, and from more dilute solutions in colourless needles also melting at 215°. This salt becomes pink on exposure to air and resinous after several crystallisations from boiling alcohol. The *picrate* crystallises from hot alcohol in rosettes of brilliant yellow needles, m. p. 199°. The *picrolonate*, precipitated in minute, yellow needles, darkens at 160° and froths at 194°. On dissolution in hot alcohol it deposits a deep blue dye.

No chloroaurate has been prepared, as akuammine hydrochloride,

reduces gold chloride immediately. It also reduces platinic chloride and silver nitrate in the cold and Fehling's solution on warming.

Methoxyl and methylimino-groups. Determinations of these groups were made on the base and the hydrochloride (Found for base : MeO, 8·87 ; NMe, 8·2. Calc. for MeO, 8·0 and for NMe, 7·5%. Found for hydrochloride : MeO, 7·73 ; NMe, 6·6. Calc. for MeO, 7·4 and for NMe, 6·9%).

Akuammine hydrochloride gives (1) a rose-red colour with vanillin or piperonal in presence of hydrochloric acid, (2) a yellowish-brown colour with dimethylaminobenzaldehyde (Ehrlich's reagent), changing on long standing to red with a green fluorescence, (3) with bromine water a pink colour, the solution becoming cloudy on further addition of bromine.

Action of methyl iodide on akuammine. The pure base does not dissolve in methyl iodide, but when suspended in the reagent the latter gradually contracts in volume and in about 2 days conversion into a *monomethiodide* appears to be complete. This separates from solutions in hot methyl alcohol in rosettes of colourless prisms, m. p. 274°. On melting, the substance froths vigorously and gives off a vapour with a fishy odour, probably due to dimethylamine. The methiodide in solution gives no precipitate with alkali hydroxides or carbonates and is therefore the iodide of a quaternary base (Found: C, 52·7 ; H, 5·7 ; I, 24·4 ; MeO, 6·8 ; NMe, 9·7. $C_{22}H_{28}O_4N_2,CH_3I$ requires C, 52·4 ; H, 5·9 ; I, 24·1 ; MeO, 5·9 ; 2NMe, 11·1%). The results for methoxyl are high and those for methylimino-groups low. In carrying out these estimations, it was noticed that elimination of methyl iodide in the second stage (methylimino-determination) began at the low temperature of 180°, immediately after addition of ammonium iodide, so that it appears likely that part of the methyl iodide collected in the earlier stage (methoxyl determination) is really due to methylimino-groups. The total amount of methyl iodide formed in the estimation, calculated from the amount of silver iodide weighed, was 79·07%, whilst there should be formed, assuming the presence of one methoxyl and two methylimino-groups, 80·9%. Cases in which there is no sharp distinction between the conversion of methoxyl and methylimino-groups into methyl iodide in such estimations have been observed previously, *e.g.*, in ergotoxine (Barger and Ewins, J., 1918, **113**, 235 ; a summary of literature on this subject is given on page 237).

Action of methyl iodide and alkali on akuammine. Akuammine base (1 g.) was dissolved in *N*-sodium methoxide solution in methyl alcohol (2·7 c.c.), and methyl iodide (4 c.c.) was added. This mixture, after standing for 4 days, was boiled for 4 hours. The liquid was taken to dryness under reduced pressure, and the residue

dissolved in boiling water, from which it separated on cooling as a colourless oil. The solution in water gives a precipitate of a new oily base on addition of sodium carbonate or alkali hydroxide. Neither the base nor any of its salts, except the picrate, have so far been induced to crystallise. The *picrate* is precipitated on adding picric acid in methyl alcohol to a solution of the base or the hydriodide in the same solvent, and can be crystallised either from boiling water or from methyl alcohol, producing in the former case canary-yellow needles or rosettes of needles and in the latter bronze-tinted, dense rosettes of prisms, both forms melting at 205° (Found : MeO, 10·0; NMe, 6·0. $C_{22}H_{29}O_5N_2\cdot CH_3,C_6H_3O_7N_3$ requires 2MeO, 9·6; NMe, 4·5%). These results agree with the assumption that in this reaction the akuammine is first hydrated by the alkali (see below) and that the hydrate undergoes *O*-methylation either on the hydroxyl group originally present in akuammine or on a new group formed in the hydration.

Acetylation of akuammine. The pure base (3·8 g.) was boiled for 5 minutes with acetic anhydride (10 c.c.), the solution left to cool, and the excess of reagent removed by distillation under reduced pressure. The residue was dissolved in water, the liquid poured into sodium carbonate solution, and the precipitate collected, sucked dry on the filter, and dissolved in the minimum quantity of boiling alcohol, from which it separated on cooling in rosettes of colourless prisms (yield, 2·4 g.), m. p. 226°. The melting point was not changed by recrystallisation. The concentrated mother-liquors, which had ceased to deposit crystals, were taken to dryness, the residue was dissolved in four times its weight of boiling *N*/2-hydrobromic acid, and the solution filtered hot. On cooling, it deposited a silky mass of hair-like needles, m. p. 236°, of *acetylakuammine hydrobromide* (yield, 1·1 g.), the melting point of which remained unchanged on recrystallisation. This hydrobromide on solution in boiling water and precipitation with sodium carbonate solution furnished the pure *base*, m. p. 226°. From the mother-liquors of the hydrobromide the rest of the acetylated base was precipitated as the *picrate* (0·5 g.), which crystallised with difficulty from concentrated solutions in methyl alcohol, in gelatinous masses of rosettes of minute, yellow needles, m. p. 168° after drying in air. The acetylated base becomes pink on exposure to air and has $[\alpha]_D^{20°}$ −52·08° ($c = 0·64$ in alcohol) (Found for the base : C, 67·5, 67·45; H, 6·9, 6·7; MeO, 9·3; NMe, 6·9; acetic acid formed on alkaline hydrolysis, 13·1. $C_{22}H_{27}O_4N_2\cdot CO\cdot CH_3$ requires C, 67·6; H, 7·1; MeO, 7·3; NMe, 6·8; acetic acid, 14·1%. Found for hydrobromide : C, 57·3, 57·1; H, 5·9, 6·0; Br, 15·95. $C_{22}H_{27}O_4N_2\cdot CO\cdot CH_3,HBr$ requires C, 56·8; H, 6·2; Br, 15·75%).

The base recovered from the acetic acid estimation appeared to be akuammine hydrate, m. p. above 300° (see below).

Action of alkalis on akuammine. Akuammine dissolves slowly in solutions of ammonia or alkali hydroxides, forming in the course of a few days dark brown liquids, which on neutralisation by acids deposit precipitates of a mixture of bases. For the examination of these products it has been found most convenient to treat akuammine with a known quantity of a normal solution of sodium ethoxide in alcohol, in which it dissolves immediately, keep the solution for several days, remove the alcohol, and treat the residue with water; the sodium derivatives presumably first formed and stable in alcohol are then almost completely dissociated, leaving a dark brown precipitate. The latter on digestion first with alcohol and then with chloroform is obtained as a nearly colourless powder, which does not sinter up to 300° and after heating to this temperature can usually be shaken out of the melting point tube as an orange-brown powder. The product is insoluble in all ordinary solvents, and is finally purified by dissolving it in a known quantity of sodium ethoxide in alcohol, adding sufficient alcohol to dilute the solution to a concentration of about 1 part in 5 parts, and then neutralising the filtered liquid with the calculated quantity of *N*/2-acetic acid; after a few minutes, practically the whole of the product crystallises in small, spheroidal granules of minute needles, which do not sinter or melt up to 310°. It dissolves immediately in solutions of ammonia or alkali hydroxides, but such solutions gelatinise when carbon dioxide is passed into them: the jelly can be filtered out and dries up to a brown powder having the characters of the original substance. The product appears to be an *akuammine hydrate* formed by addition of a molecule of water to akuammine (Found: C, 65·0, 65·1; H, 6·9, 6·8. $C_{22}H_{28}O_4N_2,H_2O$ requires C, 65·6; H, 7·5%). The yield in the above process has varied from 15 to 41% of the akuammine used. The by-products soluble in alcohol and chloroform are brown, amorphous substances soluble in alkalis, but they also form salts, *e.g.*, hydrobromides, which are sparingly soluble in cold water or saline aqueous solutions but very readily soluble in alcohol, acetone, or chloroform.

Base D.

The akuamma seeds used for this work consisted of a number of samples and from one of these the crude alkaloidal sulphates, prepared as described on p. 1953, on recrystallisation from water gave a fraction crystallising in colourless, transparent, flattened cubes. This *sulphate*, m. p. 161°, $[\alpha]_D^{14°}$ −594·1° ($c = 0·4226$ in water) or −539·8° ($c = 0·2860$ in water), contains 8·9% of water

of crystallisation, of which 2·4% is lost in a vacuous desiccator at atmospheric temperature. The *base*, obtained by adding sodium carbonate solution to an aqueous solution of the sulphate, crystallises from hot alcohol in brilliant, colourless leaflets, m. p. 177·5°, $[\alpha]_D^{19°}$ −737·5° (c = 0·4932 in alcohol), −737·7° (c = 0·3504 in chloroform). The *nitrate* forms colourless needles, m. p. 180—181°. The *picrate* can be crystallised by dissolving it in boiling chloroform and adding an equal volume of boiling alcohol. From this mixture on cooling, it separates in dull yellow needles, m. p. 169°.

Base D gives a grass-green coloration when a mere trace is added to a drop of concentrated nitric acid. Like akuammine, it gives colours with aromatic aldehydes in presence of hydrochloric acid, *viz.*, indigo-blue with vanillin and magenta with piperonal, both changing to bright ultramarine-blue after a few days and remaining stable for at least 14 days. The alkaloid gives no coloration with Gaebel's test for methylenedioxy-groups.

The authors are indebted to the late Mr. S. E. Pusey and to Messrs. L. Barnett and H. C. Clarke for much assistance in the extraction of the alkaloids and in the analyses of the various preparations described.

WELLCOME CHEMICAL RESEARCH LABORATORIES.

[*Received, July 11th*, 1927.]

CCLV.—*The Isomerism of the Oximes. Part XXXI. The Furfuraldoximes and 2-Methoxy- and 4-Methoxy-1-naphthaldoximes.*

By OSCAR LISLE BRADY and RICHARD FRANK GOLDSTEIN.

THE greater part of the study of the aldoximes from the point of view of stereoisomerism has been devoted to those in which the aldoximino-group is attached to the benzene ring. The stability of the α-isomeride in the benzaldoximes, in contrast with the aliphatic aldoximes where the β-form is the normal product, makes it of some interest to consider the effect of other ring systems on the relative stability of the two isomerides. The case of furfuraldoxime is of historic importance, since this was the first aldoxime to be obtained in two forms (Odernheimer, *Ber.*, 1883, **16**, 2988). Goldschmidt and Zanoli (*Ber.*, 1892, **25**, 2573) also prepared the two isomerides and determined their configuration, but thought they found indications of abnormal behaviour, since in the acetylation of the α-oxime and subsequent hydrolysis some furfuronitrile and a mixture of the two oximes were obtained. Similarly, Minunni

(*Gazzetta*, 1896, **26**, i, 463) obtained a mixture of oximes on hydrolysis of benzoyl-α-furfuraldoxime.

This work has now been repeated and the origin of the difficulties of previous workers traced to the fact that the α-oxime in the presence of hot solvents is partly converted into the β-isomeride, a phenomenon never observed in the benzaldoximes. With care, a crystalline acetyl-α-furfuraldoxime can be prepared; this on hydrolysis gives nearly pure α-furfuraldoxime, which can also be obtained by hydrolysis of the benzoyl compound and isolation of the oxime by special means. β-Furfuraldoxime is obtainable under conditions which will not give β-benzaldoxime, being much more stable than that compound. The furfuraldoximes accordingly occupy an intermediate position between the benzaldoximes and the aliphatic aldoximes.

No oximes of the naphthalene series have been investigated from the point of view of the stereochemical hypothesis, so 2-methoxy-1-naphthaldoxime and 4-methoxy-1-naphthaldoxime have now been studied. The products of oximation have the α-aldoxime structure and we have been unable to convert either into the β-isomeride. As they may both be regarded as *o*-substituted benzaldoximes, this was not unexpected. On methylation of 2-methoxy-1-naphthaldoxime, a mixture of *N*- and *O*-ethers was obtained, the former predominating; 4-methoxy-1-naphthaldoxime gave a mixture of about equal amounts of *N*- and *O*-ethers. Both oximes therefore differ markedly from the α-benzaldoximes in the relative amounts of *N*- and *O*-ethers produced on methylation.

Experimental.

α-Furfuraldoxime.—Furfuraldehyde (13·5 g.) was added slowly to a cold mixture of sodium hydroxide (14 g. in 15 c.c of water) and hydroxylamine hydrochloride (12 g. in 30 c.c. of water). After 1 hour, the solution was filtered and cooled in a freezing mixture and a slight excess of an ice-cold, saturated aqueous solution of ammonium chloride was slowly added with stirring. The crystalline precipitate was washed with a little ice-cold water and air-dried. The yield of crude oxime (m. p. 51—64°) was 11·5 g. After crystallising three times from benzene and light petroleum, 4 g. of pure α-oxime were obtained, m. p. 75—76° (Goldschmidt and Zanoli, *loc. cit.*, give 73°). The details must be carefully followed, otherwise an inseparable mixture of the two isomerides may be obtained. In one experiment, a crude oxime, m. p. 42—45°, was obtained and repeated crystallisations failed to raise the melting point above 48—52°. It is probable that the material (m. p. 49—56°) obtained by Odernheimer (*loc. cit.*) was a similar mixture. When the pure

α-oxime (0·5 g.) was boiled with benzene (20 c.c.) under reflux for 4 hours and the solvent evaporated, a product, m. p. 47—48°, was obtained which was apparently a mixture of the α- and β-isomerides, since the addition of either raised its melting point.

Acetyl-α-furfuraldoxime.—α-Furfuraldoxime (2·5 g.) was slowly added to acetic anhydride (12 c.c.), and warmed to 30°; it then dissolved. On decomposing the excess of anhydride with 2*N*-sodium carbonate, crystals separated which were collected, air-dried, and dissolved in warm light petroleum; on cooling the solution to — 20° or — 40°, *acetyl-α-furfuraldoxime* separated in colourless prisms, m. p. 34—35° (Found: N, 9·4. $C_7H_7O_3N$ requires N, 9·2%). The acetyl derivative was warmed with 2*N*-sodium hydroxide until it dissolved; there was no odour of furfuronitrile. On cooling the solution, adding saturated ammonium chloride solution, extracting the mixture twice with ether, and evaporating the solvent with a current of air, an oxime was obtained which, after being pressed on a porous tile, melted at 69—72° and was nearly pure α-oxime. Goldschmidt and Zanoli (*loc. cit.*) obtained on acetylation an oil which on hydrolysis gave some furfuronitrile and an oxime, m. p. 49—60°.

Benzoyl-α-furfuraldoxime.—Crude α-furfuraldoxime, m. p. 51—57° (7 g.) was slowly added with cooling to benzoyl chloride (30 g.) and the product was poured into 2*N*-sodium hydroxide (250 c.c.), vigorously shaken for 30 minutes, and kept for 12 hours. The benzoyl derivative which separated was crystallised three times from alcohol; it then melted at 138—139° (compare Minunni, *loc. cit.*). The benzoyl derivative (5 g.) was heated with 2*N*-sodium hydroxide (50 c.c.), and the solution was cooled, saturated with carbon dioxide, and extracted with ether; removal of the solvent by a current of air gave a nearly pure α-oxime, m. p. 68—73°. It is essential that the solutions of the α-oxime should not be warmed, otherwise partial conversion into the β-oxime occurs.

β-*Furfuraldoxime.*—Hydroxylamine hydrochloride (10 g.) in methyl alcohol (40 c.c.) was treated with crystallised sodium acetate (19·5 g.) in dilute alcohol (40 c.c.), and furfuraldehyde (12 g.) added. The mixture was kept for 24 hours, the precipitated sodium chloride removed, and the solution evaporated in a vacuum at room temperature to about 30 c.c. and then poured into water (70 c.c.). The precipitated β-oxime (m. p. 89—91°) was crystallised three times from 10% alcohol with the addition of a little animal charcoal; a nearly quantitative yield was then obtained of the pure β-oxime, m. p. 91—92° (Goldschmidt and Zanoli give 89°). The β-oxime (2·5 g.) was dissolved in acetic anhydride (10 c.c.) at 30° and poured into 2*N*-sodium carbonate. When all the anhydride was decom-

posed, the oil was extracted with ether and hydrolysed, after removal of the solvent, by boiling it with 40% potassium hydroxide solution. Ammonia was evolved and extraction of the acidified solution with ether yielded pyromucic acid, identified by its reactions and by comparison with an authentic specimen.

α-2-*Methoxy*-1-*naphthaldoxime*.—To a mixture of hydroxylamine hydrochloride (7·5 g.) and sodium hydroxide (10 g.) in water (110 c.c.) was added a solution of 2-methoxy-1-naphthaldehyde (14 g.) in hot alcohol (20 c.c). The sodium salt of the oxime (which is very sparingly soluble in water) separated as a mass of crystals; after 1 hour, the oxime was liberated by addition of excess of a saturated solution of ammonium chloride, filtered off, washed, and dried (yield, almost quantitative). After three crystallisations from hot benzene, α-2-*methoxy*-1-*naphthaldoxime* formed white plates, m. p. 154—155° (Found: N, 7·3. $C_{12}H_{11}O_2N$ requires N, 7·0%).

α-*Acetyl*-2-*methoxy*-1-*naphthaldoxime*, prepared in the usual way, and crystallised from alcohol, formed white needles, m. p. 79—80° (Found: N, 5·9. $C_{14}H_{13}O_3N$ requires N, 5·8%). On hydrolysis with hot 2*N*-sodium hydroxide, the needles of the acetyl derivative are gradually replaced by the plates of the sodium salt of the oxime. On addition of ammonium chloride, the α-oxime was recovered unchanged.

α-2-*Methoxy*-1-*naphthaldoxime Hydrochloride*.—The oxime (2 g.) was dissolved in boiling chloroform (75 c.c.), and dry hydrogen chloride passed in for 20 minutes. The precipitated *hydrochloride* was collected, washed with chloroform, and pressed on a porous tile. It formed a bright yellow powder, m. p. 145—147° (decomp.) (Found: Cl, 16·4. $C_{12}H_{11}O_2N,HCl$ requires Cl, 14·9%). With sodium hydroxide and ammonium chloride, the hydrochloride regenerated the α-oxime; no inversion had taken place.

Methylation of α-2-*Methoxy*-1-*naphthaldoxime*.—The oxime (7·0 g.), dissolved in hot alcohol (85 c.c.), was treated with sodium ethoxide (1·05 g. of sodium in 25 c.c. of alcohol), and methyl iodide (5 g.) added. The solution was boiled under reflux for 30 minutes and kept for 12 hours, the alcohol allowed to evaporate somewhat, and excess of water added. An emulsion was formed, which was extracted first with ether, then with chloroform. The ethereal extract on evaporation gave a thick oil (2·4 g.) which solidified when cooled, yielding a hard, brown solid, m. p. 51—54°, consisting mainly of *O*-ether, but also containing a little *N*-ether, unchanged oxime, and other impurities. The *O*-ether is best separated by prolonged distillation in steam, in which it is difficultly volatile; it was identified in the distillate by comparison with an authentic specimen obtained by synthesis.

The chloroform extract gave a solid (4·6 g.), m. p. 106—107°. After some weeks, the m. p. had fallen to 83—87°. This compound on crystallisation from benzene gave pure *N-methyl-2-methoxy-1-naphthaldoxime hydrate*, fine needles, m. p. 88—89° (Found: N, 6·0; H_2O, 7·6. $C_{13}H_{13}O_2N,H_2O$ requires N, 6·0; H_2O, 7·7%). The anhydrous *N-methyl-2-methoxy-1-naphthaldoxime*, obtained by desiccation of the hydrate in a vacuum over calcium chloride, formed stout prisms, m. p. 118—119°, which hydrate readily (Found: N, 6·5. $C_{13}H_{13}O_2N$ requires N, 6·5%). Both the hydrated and the anhydrous ether yield *N*-methylhydroxylamine and 2-methoxy-1-naphthaldehyde on gentle boiling with acids.

α-*O-Methyl-2-methoxy-1-naphthaldoxime*.—2-Methoxy-1-naphthaldehyde (3·5 g.) and *O*-methylhydroxylamine (0·95 g.) were dissolved in alcohol (30 c.c.) and kept for 12 hours. The alcohol was allowed to evaporate spontaneously, and the dark solid residue purified by steam distillation and crystallisation from alcohol. α-*O-Methyl-2-methoxy-1-naphthaldoxime* formed colourless, short prisms, m. p. 65° (Found: N, 6·8. $C_{13}H_{13}O_2N$ requires N, 6·5%).

4-*Methoxy-1-naphthaldehyde*.—4-Hydroxy-1-naphthaldehyde (24 g.) was heated with potassium hydroxide (8 g. in 35 c.c. of water), and methyl sulphate (13 c.c.) added slowly with shaking. The mixture was heated on the water-bath for 30 minutes, potassium hydroxide (5·5 g. in 20 c.c. of water) and methyl sulphate (8 c.c.) were then added alternately in small quantities with shaking. Heating was continued for 30 minutes, and the solution was cooled and extracted with ether. The aqueous portion on acidification gave 4·8 g. of impure 4-hydroxy-1-naphthaldehyde. The ethereal portion was well washed with dilute sodium hydroxide solution, then with water, dried, and evaporated. The yield of crude methoxyaldehyde, which was sufficiently pure for the next operation, was 10·8 g. A considerable quantity of tar was formed. 4-Methoxy-1-naphthaldehyde has previously been prepared by boiling 4-hydroxy-1-naphthaldehyde with methyl iodide and potassium hydroxide in alcoholic solution (Gattermann, *Annalen*, 1907, **357**, 365).

α-*4-Methoxy-1-naphthaldoxime*, prepared from the crude aldehyde in a similar way to the 2-methoxy-compound, crystallised from benzene in white needles, m. p. 107—108° (Found: N, 7·3. $C_{12}H_{11}O_2N$ requires N, 7·0%).

α-*Acetyl-4-methoxy-1-naphthaldoxime*, prepared in the usual way, crystallised from alcohol in colourless needles, m. p. 102° (Found: N, 5·8. $C_{14}H_{13}O_3N$ requires N, 5·8%). On warming it with 2*N*-sodium hydroxide and saturating the solution with carbon dioxide, the original α-oxime was obtained.

α-*4-Methoxy-1-naphthaldoxime hydrochloride*, prepared in the

same way as the corresponding 2-methoxy-compound, formed a yellowish-green powder, m. p. 144—145° (decomp.) (Found: Cl, 15·1. $C_{12}H_{11}O_2N$,HCl requires Cl, 14·9%). On decomposing it with 2*N*-sodium carbonate, the original oxime was regenerated.

Methylation of α-4-*Methoxy*-1-*naphthaldoxime*.—The oxime (6·55 g. in 59 c.c. of alcohol), sodium (0·8 g. in 20 c.c. of alcohol), and methyl iodide (5·1 g. in 20 c.c. of alcohol) were boiled under reflux for 20 minutes and kept for 12 hours. The methylated product was worked up in the same way as the 2-methoxy-oxime, there being obtained 3·1 g. of *O*-methyl ether and 3·0 g. of *N*-methyl ether. α-O-*Methyl*-4-*methoxy*-1-*naphthaldoxime* formed colourless needles, m. p. 38—39°, from alcohol and water (Found: N, 6·5. $C_{13}H_{13}O_2N$ requires N, 6·5%). α-N-*Methyl*-4-*methoxy*-1-*naphthaldoxime* is dimorphic and separated from hot benzene in yellow prisms, m. p. 158—159° (Found: N, 6·4%), which changed to dark grey plates on keeping in contact with the mother-liquor for 2 hours. The grey modification passed back into the yellow on crystallisation or on heating at 100° for some time.

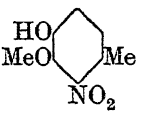
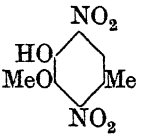
UNIVERSITY COLLEGE, LONDON. [*Received, June 15th*, 1927.]

CCLVI.—*Nitro-derivatives of the Homopyrocatechol Ethers.*

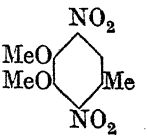


By ALBERT EDWARD OXFORD.

IT has previously been shown (Oxford, J., 1926, 2004) that the action of acetyl nitrate on *o*-methoxyphenyl acetate at −15° gives rise to 3-nitro- and 5-nitro-2-methoxyphenyl acetates in about equal quantities. It was hoped that the application of this method to *m*-methoxy-*p*-tolyl acetate (I) would yield a relatively considerable proportion of the 2-nitro-derivative and provide a new and more direct route to 2-nitrohomoveratrole, although it was, of course, recognised that the effect of the methyl group would be to suppress substitution in the position between it and the methoxyl group (compare the nitration of aceto-*m*-toluidide, Cohen and Dakin, J., 1903, **83**, 331; and of *m*-cresol, Gibson, J., 1923, **123**, 1269). In point of fact, the effect was such that the yield of the 2-nitro-derivative could not be raised above 5%, although nearly every possible variation in the experimental conditions was tried, including a nitration at −40°. The method did, however, provide a means of preparing the hitherto unknown nitro-derivatives of creosol and homoveratrole, *viz.*, 2-*nitrocreosol* (II), 2 : 5-*dinitrocreosol* (III)

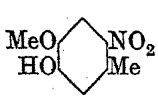


(readily obtained by nitrating II in acetic acid solution), and 2 : 5-*dinitrohomoveratrole* (IV).

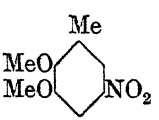


(I.)

(II.)

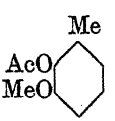


(III.)

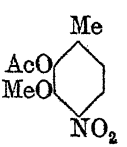


(IV.)

In view of the interest attaching to 2-nitrohomoveratrole (see Oberlin, *Arch. Pharm.*, 1925, **263**, 641; Gulland and Robinson, J., 1926, 1976; compare also Dadswell and Kenner, this vol., p. 580), and of the strong probability that, like homoveratrole and 2-nitro-*m*-tolyl methyl ether, it should be a solid at the ordinary temperature, a method for its complete separation from 6-nitrohomoveratrole was much needed. It was found that under conditions of alkaline hydrolysis which leave the 2-nitro-isomeride unaffected, 6-nitrohomoveratrole is quantitatively demethylated to 6-nitro*iso*creosol (V), and a specimen of 2-nitrohomoveratrole prepared from 2 : 6-dinitrohomoveratrole according to Oberlin's details, after being submitted to this treatment, was found to contain only a trace of 6-nitrohomoveratrole. The purified 2-nitrohomoveratrole could then for the first time be obtained crystalline, having m. p. 6—7·5°. Apparently sodium sulphide (the reducing agent used by Gulland and Robinson, whose final product was undoubtedly a mixture of the two nitrohomoveratroles) attacks both nitro-groups in 2 : 6-dinitrohomoveratrole, whilst ammonium sulphide (the reducing agent used by Oberlin), being milder and more specific in its action, reduces only the 6-nitro-group.



In conclusion, some comparative experiments have been carried out in the *o*-creosol series. The nitration of *o*-homoveratrole by concentrated nitric acid yields only the 5-nitro-derivative (VI) (Cain and Simonsen, J., 1914, **105**, 156; Majima and Okazaki, *Ber.*, 1916, **49**, 1482), and the same result is obtained if acetyl



(V.)

(VI.)

(VII.)

(VIII.)

nitrate at −15° is the nitrating agent. The nitration of 3-methoxy-*o*-tolyl acetate (VII) under conditions which convert *o*-methoxyphenyl acetate into its 5-nitro-derivative only, yields chiefly the 4-nitro-derivative (VIII) and not, as might be expected, the 6-nitro-derivative.

Experimental.

Nitration of m-*Methoxy*-p-*tolyl Acetate* (I).—A mechanically stirred solution of the acetate (32·2 g.) and redistilled acetyl chloride (35 c.c.) in pure dry carbon tetrachloride (140 c.c.), cooled in a freezing mixture and protected from moisture, was treated during 2½ hours with dry, very finely powdered silver nitrate (36 g.). The 6-nitro-derivative began to crystallise just before all the silver nitrate had been added. Stirring was continued for a further hour, the reaction mixture filtered, and the precipitate—which contained the greater part of the 6-nitro-derivative mixed with silver salts—washed with carbon tetrachloride. The deep red filtrate was shaken twice with water, dried over anhydrous sodium sulphate, and, after evaporation of the solvent, distilled in a vacuum, three fractions being collected : (i) (Up to 167°/13 mm.) 5 g. of a red liquid; (ii) (167—177°/13 mm.) 8 g., mostly liquid; (iii) (177—210°/13 mm.) 5 g. of a solid (6-nitro-3-methoxy-*p*-tolyl acetate); (i) and the liquid part of (ii) were combined and hydrolysed by warming on the steam-bath with 2*N*-sodium hydroxide.

6(?)-*Chlorocreosol*.—The crude phenolic mixture was steam-distilled; the brown, semi-solid material (about 4 g.) that came over, after repeated crystallisation from water, was obtained in colourless, glistening, rectangular leaflets, m. p. 71° (Found : Cl, 19·7; *M*, in camphor, 174. $C_8H_9O_2Cl$ requires Cl, 20·5%; *M*, 172). It is sparingly soluble in cold water and dissolves readily in all organic solvents with the exception of light petroleum. It has a faint, guaiacol odour, gives no coloration with ferric chloride, and does not dissolve chemically in sodium bicarbonate solution.

Its *acetyl* derivative crystallises from light petroleum in colourless, thick tablets, m. p. 61° [Found : MeO (micro-Zeisel), 14·2. $C_{10}H_{11}O_3Cl$ requires MeO, 14·5%]. It is readily soluble in ethyl and methyl alcohols and moderately easily soluble in hot water.

The *methyl ether*, obtained by the xylene–methyl sulphate–potassium carbonate method, crystallises from aqueous alcohol in colourless, shining leaflets, m. p. 37—38°. It has an almost ethereal odour recalling that of *m*-methoxy-*p*-tolyl acetate, and gives a yellow coloration with concentrated sulphuric acid. In order to decide which position (2 or 6) is occupied by the chlorine atom, the behaviour of this ether on nitration was investigated. It dissolved in concentrated nitric acid to a red solution, from which nothing was precipitated by addition of water at the end of 10 minutes, but when nitrated in acetic anhydride solution at 0°, by concentrated nitric acid, it yielded a minute amount of a brown solid which crystallised from light petroleum in colourless, well-defined prisms, m. p. 89°. The amount of this substance obtained

was insufficient for further investigation, but the behaviour of the chlorocreosol towards nitrating agents recalls that of 6-nitrohomoveratrole and is quite unlike that of 2-nitrohomoveratrole, which is readily nitrated to 2 : 6-dinitrohomoveratrole.

2-*Nitrocreosol* (II).—The nitrocreosols remaining in the distillation flask after the removal of chlorocreosol * were extracted with ether, and after evaporation of the solvent a dark oil remained, the solution of which in boiling light petroleum (b. p. 60—80°) deposited, on cooling, 6-nitrocreosol mixed with a little tar. After evaporation of the mother-liquor, a yellow oil remained (1·5 g.) which proved to be fairly pure 2-nitrocreosol. It was again heated with a little light petroleum, and the undissolved oil (1 g.), which would not crystallise at — 15°, was used in the experiments described below.

2-*Nitro*-3-*methoxy*-4-p-*nitrobenzyloxytoluene*.—The benzoyl derivative of 2-nitrocreosol was an uncrystallisable oil, and the phenol had to be characterised by the preparation of its p-*nitrobenzyl ether*. 2-Nitrocreosol (1·6 g., a slight excess) together with *p*-nitrobenzyl bromide (1·83 g.) was dissolved in a solution of sodium (0·19 g.) in absolute alcohol (60 c.c.), and the whole boiled under reflux for 3½ hours; much water was then added. The precipitate (m. p. 100°) obtained, after five crystallisations from alcohol, separated in fern-like aggregates of minute, colourless, flat rods, m. p. 114—114·5°, unaltered by further crystallisations from alcohol or light petroleum (Found : N, 9·1, 8·9. $C_{15}H_{14}O_6N_2$ requires N, 8·8%). It is readily soluble in most organic solvents.

6-*Nitro*-3-*methoxy*-4-p-*nitrobenzyloxytoluene* was prepared from 6-nitrocreosol by an exactly similar method. It was crystallised from hot alcohol, in which it was very sparingly soluble, and then from benzene, separating in pale yellow, feathery needles, m. p. 202—203° (Found : C, 56·1; H, 4·8. $C_{15}H_{14}O_6N_2$ requires C, 56·6; H, 4·4%).

2 : 5-*Dinitrocreosol* (III).—2-Nitrocreosol (2·6 g.) dissolved in glacial acetic acid (9 c.c.) was nitrated by the addition of a solution of nitric acid (*d* 1·42; 3·5 c.c.) in glacial acetic acid (3 c.c.) with constant stirring and cooling in ice-water, the first half of this solution being added during 10 minutes and the rest during 1 minute. Water was added immediately and the product was collected, washed, and dried (yield, 0·67 g., *i.e.*, 25% of the theoretical). It separated from light petroleum (b. p. 40—60°) in yellow leaflets, m. p. 86—87°, not altered by a second crystallisation from that solvent, from which it was also deposited in flat needles

* By substituting acetic anhydride for the excess of acetyl chloride used in the nitration, the formation of chlorocreosol can largely be suppressed; the yield of 2-nitrocreosol is, however, if anything diminished.

by rapid crystallisation from a saturated solution (Found : N, 12·1. $C_8H_8O_6N_2$ requires N, 12·3%). It is readily soluble in hot, but only sparingly soluble in cold water, dissolves in aqueous sodium carbonate to a red solution, and gives no coloration with ferric chloride.

Its *acetyl* derivative, obtained by boiling the phenol with excess of acetic anhydride for several hours, crystallises from light petroleum in flat rods, m. p. 53—54°. It is readily soluble in alcohol and gives a pale yellow colour with concentrated sulphuric acid.

The aqueous mother-liquor from the nitration of 2-nitrocreosol was made alkaline with caustic soda, then neutralised with dilute sulphuric acid and extracted with ether. A solid remained after evaporation of the solvent which, when repeatedly crystallised from light petroleum, eventually yielded pure 5 : 6-dinitrocreosol. This observation proves that the 2-nitrocreosol originally used contained a considerable proportion of the 6-nitro-isomeride.

2 : 5-*Dinitrohomoveratrole* (IV).—2 : 5-Dinitrocreosol (0·45 g.) dissolved in dry xylene (7 c.c.) was boiled under reflux with methyl sulphate (0·5 c.c.) and anhydrous potassium carbonate (2 g.). After 30 minutes, a further 0·2 c.c. of methyl sulphate was added, and the liquid was boiled for a further 20 minutes and then worked up in the usual way. When the crude product was distilled, four drops of a nearly colourless oil came over at 190°/15 mm. Its solidification was effected by first cooling in solid carbon dioxide, when it set to a glass, and then transferring it to an ice–salt mixture and scratching vigorously; almost immediate crystallisation then set in.* The solid was obtained in colourless, six-sided plates, m. p. 36°, after two crystallisations from aqueous alcohol (Found : N, 11·5. $C_9H_{10}O_6N_2$ requires N, 11·6%). It gives a pale yellow colour with concentrated sulphuric acid, and the diamine it yields on reduction will not condense with phenanthraquinone to a derivative of phenazine.

2-*Nitrohomoveratrole from* 2-*Nitrocreosol*.—Distillation in steam, followed by repeated fractional distillation in a vacuum, provides a fairly efficient means of separating the two nitrohomoveratroles. The nitrocreosols remaining after all the chlorocreosol had been removed (see p. 1966) were therefore methylated (preferably with methyl iodide) and the methyl ethers were isolated and submitted to steam distillation until the liquid distilling over no longer con-

* This method was applied with equal success to the purified 2-nitrohomoveratrole (see p. 1965) and to 3-nitro-2-methoxyphenyl acetate (Oxford, *loc. cit.*), an oil which had also previously resisted all attempts at crystallisation. This acetate separates from slightly aqueous alcohol in colourless, well-defined, hexagonal tablets, m. p. 29—30°.

tained any trace of oily drops. 6-Nitrohomoveratrole is appreciably volatile in steam (to the extent of 0·5 g. per litre), although much less so than its isomeride. The distillate was kept for several days in the ice-chest, filtered from 6-nitrohomoveratrole, and extracted with ether. A further separation of the two isomerides by repeated fractional distillation in a vacuum is possible, 2-nitrohomoveratrole being slightly the more volatile (Found in the best fraction: C, 54·9; H, 5·6. Calc. for $C_9H_{11}O_4N$: C, 54·8; H, 5·6%). The proportion of 2-nitrohomoveratrole in a given fraction can roughly be estimated by nitration to 2 : 6-dinitrohomoveratrole under the following conditions: The oil (about 1 g.) is nitrated by stirring with nitric acid (*d* 1·42; 3 c.c., previously boiled) for 2·5 minutes (cooling by means of running water). Much water is then added and the precipitate, after standing for a while, is collected in a Gooch crucible, dried, and weighed. Under these conditions, 6-nitrohomoveratrole gives only a 9·7% yield of somewhat impure 5 : 6-dinitrohomoveratrole. Three different specimens of 2-nitrohomoveratrole, prepared from impure 2-nitrocreosol and purified as outlined above, were found to contain at the least 77%, 80%, and 66% of that constituent respectively. On further nitration, they all gave specimens of almost pure 2 : 6-dinitrohomoveratrole with m. p. 85—89° instead of 90—91°.

5 : 6-*Dinitrohomoveratrole*.—According to Oberlin (*loc. cit.*), the direct nitration of 6-nitrohomoveratrole by fuming nitric acid below 5° gives 5 : 6-dinitrohomoveratrole in 36% yield. The present author found the yield could be increased to 60% by allowing a solution of 6-nitrohomoveratrole (0·7 g.) in acetic anhydride (5 c.c.) mixed with nitric acid (*d* 1·42; 1 c.c.) to stand for ½ hour, the temperature being maintained at 0°.

6-*Nitro*isocreosol (V).—6-Nitrohomoveratrole (6 g.) was boiled under reflux during 28 hours with a solution of caustic potash (23 g.) in water (150 c.c.). A further quantity of caustic potash solution (6 g. in 25 c.c. of water) was then added, and the boiling continued for a further 9 hours until 6-nitrohomoveratrole could no longer be seen in the condenser. On cooling, the deep red liquid deposited slender, orange needles of the potassium salt of the nitro*iso*creosol. Sufficient water was added to dissolve the crystals, and on addition of dilute sulphuric acid nearly pure 6-nitro*iso*creosol was precipitated. It was crystallised from very dilute hydrochloric acid (charcoal) and then from benzene, from which it separated in long, slender, pale yellow needles, m. p. 168—170°. The nitro-*iso*creosol, m. p. 166—167°, isolated in small amount by Gulland and Robinson (*loc. cit.*) in some experiments on the nitration of *iso*creosol in ethereal solution, must therefore be the 6-nitro-deriv-

ative (Found : C, 52·7; H, 4·9. $C_8H_9O_4N$ requires C, 52·5; H, 4·9%).

6-Nitro*iso*creosol is readily soluble in alcohol and ethyl acetate, moderately easily soluble in chloroform in the cold, and very sparingly soluble in cold benzene and carbon tetrachloride. Its golden-orange solution in saturated aqueous sodium carbonate deposits the bright yellow *sodium* salt on addition of concentrated sodium hydroxide. It gives no coloration with ferric chloride.

Its constitution was proved by methylation to 6-nitrohomoveratrole, the methylation being almost complete after 2 hours' boiling with methyl sulphate, xylene, and potassium carbonate.

The *acetyl* derivative was obtained by boiling the nitrophenol with excess of acetic anhydride for 2 hours. It crystallises from alcohol in pale yellow leaflets, m. p. 98—98·5°, and gives a deep red coloration with concentrated sulphuric acid.

Separation of the Two Nitrohomoveratroles.—When a mixture of about equal quantities of 2- and 6-nitrohomoveratroles is demethylated under the foregoing conditions, the oil remaining unattacked contains less than 5% of 6-nitrohomoveratrole. If the original mixture consists largely of 2-nitrohomoveratrole, the removal of the 6-nitro-isomeride is complete. The accumulated mother-liquors from which crude 6-nitro*iso*creosol had been precipitated by acidification were extracted with ether, and the residue remaining after the evaporation of the solvent was submitted to distillation in steam in the hope of isolating 2-nitro*iso*creosol, but the distillate contained only 6-nitro*iso*creosol, which is slightly volatile in steam.

6-*Bromo*-2-*nitrohomoveratrole.*—Bromine (6 g.; 1½ equivs.) was added drop by drop with shaking to a solution of 2-nitrohomoveratrole (4·8 g.; 1 equiv., prepared from 2 : 6-dinitrohomoveratrole by Oberlin's method, but not further purified by the alkali treatment) in glacial acetic acid (10 c.c.). Considerable heat was developed. The liquid was kept at room temperature for 48 hours, a considerable proportion of the bromo-derivative crystallising, and then shaken with a large volume of sodium bisulphite solution. The precipitate, after being thoroughly washed with water and dried (yield, 5·8 g. or 86% of the theoretical; m. p. 99—100°), crystallised from methyl alcohol in large, colourless, four-sided tablets, m. p. 102—103° (Found : Br, 28·5. $C_9H_{10}O_4NBr$ requires Br, 29·0%) and was readily soluble in all the usual organic solvents with the exception of cold methyl and ethyl alcohols, and light petroleum, in which it was moderately easily soluble when hot and very sparingly soluble in the cold.

5 : 6-*Dinitroisocreosol.*—A solution of the acetyl derivative of 6-nitro*iso*creosol (0·6 g.) in ice-cold nitric acid (*d* 1·5; 3·5 c.c.)

was kept at 0° for 3 hours. Water was then added, and the precipitate collected, washed, and dried (0·2 g.). The filtrate became deep red on the addition of alkali, hence considerable demethylation had taken place. The crude acetyl derivative crystallised from aqueous alcohol in colourless, flat needles, m. p. 109—110°. It was then hydrolysed by warming with sodium carbonate solution and alcohol on the steam-bath. The crude nitrophenol, precipitatated by the addition of hydrochloric acid, was recrystallised from water several times, forming very pale yellow, minute, slender needles, m. p. 128—129° (Found : N, 12·3. $C_8H_8O_6N_2$ requires N, 12·3%). It is readily soluble in alcohol, moderately easily soluble in cold benzene, and sparingly soluble in light petroleum and cold carbon tetrachloride. Its orange-coloured solution in saturated aqueous sodium carbonate deposits orange-yellow, flat, pointed rods of the *sodium* salt on addition of concentrated caustic soda. It gives a brownish-red coloration with alcoholic ferric chloride. Its constitution follows from the fact that it yields 5 : 6-dinitrohomoveratrole (m. p. 119—120°) on methylation.

Nitration of 3-*Methoxy*-o-*tolyl Acetate* (VII).—This was carried out according to the details given by Graesser-Thomas, Gulland, and Robinson (J., 1926, 1973) for the preparation of 6-nitro-*m*-methoxy-*p*-tolyl acetate (method B). A solution of nitric acid (1·8 c.c.; *d* 1·4) in acetic anhydride (2 c.c.) to which a few small crystals of urea had been added was very slowly introduced, drop by drop, into a mixture of the acetate (2·5 g.) and acetic anhydride (2·5 c.c.) cooled to — 15°. Addition of water after 15 minutes precipitated an oil, which was hydrolysed by warming it on the steam-bath with *N*-caustic soda. Acidification with dilute sulphuric acid then precipitated an oil; this, after a tedious treatment with light petroleum followed by two crystallisations from water, yielded a minute quantity of a substance, m. p. 60—61°, which crystallised from water in colourless, silky needles, gave no coloration with ferric chloride, and dissolved in saturated sodium carbonate to a golden-yellow solution. It was probably 4-nitro-*o*-creosol, since it yielded a nitrophenol when nitrated in acetic acid solution, the aminophenol from which condensed with phenanthraquinone to give a derivative of phenazine which gave a dull cherry-red colour with concentrated sulphuric acid and exhibited a perceptible green fluorescence in benzene solution (compare the behaviour of 3 : 4-dinitroguaiacol; Oxford, *loc. cit.*).

The various aqueous mother-liquors from the foregoing operations were extracted with ether, the extract was added to the light petroleum mother-liquors, and the residue remaining after evaporation of the combined extracts was methylated by the xylene-

methyl sulphate–potassium carbonate method. The methyl ethers were nitrated by heating them on the steam-bath for 10 minutes with a considerable excess of fuming nitric acid diluted with an equal volume of glacial acetic acid. Addition of water then precipitated almost pure 4 : 5-dinitro-*o*-homoveratrole, m. p. 125—127° after one crystallisation from alcohol (Majima and Okazaki, *loc. cit.*, record m. p. 126—127°). Further proof of the position of the nitro-groups was afforded by condensing the diamine obtained by reduction with zinc and hydrochloric acid, with phenanthraquinone; a substance exhibiting all the colour reactions of a 1 : 2-dimethoxyphenanthraphenazine was then obtained.

I wish to thank Professor R. Robinson, F.R.S., for his continued interest in this work and for many helpful suggestions during its progress.

CCLVII.—*Nitration of β-Naphthyltrimethylammonium Nitrate.*

By BERTRAM HOBART INGHAM.

IT has been shown by Vorländer and Sieberts (*Ber.*, 1919, **52**, 283) that in simple benzene derivatives the positively charged ammonium group in immediate proximity to the nucleus has an almost exclusive meta-orienting effect. This is a particular example of the generalisation, first enunciated by Robinson, that a positively charged group in immediate proximity to the nucleus always conduces to the formation of a high proportion of meta-substitution products. The former authors showed that on nitration of phenyltrimethylammonium nitrate or bromination of the bromide the corresponding meta-derivatives were produced, whilst *o*-, *m*-, and *p*-tolyltrimethylammonium nitrates yield, on nitration, 5-nitro-2-tolyl-, 4-nitro-3-tolyl-, and 3-nitro-4-tolyl-ammonium nitrates respectively. The so-called "effect" of this group is therefore strongly opposed to that of hydroxyl or methoxyl. In β-naphthol and its methyl ether the positions most readily substituted are precisely those which may be deduced from the simplest application of the rule of alternation, namely 1, 8, 6, and 3, and on such grounds it must be inferred that substitution at these positions in β-naphthyltrimethylammonium salts will occur less readily than in the corresponding positions in naphthalene itself. The simple rules of alternation, however, give no clue as to which of the remaining positions, namely, 7, 5, or 4, will be most readily attacked. It is well known that, in the

naphthalene series, substitution occurs preferentially in the α-positions, and therefore positions 5 and 4 are more probable points of substitution than position 7. There remains yet a choice to be made between positions 5 and 4. If the action of the "meta-directive" group is to assist in the process of substitution in any way, then, other things being equal, the nucleus containing the directive group should be the more susceptible to substitution (as is the case with the two naphthols, for example). On the contrary, if its influence be inhibitory, and if the inhibition applies not only to the ortho- but also to the meta-position (to a smaller extent), then such influence should be most effective in the nucleus to which the group is attached, and position 5, being less affected than position 4, should be the more susceptible to substitution.

The author's experiments emphatically support the latter view, which, moreover, is entirely consistent with the results obtained in the schools of H. E. Armstrong and of A. F. Holleman. The product obtained on nitration of β-naphthyltrimethylammonium nitrate was nearly pure 5-nitro-β-naphthyltrimethylammonium nitrate in almost theoretical yield.

EXPERIMENTAL.

β-Naphthyltrimethylammonium iodide was prepared by a method similar to those of Bamberger (*Ber.*, 1889, **22**, 1306) and of Morgan (J., 1900, **77**, 882), but it was found to be unnecessary to heat the reactants in a sealed tube, refluxing for 3½ hours (in a copper flask) and allowing the crude product to stand over-night before purification being found to give practically as good a yield (approx. 60%). The substance was purified by extraction with and crystallisation from water, followed by recrystallisation from alcohol; it was thus obtained in colourless, hexagonal plates, m. p. 193° (decomp.).

The *nitrate* and the *picrate* were obtained by double decomposition from the iodide with silver nitrate and with picric acid, respectively; they crystallised from water, the nitrate in colourless, rectangular plates, m. p. 190° (decomp.), and the picrate in golden-yellow needles, m. p. 194—195° (decomp.).

Nitration of β-Naphthyltrimethylammonium Nitrate.—The salt was dissolved in three times its weight of 99% nitric acid (*d* 1·52) with water-cooling, a vigorous momentary reaction taking place. After having stood at room temperature for 2 hours, the solution was poured on 1½—2 times its weight of ice, and the product made almost neutral * with (solid) sodium bicarbonate, separation of the

* The substance acts as its own indicator, any alkalinity (even that of sodium bicarbonate) producing an intense red colour.

nitro-compounds proceeding with the neutralisation. The yield was almost theoretical. After two crystallisations from water and one from aqueous alcohol, a *mononitro-β-naphthyltrimethylammonium nitrate* was obtained in orange-yellow, rectangular prisms, m. p. 231° (decomp.) (Found: C, 52·5; H, 5·6; N, 14·4. $C_{13}H_{15}O_5N_3$ requires C, 53·2; H, 5·1; N, 14·3%). The nitrate was homogeneous, for when it was subjected to fractional crystallisation and subsequent conversion into the iodide, followed by refractionation, no difference in melting point or in appearance under a polarising microscope of any of the fractions could be detected.

The *iodide* was obtained from water in golden-yellow, rectangular prisms, m. p. 194° (decomp.) (Found: I, 35·9. $C_{13}H_{15}O_2N_2I$ requires I, 35·5%). The *picrate* was obtained from aqueous acetone in canary-yellow, rectangular prisms, softening from 248°, m. p. 254° (decomp.).

Unsuccessful attempts were made to determine the constitution of this nitration product of β-naphthyltrimethylammonium nitrate by oxidation, and also by treatment with concentrated aqueous solutions of alkalis, which caused the substance to undergo a peculiar and complicated change. In the circumstances, it was decided to proceed by synthesis as described below.

Methylation of 5-Nitro-β-naphthylamine.—5-Nitro-β-naphthylamine (Friedländer and St. Szymanski, *Ber.*, 1892, **25**, 2076) (1 mol.) in benzene (15 parts by weight) and methyl sulphate (4 mols.) in benzene (4 parts) were mixed and refluxed for 6½ hours, a dirty-white solid gradually separating. Next day, the precipitate was collected, washed with benzene, and boiled with water (100 parts), and the aqueous extract was cooled and made alkaline with ammonia, whereby the methylated bases were precipitated. The filtered solution, which contained 5-nitro-β-naphthyltrimethylammonium methosulphate, was divided into two portions, one of which was converted into the *iodide* (Found by micro-analysis: N, 8·4. $C_{13}H_{15}O_2N_2I$ requires N, 7·8%) and the other into the *picrate* by means of sodium iodide and picric acid, respectively.

Comparative and mixed m. p. tests showed that the nitration product of β-naphthyltrimethylammonium nitrate was 5-nitro-β-naphthyltrimethylammonium nitrate (see table).

As the yield of the quaternary salt obtained in the methylation experiment was very small, and also for comparative purposes, it was considered desirable to methylate the 8-nitro-isomeride and thereby furnish conclusive proof that the above quaternary salt was derived from 5-nitro-β-naphthylamine, and not from any impurity in it. The methylation was performed in the same way as that of the 5-isomeride.

Melting points of Nitro-β-naphthyltrimethylammonium Salts.

	5-Iso-meride.	8-Iso-meride.	Corresponding salt (X) from nitration product.	5-Iso-meride mixed with X.	8-Iso-meride mixed with X.
Iodide (1st sample)	189°	180°	192°	190°	180°
(2nd sample)	190	—	191	191	—
Picrate (1st sample)	254*	221—223	254*	254*	212—218
(2nd sample)	254*	221—223	254*	254*	212—229

* With softening from approximately 248° in each case.

The discrepancies of one or two degrees between some of the melting points given in the table and those of the corresponding substances given hitherto are due to the rate of heating; the m. p.'s in the table are strictly comparable, for they were taken simultaneously in the same bath.

The author wishes to express his thanks to Professor Lapworth for his interest in the investigation.

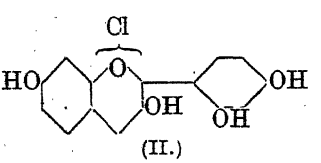
CCLVIII.—*A Synthesis of Pyrylium Salts of Anthocyanidin Type. Part XII.*

By DAVID DOIG PRATT, ALEXANDER ROBERTSON, and ROBERT ROBINSON.



WHEN acacetinidin chloride (I) (Part IV, Pratt, Robinson, and Williams, J., 1924, **125**, 200) was demethylated, it yielded a very well-characterised trihydroxyflavylium chloride which had the reactions but not the crystalline form of apigeninidin chloride prepared by demethylation of its trimethyl ether (Part VI, J., 1925, **127**, 1133). The properties of the two specimens were closely similar, but not identical in every respect, and for this reason there was a doubt in regard to the course of the condensation of benzoylacetaldehyde and its derivatives with phloroglucinol in the presence of hydrogen chloride. Hitherto no unmethylated phloroglucinaldehyde derivative could be condensed with ketones of the form $CH_3 \cdot CO \cdot R$ to flavylium salts, but we have now found that *O*-benzoylphloroglucinaldehyde (this vol., p. 1713) can be utilised for this purpose. With *p*-methoxyacetophenone, it gives a benzoylacacetinidin chloride, and, after hydrolysis with methyl-alcoholic ammonia and subsequent treatment with hydrochloric acid, acacetinidin chloride, identical with the salt already described, was obtained. There is, therefore, no doubt that the condensation of anisoylacet-

aldehyde and phloroglucinol proceeds normally and does not, as was at one time suspected, give rise to an *epi*flavylium derivative. The specimen of apigeninidin chloride, prepared as described in this communication, is unquestionably more pure than that which was obtained previously by demethylation of the trimethyl ether. These results have been confirmed in the chrysinidin series and one and the same chrysinidin has been obtained on the one hand by the condensation of benzoylacetaldehyde and phloroglucinol, and on the other by hydrolysis of the benzoylchrysinidin chloride derived from *O*-benzoylphloroglucinaldehyde and acetophenone.

The condensation of benzoylacetaldehyde with acetophenone by means of hydrogen chloride in acetic acid solution was first described by Bülow and Sicherer (*Ber.*, 1901, **34**, 3896). The quantity of acetic acid employed was not stated, but the red product, $C_{15}H_{13}O_4Cl$, was very sparingly soluble in organic solvents and soon separated from the reaction mixture. These authors do not mention the necessity for any special precautions in carrying out the process, and in the first attempts which we made to repeat it the product was invariably an ochre-red, very sparingly soluble substance which separated quickly in almost quantitative amount. This substance can be easily prepared by adding phloroglucinol and benzoylacetaldehyde in molecular proportion to formic acid or by adding a few drops of hydrochloric acid to an acetic acid solution of the components. It appears to have the composition $C_{30}H_{22}O_7$ and, on treatment with a boiling mixture of acetic and hydrochloric acids, it slowly passes into chrysinidin chloride. Later it was found that the Bülow condensation could be effected in ethereal solution, and also in acetic acid solution if the materials were free from water and access of moisture to the reaction mixture was prevented. In the latter case, the dark reddish-brown product had the composition $C_{15}H_{11}O_3Cl$ and only began to separate after some hours. An account of the preparation of resomorinidin chloride (II) is included in this communication.

(I.)

(II.)

EXPERIMENTAL.

Trianhydrobisbenzoylacetaldehydephloroglucinol. — Cold filtered solutions of benzoylacetaldehyde (2·9 g.) in formic acid (5 c.c.) and of phloroglucinol (2·5 g.) in formic acid (40 c.c.) were mixed; an orange-red product soon began to separate. After 2 hours,

water was added and the substance was collected, washed, and dried at 100° (Found: C, 72·9, 73·2; H, 4·5, 4·6. $C_{30}H_{22}O_7$ requires C, 72·8; H, 4·5%). The yield was 5·1 g., and only when relatively more phloroglucinol was employed could the phenol be detected in the filtrate. The substance can also be obtained by addition of a few drops of hydrochloric acid to a solution of the components in equimolecular proportion in acetic acid or by passing hydrogen chloride into an acetic acid solution of benzoylacetaldehyde and phloroglucinol without precautions aimed at the exclusion of water. Attempts to crystallise this very sparingly soluble compound were unsuccessful. On heating, the substance darkens slightly from 210—280° and above this temperature gradually chars without melting.

Chrysinidin Chloride (5 : 7-*Dihydroxyflavylium Chloride*).—(A) The product of condensation of benzoylacetaldehyde and an equivalent amount of anhydrous phloroglucinol in ethereal solution by means of hydrogen chloride in the cold during 4 hours was collected and extracted with boiling dilute hydrochloric acid. The salt crystallised from the hot filtrates (poor yields) in reddish-brown prismatic needles, which were dried over sulphuric acid (Found: C, 58·7; H, 4·7. $C_{15}H_{11}O_3Cl,2H_2O$ requires C, 58·1; H, 4·8%). This salt darkens at 250° but does not melt at 300°. Its yellow solution in concentrated sulphuric acid does not fluoresce, nor do the orange-red alcoholic solutions exhibit this property. The salt is sparingly soluble in aqueous hydrochloric acid (even 0·05%) and dissolves in aqueous sodium carbonate to a deep brownish-red solution which is orange in thin layers. Sodium hydroxide gives the same colour, but the solutions soon become orange, especially on heating.

(B) A solution of the salt was obtained by boiling the orange-red compound, $C_{30}H_{22}O_7$, for 6 hours with an excess of a mixture of acetic acid (2 vols.) and concentrated hydrochloric acid (1 vol.). Water was added, and the perchlorate precipitated from the filtered solution.

(C) A solution of anhydrous phloroglucinol (5 g.) and benzoylacetaldehyde (8 g.) in pure glacial acetic acid (35 c.c.) was saturated with hydrogen chloride in an apparatus designed to exclude moist air, and then kept for 12 hours. The deep reddish-brown crystals which slowly separated were collected, washed with acetic acid, and dried over sodium hydroxide in a vacuum (Found: C, 65·6, 65·4; H, 4·4, 4·1. $C_{15}H_{11}O_3Cl$ requires C, 65·6; H, 4·0%). The yield was 2 g. By adding ether to the filtrate a solid was precipitated which was extracted by boiling 0·5% hydrochloric acid; this gave a further 2·2 g. of chrysinidin chloride and left 5·5 g. of a dark red, insoluble material.

(D) A cold solution of *O*-benzoylphloroglucinaldehyde (1·6 g.) and acetophenone (3 g.) in dry ethyl acetate (30 c.c.) was saturated with hydrogen chloride and kept for 3 days. The orange-red liquid acquired a greenish-yellow fluorescence and gradually deposited crystals (2 g.). The orange *O*-benzoylchrysinidin chloride (1·9 g.) was dissolved in methyl alcohol (100 c.c.) and the solution was saturated with ammonia at 0° and kept at this temperature for 24 hours. The ammonia and methyl alcohol having been removed under diminished pressure at room temperature, the residue was dissolved in warm methyl alcohol (20 c.c.), and hot hydrochloric acid (40 c.c.) added. The amorphous precipitate was collected and extracted with boiling 0·5% hydrochloric acid, and the salt again precipitated from the filtered solution by the addition of concentrated hydrochloric acid. It was now partly crystalline and was converted into the perchlorate, which was fully purified.

Chrysinidin perchlorate. The various specimens of chrysinidin chloride have been identified with each other by conversion into this characteristic derivative, which crystallises from acetic acid in glistening, deep red, rectangular, prismatic needles (Found in material from B above: C, 53·3; H, 3·4. $C_{15}H_{11}O_7Cl$ requires C, 53·2; H, 3·3%). The substance darkens at 208° and melts with decomposition at 244°. It is very readily soluble in alcohol and on the addition of aqueous perchloric acid the substance crystallises in slender, glistening, orange-red needles. Careful comparison showed that all the specimens were identical; on the other hand, the chrysinidin obtained by demethylation of the dimethyl ether (Part VI, *loc. cit.*) must have been contaminated with methoxy-containing salts, since the perchlorate decomposed at 185°.

O-*Benzoylacacetinidin Chloride.*—A solution of *O*-benzoylphloroglucinaldehyde (0·6 g.) and *p*-methoxyacetophenone (2 g.) in dry ethyl acetate (30 c.c.) was saturated in the cold with hydrogen chloride; in the course of an hour it became deep orange and exhibited a striking greenish-yellow fluorescence. The mixture was kept for 3 days and the salt which had separated was then collected (2 g.); a further quantity (0·5 g.) was obtained by addition of ether to the filtrate. Concentrated hydrochloric acid was added to a solution of the salt in a hot mixture of equal volumes of alcohol and 0·5% hydrochloric acid until a faint turbidity appeared; on cooling, the substance crystallised in bright, orange-red sheaves of slender, prismatic needles (Found in material dried over sulphuric acid: C, 64·6; H, 4·7. $C_{23}H_{17}O_5Cl,H_2O$ requires C, 64·7; H, 4·5%). The alcoholic solutions of this benzoylacetinidin chloride are orange to orange-red and exhibit strong green fluorescence.

Acacetinidin Chloride (I).—The debenzoylation of benzoylacacetin-

idin chloride (3 g.) was accomplished in much the same way as described above in the case of benzoylchrysinidin chloride and the crude acacetinidin chloride (1·5 g.) was crystallised by solution in hot 0·5% hydrochloric acid and addition of concentrated hydrochloric acid until turbidity appeared. After three such processes, the salt was obtained in microscopic, reddish-brown balls. It was then crystallised by addition of concentrated hydrochloric acid to an alcoholic solution and obtained in prismatic needles, and on repetition in diamond-shaped and rhombic plates with a brilliant green reflex but exhibiting much twinning. A third crystallisation in this way gave clear-cut, individual crystals having a form identical with that of crystals of acacetinidin chloride (Part IV, *loc. cit.*). The reactions of the two specimens were also identical and in addition the perchlorates and picrates were examined and compared, with the result that no difference could be detected between the specimens of the respective derivatives obtained from benzoylacacetinidin chloride from acacetinidin chloride.

Acacetinidin perchlorate crystallised from hot aqueous perchloric acid in red, glistening, slender, prismatic needles and from acetic acid in red, elongated, pointed prisms having a bluish-green reflex. The substance darkens at 260° and melts at 278—280° (decomp.). A mixture of the two specimens behaved in the same way.

Acacetinidin picrate crystallised from 40% alcohol, containing picric acid, in long, red, prismatic needles which darkened at 220—225° and melted to a black liquid at 231—233° (mixed—the same).

Apigeninidin Chloride (5 : 7 : 4′-*Trihydroxyflavylium Chloride*).—Acacetinidin chloride (2·1 g.) was demethylated by gently boiling with hydriodic acid (60 c.c.; *d* 1·7) and phenol (9 g.) in a stream of carbon dioxide. Methyl iodide was rapidly evolved and after 15 minutes the acacetinidin iodide had passed into solution. The reaction was continued for a further 10 minutes; a test then proved that only traces of methyl iodide were being produced. On cooling, the apigeninidin iodide quickly crystallised in scarlet, prismatic needles and these were collected on asbestos, washed with ether, and dried at 100° (2·2 g.). The substance is readily soluble in hot alcohol and on the addition of hydrochloric acid the chloride crystallises from the solution, but in order to ensure complete conversion the following method was adopted. The iodide (2·2 g.) and silver chloride (about 10 g.) were added to ethyl alcohol (400 c.c.) and concentrated hydrochloric acid (5 c.c.), and the solution was boiled during 10 minutes, filtered and mixed with concentrated hydrochloric acid (50 c.c.). On cooling, apigeninidin chloride separated in very well-shaped, glistening, rhombic prisms. Individual crystals are seen under the microscope to be light orange-yellow by transmitted

light and the mass is bright salmon-red. The substance was washed with alcohol and dried in a vacuum (Found: C, 58·5; H, 4·4. $C_{15}H_{11}O_4Cl,H_2O$ requires C, 58·4; H, 4·2%). This hydrate is very stable and when quickly heated appears to suffer no change below 200°. At about 230° it darkens and turns green. The anhydrous substance chars above 350° but does not melt. Prolonged heating at 100° does not effect dehydration, but at 140° in a vacuum the substance loses weight and becomes hæmatite-red.

Apigeninidin chloride is sparingly soluble in hot dilute hydrochloric acid and in most organic solvents. On boiling with not too much water, it dissolves and at once separates again as a flocculent precipitate consisting of orange, microscopic needles. This substance is a basic chloride and on the addition of a drop of hydrochloric acid is converted into the normal salt, recognised by its characteristic mode of crystallisation in rhombic prisms. *n*-Butyl or *iso*amyl alcohol extracts most of the salt from aqueous solution, giving an orange-red solution, but the aqueous layer always retains a canary-yellow colour. This behaviour differs from that of pelargonidin chloride, which is completely extracted from aqueous solution by *iso*amyl alcohol. The bright yellow solution in concentrated sulphuric acid exhibits an intense green fluorescence. The colour base, obtained by the action of sodium acetate on the chloride in aqueous solution, is a brownish-red precipitate, sparingly soluble in butyl alcohol to an eosin-red solution. On great dilution, the yellow solutions of apigeninidin salts become red, but under no conditions is a colourless pseudo-base formed. The chloride or the colour base dissolves in aqueous sodium carbonate or ammonia to a rich crimson solution, the colour of which is much bluer, brighter and more persistent on dilution than that of an alkaline solution of acacetinidin chloride. The orange-red solution in alcohol becomes intense yellowish-brown on the addition of ferric chloride. The ferrichloride could not be obtained because it is more soluble than the chloride. For example, a suspension of the chloride in boiling acetic acid gives a clear solution on the addition of a little ferric chloride dissolved in concentrated hydrochloric acid, but on cooling the chloride separates. The *mercurichloride* is extremely sparingly soluble in dilute hydrochloric acid containing mercuric chloride and crystallises in hair-like, orange, microscopic needles. The chloride dissolves somewhat readily in hot dilute perchloric acid and on quickly cooling the *perchlorate* separates in very slender, long, irregular fibres which, on standing in contact with the solvent, change into very dense clusters of microscopic needles. The *periodide* behaves similarly, being precipitated as a stringy, dark brown mass which is resolved into slender needles. Numerous attempts to

oxidise apigeninidin to apigenin were fruitless. The alkaline solution retains its colour when air is aspirated through it during 12 hours.

Hydroxymethyleneacetoveratrone.—Methyl alcohol (1·6 g.) was added to a suspension of granular sodium (1·1 g.) in dry ether (50 c.c.) and when the formation of alkyloxide was complete a mixture of ethyl formate (5·2 g.) and acetoveratrone (9·7 g.) was slowly introduced with frequent shaking; a white, pasty mass was formed. Next day, ice, acetic acid, and ether were added and the separated ethereal solution was shaken with a concentrated solution of copper acetate. The *copper* derivative (7·0 g.) crystallised from toluene in pale green needles which softened at 180° and decomposed at 188° (Found: Cu, 13·0. $C_{22}H_{22}O_8Cu$ requires Cu, 13·3%). Similarly, the *copper* derivative of hydroxymethylene-2:4-dimethoxyacetophenone was obtained from resacetophenone dimethyl ether (yield, 13 g. from 14 g. of the ketone). It crystallised from toluene in pale green prisms, m. p. 190° (Found: Cu, 13·4%).

5:7-*Dihydroxy*-3':4'-*dimethoxyflavylium Chloride.*—An ethereal solution of hydroxymethyleneacetoveratrone (itself an oil exhibiting the usual properties of its class) was obtained by shaking the copper derivative (5·5 g.) with dilute sulphuric acid and ether; the separated ethereal layer was dried with sodium sulphate. This solution was added to one of anhydrous phloroglucinol (3 g.) in ether, and a stream of hydrogen chloride led through the mixture for 4 hours. After 12 hours, the bright red condensation product was collected, washed with ether, and dried (5 g.). This product was boiled under reflux with alcohol (1500 c.c.) and concentrated hydrochloric acid (12 c.c.) for an hour, and the solution distilled until separation of the salt commenced. After keeping for 24 hours, the solid was collected and further purification was effected by solution in and separation from 2% hydrochloric acid. After several such processes, the substance crystallised in a homogeneous form in opaque, microscopic, spherical masses. Further slow crystallisation from hot dilute solutions gave reddish-brown, prismatic needles which decomposed at 272° (Found in material dried in a vacuum over sulphuric acid: C, 56·4; H, 4·8. $C_{17}H_{15}O_5Cl,1·5H_2O$ requires C, 56·5; H, 4·9%). This salt dissolves in aqueous sodium carbonate to an intense blood-red solution.

Demethylation. A mixture of this luteolinidin dimethyl ether (1·4 g.) with phenol (4 g.) and concentrated hydriodic acid (30 c.c.) was boiled in an atmosphere of carbon dioxide for 30 minutes. A bright red iodide crystallised from the solution and this was collected and converted in the usual manner into the corresponding *chloride.* The latter crystallised from alcohol in small, orange-red needles,

which decomposed at 282° (Found in material dried in a vacuum over sulphuric acid: C, 58·6; H, 3·4; MeO, 10·5; Cl, 10·1; loss at 105° in a high vacuum, 2·7. $C_{16}H_{12}O_5Cl,0{\cdot}5H_2O$ requires C, 58·4; H, 3·7; 1MeO, 9·5; Cl, 10·7; H_2O, 2·8%). The substance is therefore a luteolinidin chloride monomethyl ether. It gives a Bordeaux-red to reddish-purple solution in aqueous sodium carbonate and its acid solutions have the same colour as those of luteolinidin chloride. The alkali colour reaction provides the only available evidence in regard to constitution and suggests that the salt is 5 : 7 : 4′-trihydroxy-3′-methoxyflavylium chloride rather than the possible isomeride. The purified substance must contain a trace of luteolinidin chloride, since it gives a weak ferric chloride reaction. On further demethylation with a mixture of hydriodic acid (*d* 1·75) and phenyl acetate, during the course of which the rate of evolution of methyl iodide was observed, luteolinidin iodide was obtained. The corresponding chloride showed all the reactions and properties of the substance previously obtained from luteolinidin chloride trimethyl ether (Part VI, *loc. cit.*).

7-*Hydroxy*-3 : 2′ : 4′-*trimethoxyflavylium Chloride*.—A solution of ω : 2 : 4-trimethoxyacetophenone (4·4 g.) and β-resorcylaldehyde (2·8 g.) in dry ether (100 c.c.) was saturated with hydrogen chloride for 2 hours and kept over-night. The product separated in orange-red needles with a dark green reflex (8 g.). It crystallised from dilute hydrochloric acid in crimson, prismatic needles which darkened at 140° and decomposed at 185° (Found in material dried in a vacuum over sulphuric acid: C, 58·8; H, 5·4. $C_{18}H_{17}O_5Cl$ requires C, 59·0; H, 5·2%). The colour base is bluish-red, a pseudo-base is readily formed, and the yellow solution in concentrated sulphuric acid exhibits bright apple-green fluorescence.

3 : 7 : 2′ : 4′-*Tetrahydroxyflavylium Chloride* (*Resomorinidin Chloride*) (II).—A mixture of the trimethyl ether (4 g.), phenol (8 g.), and hydriodic acid (80 c.c.; *d* 1·7) was gently boiled during 35 minutes in a stream of carbon dioxide. On cooling, glistening prismatic needles, exhibiting golden-green reflex, separated and these were collected and dried (2·8 g.). Conversion into chloride by means of silver chloride and a trace of hydrogen chloride was accomplished in alcoholic solution and, on the addition of 10% aqueous hydrochloric acid to the filtrate, the salt crystallised in small, red needles which decomposed at 216° (Found in material dried in a vacuum over sulphuric acid: C, 54·3; H, 4·2. $C_{15}H_{11}O_5Cl,1{\cdot}5H_2O$ requires C, 54·0; H, 4·2%). Resomorinidin chloride is very sparingly soluble in cold dilute hydrochloric acid and moderately easily soluble in the hot solvent to an orange-red solution. Its solution in sulphuric acid exhibits bright apple-green

fluorescence. Sodium carbonate added to an aqueous solution gives an intense reddish-violet or permanganate-like coloration. An alcoholic solution of the salt is bluish-red and on addition of sodium carbonate becomes dichroic, red in thick layers, blue in thin layers, and exhibits dark red fluorescence. A hydrochloric acid solution was decolorised on boiling with zinc dust, and the cooled mixture was then extracted with ether. Addition of very dilute sodium hydroxide to the separated ethereal layer gave a blue solution which soon became violet and then rose-coloured. On warming, the aqueous layer became greenish-yellow and developed an intense ivy-green fluorescence.

Ethyl 2 : 4 : 6-*Trimethoxybenzoylpyruvate*, $C_6H_2(OMe)_3 \cdot CO \cdot CH_2 \cdot CO \cdot CO_2Et$. —This substance was prepared in the hope that it might prove to be a convenient source of 5 : 7-dimethoxychromone, which was required in connexion with attempts to obtain representatives of the *epi*flavylium series. Phloracetophenone trimethyl ether (5·2 g.) (Kostanecki and Tambor, *Ber.*, 1899, **32**, 2261) and ethyl oxalate (5·5 g.) were added to an absolute alcoholic solution (30 c.c.) of sodium ethoxide (1·4 g. of sodium) and next day ether was added to complete the separation of the sodium derivative. This was collected and dissolved in water and the *ester*, liberated by means of acetic acid, was isolated (5 g.); it crystallised from aqueous alcohol in long, pale yellow needles, m. p. 84° (Found: C, 58·3; H, 5·9. $C_{15}H_{18}O_7$ requires C, 58·1; H, 5·8%). This ester exhibits the usual properties of its class and in the solid state, preferably as a well dispersed precipitate suspended in a faintly acid medium, forms a highly characteristic blue compound with iodine.

The authors wish to thank the Royal Society and the Chemical Society for grants which have defrayed a part of the cost of the investigation.

CCLIX.—*The Constitution of Gentisin.*

By JUNZO SHINODA.

GENTISIN was first isolated from gentian root by Henry and Caventou (*J. Pharm. Chim.*, 1821, 178) and was subsequently examined by Baumert (*Annalen*, 1847, **62**, 106) and by Hlasiwetz and Habermann (*ibid.*, 1875, **175**, 63; 1876, **180**, 343). The investigations of Kostanecki and his co-workers have proved that gentisin is the monomethyl ether of gentisein, which is 1 : 3 : 7-

trihydroxyxanthone and was synthesised by Kostanecki and Tambor (*Monatsh.*, 1894, **15**, 1) by condensation of phloroglucinol and quinolcarboxylic acid. An attempt of these investigators to obtain 1 : 3-dihydroxy-7-methoxyxanthone along similar lines was unsuccessful (*Monatsh.*, 1895, **16**, 920). Kostanecki, however, showed that gentisein on methylation yields gentisin and that gentisin yields only a monomethyl ether. This excludes the possibility that gentisin is 3 : 7-dihydroxy-1-methoxyxanthone and this substance must therefore be 1 : 3-dihydroxy-7-methoxyxanthone (I) or 1 : 7-dihydroxy-3-methoxyxanthone (II).

(I.)  (II.) 

From the behaviour of bisazobenzene-gentisin, Perkin (J., 1898, **73**, 1028) has indicated that gentisin should be represented by the formula (II), and the present author now confirms this conclusion, since the compound (I) described in this communication is quite different from gentisin. The methyl group of gentisin is thus in a position similar to that which it occupies in rhamnetin and rhamnazin. The synthesis of (I) has been effected by an application of the Hoesch reaction following the similar preparation of 1 : 3-dihydroxyxanthone by Nishikawa and Robinson (J., 1922, **121**, 839).

EXPERIMENTAL.

2-*Hydroxy*-5-*methoxybenzaldoxime*, obtained in the usual manner from 2-hydroxy-5-methoxybenzaldehyde, crystallised from water in colourless, prismatic needles, m. p. 118° (Found: C, 57·4; H, 5·8. $C_8H_9O_3N$ requires C, 57·4; H, 5·4%). 2-*Hydroxy*-5-*methoxybenzonitrile*, obtained on treatment of the oxime with boiling acetic anhydride for 3 hours and subsequent hydrolysis with 10% sodium hydroxide solution, crystallised from water in colourless needles, m. p. 136° (Found: C, 64·0, 64·5; H, 5·0, 4·7. $C_8H_7O_2N$ requires C, 64·4; H, 4·7%).

1 : 3-*Dihydroxy*-7-*methoxyxanthonimine Hydrochloride*.—A mixture of 2-hydroxy-5-methoxybenzonitrile (5 g.), anhydrous phloroglucinol (4 g.), zinc chloride (5 g.), and dry ether (30 c.c.) was saturated with hydrogen chloride with frequent shaking. After a few hours, yellow crystals separated, but later these gave place to a deep yellow solution and then to orange crystals. After 10 days, water was added and the insoluble material (A) collected. The filtrate was extracted with ether and then concentrated; on cooling, yellow crystals (B) separated (Found: HCl, 12·1. $C_{14}H_{12}O_4NCl$ requires HCl, 12·4%). The properties of (A) and (B) are very similar; both

are very sparingly soluble in most organic solvents and dissolve in concentrated sulphuric acid to a yellow solution which exhibits green fluorescence. The solution in aqueous alkalis is yellow.

1 : 3-*Dihydroxy*-7-*methoxyxanthone* (I).—The ketimine hydrochloride was hydrolysed by means of boiling aqueous sodium hydroxide (until ammonia was no longer evolved) and the *isogentisin* was then precipitated by the addition of dilute sulphuric acid as a gelatinous mass that became crystalline when the liquid was boiled. The substance crystallised from aqueous alcohol in elongated, yellow plates, m. p. 241° (Found: C, 64·8; H, 4·3. $C_{14}H_{10}O_5$ requires C, 65·1; H, 3·9%).

The yellow solution in concentrated sulphuric acid exhibits green fluorescence, and ferric chloride added to an alcoholic solution develops a greenish-black coloration. The substance does not reduce an ammoniacal silver nitrate solution. A distinction from gentisin is that when an alkaline solution is agitated with sodium amalgam it becomes, like gentisein, blood-red; gentisin gives a deep green coloration under these conditions. On acetylation, a *derivative*, m. p. 211—212°, was obtained.

The *iso*gentisin was demethylated by means of boiling hydriodic acid; the gentisein obtained crystallised from methyl alcohol in orange-yellow needles, m. p. 318° with darkening from 310°. The substance had the properties attributed to it by Kostanecki and on acetylation gave the triacetyl derivative; this crystallised from acetic acid in white, silky needles which, alone or mixed with a specimen obtained by Kostanecki's method (*Monatsh.*, 1891, **12**, 205), melted at 226°.

CCLX.—*Syntheses of Cyclic Compounds. Part I. Ethyl βγ-Dimethylbutane-aaδδ-tetracarboxylate and some* cyclo*Butane Compounds derived therefrom.*

By ISRAEL VOGEL.

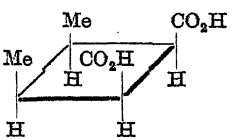
IN extending his investigations on the reduction of unsaturated compounds by moist aluminium amalgam (this vol., p. 594), the author has been led to examine the reduction of esters of the type CR′R″:CX·CO_2Et (I), where X may be CO_2Et, COMe, or CN, and R′,R″ may be Me,H; Ph,H; Me,Me; or the *cyclo*pentane or *cyclo*hexane ring. Coupling would presumably take place in the β-positions (compare Vogel, *loc. cit.*), resulting in the formation of compounds

II) which (if X = CO_2Et) are homologues, symmetrically substituted in the β- and γ-positions, of ethyl butanetetracarboxylate, a

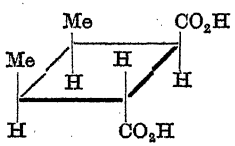
(II.) $\begin{matrix} CR'R''\cdot CHX\cdot CO_2Et \\ CR'R''\cdot CHX\cdot CO_2Et \end{matrix}$ $\begin{matrix} CHMe\cdot CH(CO_2Et)_2 \\ CHMe\cdot CH(CO_2Et)_2 \end{matrix}$ (III.)

substance which has found wide application as a synthetic agent in the hands of Professor Perkin and his collaborators (see numerous papers in J., 1884—1900). This series of researches has therefore been instituted with the following objects: (1) to synthesise compounds of the type (II); (2) to study the influence of groups and rings in the β- and γ-positions on (*a*) the relative ease of formation and stability of four-, five-, six-, and higher-membered rings by condensation with the appropriate reagents, and (*b*) the stability of the *cis*- and *trans*-anhydrides of the cyclic dibasic acids; (3) to synthesise substituted adipic acids from compounds of the type (II) and to employ them in the investigation of the stability of the *cis*- and *trans*-anhydrides as well as of their simpler cyclic derivatives.

The present communication is concerned with the reduction of ethyl ethylidenemalonate by moist aluminium amalgam.* This substance has been previously reduced by means of moist sodium amalgam by Higginbotham and Lapworth (J., 1923, **123**, 1618), who state that "products of at least two distinct types," a volatile β-ketonic ester and a bimolecular compound (III), are formed. No conclusive evidence as to the presence of the β-ketonic ester was given, nor was the dimethylbutanetetracarboxylate isolated, its presence in the primary reduction product being inferred from the production of two isomeric ββ′-dimethyladipic acids by hydrolysis, heating at 160°, and subsequent distillation under low pressure. The author, by employing moist aluminium amalgam as the reducing agent, has found no difficulty in preparing *ethyl dimethylbutanetetracarboxylate* (III) in quantity. On hydrolysis with alcoholic potassium hydroxide, it readily yields a mixture of two stereoisomeric *βγ-dimethylbutane-ααδδ-tetracarboxylic acids*, which can be separated into two forms (*meso* and racemic) melting at 152—154° (decomp.) and 185—185·5° (decomp.), respectively. The racemic configuration is provisionally assigned to the less fusible form. On heating the mixture of the two tetracarboxylic acids at 200°, carbon dioxide was eliminated and a mixture of the two corresponding ββ′-dimethyladipic acids was obtained melting over the range 105—120°, which on esterification and hydrolysis



* A description of the application of moist aluminium amalgam in the separation of mixtures of unsaturated compounds, especially those exhibiting three-carbon tautomerism, is reserved for a future communication.



yielded chiefly a mixture of acids, m. p. 113—117° (compare Higginbotham and Lapworth, *loc. cit.*, who found the upper limit of m. p. range was 75° or 128°, according as acetic acid or sodium bicarbonate was used to minimise alkalinity in the sodium amalgam reduction). The description of the separation of the two isomeric ββ′-dimethyladipic acids as well as that of some of their derivatives is reserved for a future paper.

The use of ethyl dimethylbutanetetracarboxylate (III) in synthetical work depends on the fact that it readily yields a *disodium* compound (IV) on treatment with sodium ethoxide or preferably

(IV.) $\begin{matrix}\mathrm{CHMe{\cdot}CNa(CO_2Et)_2}\\ \mathrm{CHMe{\cdot}CNa(CO_2Et)_2}\end{matrix}$ $\begin{matrix}\mathrm{CHMe—C(CO_2Et)_2}\\ \mathrm{CHMe—C(CO_2Et)_2}\end{matrix}$ (V.)

sodium methoxide, the latter being very much more reactive than the former. By bromine, (IV) is quantitatively converted into *ethyl* 2 : 3-*dimethylcyclobutane*-1 : 1 : 4 : 4-*tetracarboxylate* (V). The latter on hydrolysis with alcoholic potash yields the corresponding tetracarboxylic acid, which, on heating to 180°, esterification, and subsequent hydrolysis with alcoholic potassium hydroxide, gives rise to a mixture of the two cyclo*butanedicarboxylic acids* (VI) and (VII), melting respectively at 87—88° and 200·5—201·5°. They

(VI.) 

(VII.)

may be separated by treatment with acetyl chloride (compare Auwers and Thorpe, *Ber.*, 1895, **28**, 623; Komppa, *Annalen*, 1909, **368**, 152; 1909, **370**, 209; Perkin and Scarborough, J., 1921, **119**, 1405); the *trans*-acid remains unaffected whilst the *cis*-acid is converted into the anhydride.

Further evidence in support of ring closure is provided by comparison of the physical properties of the esters (Table I).

* Slightly impure. See p. 1991.

No details as to temperature, etc., are included, as they are given in full in the experimental section. It is evident that whilst there is no great difference in the boiling points, there are marked differences in the densities and the refractivities, those of the cyclic being greater than those of the corresponding open-chain compounds. The exaltations of the molecular refractivity for the D line of the two *cyclo*butane compounds (0·43 and 0·71) are comparable with those previously observed by other workers for the *cyclo*butane ring (compare Oestling, J., 1912, **101**, 457, mean value 0·48; Eisenlohr, "Spektrochemie organische Verbindungen," 1912, mean value 0·46; Lebedev, *J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1388, mean value 0·60; Zelinsky, *Ber.*, 1913, **46**, 1093; 1927, **60**, 711, mean value 0·45; Kon, J., 1922, **121**, 513, from *cyclo*hexane*spirocyclo*butanone, 0·77).

The analogous unsubstituted open-chain and *cyclo*butane compounds were prepared many years ago by Perkin (J., 1887, **51**, 1; 1894, **65**, 572). Whilst speculations as to the effect of groups are at present premature—it is hoped to discuss the question fully when a larger number of substituted derivatives have been studied—it may be added that the properties of the $\beta\gamma$-dimethyl homologues are very similar to those of the corresponding unsubstituted compounds, a result which would be expected from the modified strain theory of Thorpe and Ingold, since the normal tetrahedral angle of 115·3° has been altered only to 112·5° (compare Ingold, Sako, and Thorpe, J., 1922, **121**, 1177; Ingold, *ibid.*, p. 2676) by the substitution of CHMe for CH_2. It is a curious fact that the only *cyclo*butanedicarboxylic acid directly isolated by Perkin (*loc. cit.*) was the *cis*-acid, the *trans*-acid being prepared by heating the *cis*-acid with hydrochloric acid at 190°, whereas in the case of the corresponding *cyclo*pentanedicarboxylic acids the *trans*-acid was the only form directly isolated. In the present research, both forms were directly isolated.

The question of the existence of two anhydrides of a *cyclo*butane-1 : 2-dicarboxylic acid is of great interest. Baeyer (*Annalen*, 1890, **258**, 145) predicted from his strain theory that *trans*-anhydride formation should not take place in the *cyclo*propane and should occur in the *cyclo*pentane series, but he was doubtful whether it would be possible in the corresponding 1 : 2-*cyclo*butane-compounds. Perkin (J., 1894, **65**, 572), in testing this prediction experimentally for the unsubstituted *cyclo*butanedicarboxylic acids, found that the *trans*-acid was practically unaffected by heating with acetyl chloride, but on heating with acetic anhydride it was converted into the *cis*-anhydride. The author has found that *trans*-dimethyl-*cyclo*butane-1 : 2-dicarboxylic acid behaves similarly; on heating

it with acetic anhydride for 2 hours, the *cis*-anhydride is produced. It appears that the strain in the *trans*-anhydride is so great that the compound is incapable of isolation under the experimental conditions employed (compare Windaus, Hückel, and Reverey, *Ber.*, 1923, **56**, 91, who have isolated the *trans*-anhydride of hexahydrohomophthalic acid and find that an equilibrium mixture of the *cis*- and *trans*-anhydrides is formed on heating it with acetic anhydride). The question whether the *cis*-anhydride is formed *via* the *cis*-acid or the *trans*-anhydride must still be regarded as an open one.

The ethyl dimethylbutanetetracarboxylate used in this research was obtained by the reduction of ethyl ethylidenemalonate (Goss, Ingold, and Thorpe, J., 1923, **123**, 3353) by moist aluminium amalgam; the yield averaged 45%, the remainder of the product consisting of unchanged malonic ester, which was readily separated by fractional distillation in a vacuum. This yield is surprising, since, under the conditions employed, reduction takes place quantitatively (mesityl oxide, benzylideneacetone) or not at all (ethyl ββ-dimethylacrylate). Two explanations are possible: (*a*) ethyl ethylidenemalonate decomposes under the influence of the moist aluminium amalgam, and (*b*) the ethylidenemalonate contains a considerable quantity of malonic ester which cannot be removed by fractionation in a vacuum. The latter explanation is probably the correct one and receives support from the analytical results as well as from a comparison of the molecular refractivities of Goss, Ingold, and Thorpe's ethyl ethylidenemalonate and that prepared directly from the acid, only the latter exhibiting the expected exaltation due to the presence of conjugated double bonds.

EXPERIMENTAL.

The yield of ethyl ethylidenemalonate, b. p. 113—135°/20 mm., prepared by Goss, Ingold, and Thorpe's method averaged 85 g. from 100 g. of malonic ester [Found: C, 54·5; H, 7·5. Calc. for $CH_3{\cdot}CH{:}C(CO_2Et)_2$: C, 58·1; H, 7·5%. Calc. for $CH_2(CO_2Et)_2$: C, 52·5; H, 7·5%]. On redistillation in a vacuum, a fraction was obtained having b. p. 111—112°/12 mm., $d_4^{17\cdot2°}$ 1·05237, $n_D^{17\cdot2}$ 1·42567, $[R_L]_D$ 45·29.

Ethylidenemalonic acid was obtained by adding 50 g. of acetaldehyde to 75 g. of malonic acid in 100 g. of pyridine at −5°, followed by 2·5 c.c. of piperidine during 1 hour, the whole being vigorously stirred. The reaction mixture was kept at 0° overnight, the orange-coloured solid mass cooled to −5° and decomposed with a slight excess of ice-cold dilute sulphuric acid, and the pale yellow ethylidenemalonic acid, m. p. 82° (Komnenos, *Annalen*,

1883, **218**, 165, gives m. p. 84), *quickly* separated. The acid, on esterification with absolute ethyl alcohol and sulphuric acid, yielded ethyl ethylidenemalonate, which was obtained pure after two fractionations in a vacuum. It had b. p. 115—117°/15 mm., $d_4^{17\cdot4°}$ 1·01938, $n_D^{17\cdot4°}$ 1·43007, $[R_L]_D$ 47·17 (calc., 46·60) (compare Komnenos, *loc. cit.*; $d^{15°}$ 1·0435) (Found: C, 57·8; H, 7·6. Calc. for $C_9H_{14}O_4$: C, 58·1; H, 7·5%).

Reduction with Moist Aluminium Amalgam. Preparation of Ethyl βγ*-Dimethylbutane-*αα*δδ-tetracarboxylate* (III).—Ethyl ethylidenemalonate (b. p. 113—135°/20 mm.; 150 g.) was reduced by 200 g. of aluminium amalgam prepared by the author's method (this vol., p. 594). The product was worked up in the usual manner and fractionated in a vacuum. Ethyl malonate was recovered below 140°/16 mm.; the temperature then rose rapidly to 210° and *ethyl* βγ*-dimethylbutane-*αα*δδ-tetracarboxylate* distilled at 210—240°/16 mm. (yield, 68 g. or 45%). On refractionation, the pure ester was obtained; it had b. p. 225—226°/16 mm., $d_4^{17·0°}$ 1·0887, $n_D^{17·0°}$ 1·44873, $[R_L]_D$ 92·16 (calc., 91·93) (Found: C, 57·6; H, 8·0. $C_{18}H_{30}O_8$ requires C, 57·8; H, 8·0%). It is a viscid, colourless liquid having a faint odour and on exposure to the atmosphere it slowly becomes pale yellow. The *disodio*-compound (IV) is best prepared from the pure ester and anhydrous sodium methoxide (see below). After being washed with a mixture of pure dry ethyl alcohol and pure dry ether (1 : 3), it is obtained as a pale yellow solid (Found: Na, 11·0. $C_{18}H_{28}O_8Na_2$ requires Na, 11·0%). It decomposes on exposure to the atmosphere.

Hydrolysis of the ester (III). Solutions of the ester (30 g.) in ethyl alcohol (60 g.) and of potassium hydroxide (30 g.) in water (60 g.) were mixed, heated on the steam-bath for 6 hours, and evaporated to dryness. The residue was dissolved in a little water, the solution was extracted with ether to remove any unchanged ester if present and acidified with dilute sulphuric acid, the small quantity of resinous matter which separated was removed by filtration, and the pale yellowish-brown filtrate was saturated with ammonium sulphate and extracted seven times with ether. After *slow* evaporation of the ether, a yellow oil remained which immediately solidified to an almost colourless, crystalline solid (yield, 16 g.), m. p. 155—162° (decomp.). On addition of pure dry ether, the major portion dissolved and a crystalline solid, m. p. 177—179° (decomp.), remained. This was almost pure r-βγ*-dimethylbutane-*αα*δδ-tetracarboxylic acid* (Found: C, 45·6; H, 5·5; equiv., by titration, 66. $C_{10}H_{14}O_8$ requires C, 45·8; H, 5·3%; equiv., 65·5).

Separation of the Two βγ*-Dimethylbutane-*αα*δδ-tetracarboxylic Acids.*—The *r*-acid could be readily isolated from the mixture,

m. p. 155—162° (decomp.) (Found: C, 45·5; H, 5·5%; equiv., by titration, 66), by fractional crystallisation from concentrated hydrochloric acid, in which it was only moderately easily soluble. It was thus obtained in small, hard prisms, m. p. 185—185·5° (decomp.) (Found: C, 45·7; H, 5·4%; equiv., by titration, 66). Other solvents which may be used for the separation are acetone, benzene–alcohol, and ethyl acetate. The *meso*-acid, which is much more soluble than the *r*-acid, can be isolated from the mother-liquors and has m. p. 152—154° (decomp.).

Conversion into a Mixture of ββ′-Dimethyladipic Acids.—Ten g. of the mixture of the tetracarboxylic acids were gradually heated to 200°; the evolution of carbon dioxide then ceased. The whole solidified on cooling to a yellowish-brown mixture (6 g.), m. p. 105—120°, of the two stereoisomeric ββ′-dimethyladipic acids (compare Higginbotham and Lapworth, *loc. cit.*). On esterification with absolute ethyl alcohol and sulphuric acid, the mixed esters, *ethyl ββ′-dimethyladipate*, were obtained. After two fractionations in a vacuum, the liquid had b. p. 139—141°/15 mm., $d_4^{19\cdot5°}$ 0·98777, $n_D^{19\cdot5°}$ 1·43447, $[R_L]_D$ 60·74 (calc., 60·92) (Found: C, 62·4; H, 9·7. $C_{12}H_{22}O_4$ requires C, 62·6; H, 9·6%). It was a mobile liquid with a pleasant ethereal odour. The mixture of esters on hydrolysis with alcoholic potassium hydroxide yielded chiefly a crystalline solid, m. p. 113—117° (Found: equiv., by titration, 89. $C_8H_{14}O_4$ requires equiv., 87).

Synthesis of the cyclo*Butane Ring. Formation of Ethyl* 2 : 3-*Dimethyl*cyclo*butane*-1 : 1 : 4 : 4-*tetracarboxylate* (V).—To 5·3 g. of "molecular" sodium under 200 c.c. of pure dry ether, 15·0 c.c. of pure dry ethyl alcohol were added. When all the sodium had reacted (gentle warming was necessary), a solution of the pure ester (III) (40 g.) in pure dry ether (160 c.c.) was carefully added; the disodio-compound (IV) gradually separated. The mixture was stirred mechanically and dry bromine (5·7 g.) added during 1 hour. The stirring was continued for a further hour, and water then added to dissolve the precipitated sodium bromide. The solution was washed with dilute aqueous sodium bicarbonate and with water and dried with anhydrous sodium sulphate. On evaporation of the ether, a viscid reddish-brown oil (39 g.) was obtained: this was used in all the experiments described below. On fractionation in a vacuum, some carbonisation occurred (compare the corresponding open-chain ester, which distilled unchanged), but most of the liquid distilled as a colourless oil, b. p. 208—210°/16 mm.; this, however, darkened somewhat on exposure to the atmosphere. It had $d_4^{16\cdot7°}$ 1·1216, $n_D^{16\cdot7°}$ 1·45573, $[R_L]_D$ 90·16 (calc., 89·73). Owing probably to the presence of a trace of bromine in the ester, the

analytical results were unsatisfactory (Found: C, 56·4; H, 7·7. $C_{18}H_{28}O_8$ requires C, 58·1; H, 7·5%) (compare Perkin and Robinson, J., 1921, **119**, 1397, who obtained unsatisfactory analytical results for ethyl *cyclo*pentane-1 : 2 : 2 : 3-tetracarboxylate).

It was subsequently found that a much more convenient method of preparation was to use anhydrous sodium methoxide, prepared from "molecular" sodium and pure dry methyl alcohol; the separation of the disodio-compound was then practically complete after 1 hour. The procedure was as described above, the quantities being 6·5 g. of sodium, 11·3 c.c. of methyl alcohol, 250 c.c. of ether; 50 g. of ester in 200 c.c. of ether; and 13·5 c.c. of bromine. The yield of crude *cyclo*butane ester was 49 g. It is not advisable to work with larger quantities, as the yield is thereby materially diminished.

Hydrolysis of the ester (V). Solutions of the ester (50 g.) in alcohol (100 g.) and of potassium hydroxide (50 g.) in water (100 g.) were used. The procedure was that described for the hydrolysis of the ester (III) (p. 1990). The dried ethereal extracts yielded 23 g. of a thick, pale yellow oil—this was employed in all the experiments described below. It slowly crystallised in a vacuum desiccator over concentrated sulphuric acid. The acid separated from ether–light petroleum (b. p. 40—60°) in star-shaped clusters or from benzene–light petroleum in needles, m. p. 138—139° (slight softening at 80°). Correct analytical results for the tetrabasic acid could not be obtained (compare Simonsen, J., 1908, **93**, 1785, who could not obtain correct analytical results for δ-methoxybutane-αα*γγ*-tetracarboxylic acid).

Preparation of a Mixture of the cis- *and* trans-*Forms of* 2 : 3-*Dimethyl*cyclo*butane*-1 : 4-*dicarboxylic Acid*, (VI) *and* (VII).—The tetracarboxylic acid (V) (20 g.) was heated gradually to 180°; the evolution of carbon dioxide then ceased. The gummy residue (compare the ββ′-dimethyladipic acids, which gave a crystalline solid) was esterified with absolute ethyl alcohol and sulphuric acid, and after two fractionations in a vacuum the mixed esters (9·5 g.), *ethyl* 2 : 3-*dimethyl*cyclo*butane*-1 : 4-*dicarboxylate*, were obtained as a fairly mobile liquid with a pleasant ethereal odour and having b. p. 138—139°/14 mm., $d_4^{16\cdot8°}$ 1·00955, $n_D^{16\cdot8°}$ 1·43888, $[R_L]_D$ 59·43 (calc., 58·72) (Found: C, 63·5; H, 8·6. $C_{12}H_{20}O_4$ requires C, 63·2; H, 8·8%). The ester (10 g. in 20 g. of ethyl alcohol) was refluxed with potassium hydroxide (10 g. in 20 g. of water) on the steam-bath for 5 hours. The solution was then evaporated to dryness, the almost colourless residue dissolved in a little water, and the solution extracted with ether, carefully acidified with dilute sulphuric acid, and extracted seven times with ether. The ethereal solution, after being dried with anhydrous sodium sulphate and

evaporated, yielded a colourless oil which immediately crystallised on agitation. On treatment with small quantities of pure dry ether, all the *cis*- and some *trans*-acid dissolved, leaving pure trans-2 : 3-*dimethylcyclobutane*-1 : 4-*dicarboxylic acid*, m. p. 200—201·5°, as a crystalline solid (Found: C, 55·7; H, 7·1; equiv., by titration, 85. $C_8H_{12}O_4$ requires C, 55·9; H, 7·0%; equiv., 86). On evaporation of the ether, a mixture of the *cis*- and *trans*-acids was obtained.

Separation of the cis- *and* trans-*Forms of* 2 : 3-*Dimethylcyclobutane*-1 : 4-*dicarboxylic Acid.*—The mixed acids (2 g.) were warmed to 50° with 4 g. of pure acetyl chloride; a vigorous reaction ensued and hydrogen chloride was evolved. After 1 hour, the liquid mass, containing some suspended crystalline solid (*trans*-acid), was placed in a vacuum desiccator over caustic potash; the excess acetyl chloride was almost wholly removed after 2 days. The semi-solid mass was treated with pure dry ether; some *trans*-acid remained undissolved which, after being washed with small quantities of ether, melted at 200·5—201·5°; the m. p. was unaffected by recrystallisation from acetone–petroleum (b. p. 40—60°). The ethereal solution was washed with dilute aqueous sodium carbonate then with water, and dried with anhydrous sodium sulphate, and the ethereal solution was allowed to evaporate spontaneously. The cis-*anhydride* of 2 : 3-*dimethylcyclobutane*-1 : 4-*dicarboxylic acid* separated in needles, m. p. 50—51° (Found: C, 62·0; H, 6·5. $C_8H_{10}O_3$ requires C, 62·3; H, 6·5%). On acidifying the sodium carbonate washings and repeatedly extracting them with ether, more *trans*-acid was obtained. An aqueous solution of the *cis*-anhydride, on being allowed to concentrate over sulphuric acid, yielded the crystalline cis-*acid*, m. p. 87—88° (Found: C, 55·8; H, 7·0; equiv., by titration, 87. $C_8H_{12}O_4$ requires C, 55·9; H, 7·0%; equiv., 86).

By distilling the mixed acids in a vacuum, the *cis*-acid together with some anhydride, which passes over at a slightly lower temperature, is obtained; this provides the simplest method for the preparation of the pure *cis*-acid or of the *cis*-anhydride.

Attempt to Prepare the Anhydride of trans-2 : 3-*Dimethylcyclobutane*-1 : 4-*dicarboxylic Acid.*—The pure *trans*-acid (1 g.) was gently boiled with an excess of pure redistilled acetic anhydride for 2 hours, and the excess of acetic anhydride removed over caustic potash in a vacuum desiccator. An ethereal solution of the oily residue was washed with dilute aqueous sodium carbonate and with water, dried with anhydrous sodium sulphate, and allowed to evaporate. The *cis*-anhydride, m. p. 50—51°, either alone or when mixed with a specimen prepared from the *cis*-acid, separated in needles.

In conclusion, I wish to thank Professor J. F. Thorpe, F.R.S., for his kind interest and advice. Some of the expenses of the research were met by a grant from the Chemical Society Research Fund.

CCLXI.—*Chlorocamphoranilic Acids and Camphorochlorophenylimides.*

By MAHAN SINGH and RAM SINGH.

IN a previous communication (J., 1925, **127**, 1966) it was shown that the reaction

$$C_8H_{14}\begin{matrix}CO\cdot NH\cdot C_6H_4R\\ CO\cdot OH\end{matrix} \longrightarrow C_8H_{14}\begin{matrix}CO\\ CO\end{matrix}N\cdot C_6H_4R + H_2O$$

is dependent on the nature of the group R and other factors, the stability of the acid increasing as R becomes more negative. The carboxycamphoranilic acids (*loc. cit.*) produced by the condensation of camphoric anhydride with aminobenzoic acids are very stable and have not been converted into camphorimides.

The reactions of camphoric anhydride with *o*-, *m*-, and *p*-chloroanilines have now been investigated. The object was to examine the effect of decrease in the negativity of R(CO_2H to Cl) on the above reaction. As expected, the condensation products yielded a mixture of chlorocamphoranilic acids and camphorimide derivatives, thus showing that with the decrease in the negativity of the group there is a tendency towards the formation of ring compounds. The position of the substituent seems to have some effect on the yield of the camphorimide, which is about 20% in the case of the para-derivative and 5 to 6% in the case of the ortho- and meta-derivative. This question is being fully investigated in the condensation products of camphoric anhydride and bromoanilines and iodoanilines.

Wootton (J., 1910, **97**, 405) also has condensed camphoric anhydride with chloroanilines. The melting points of his acids are lower than ours, because they contain the corresponding camphorimides formed in the condensations.

With regard to the optical rotations of the chlorocamphoranilic acids, (*a*) the *o*-chloro-acid gives negative values in acetone and methyl ethyl ketone and positive values in methyl alcohol and ethyl alcohol; (*b*) the relation between the molecular rotation and the position of the chlorine atom is in all solvents $p>m>o$; (*c*) the

molecular rotatory powers of these acids do not follow the order of the dielectric constants of the solvents used.

The following table gives the molecular rotatory powers of camphoranilic acid and some of its ortho-derivatives in methyl alcohol, ethyl alcohol, and acetone.

	$[M]_D$.		
	Methyl alcohol.	Ethyl alcohol.	Acetone.
H*	+150°	+131°	+101°
CO_2H	−584	−574	−551
CH_3*	+146	+144	+ 98
Cl	+ 57·8	+ 35·6	− 40·3

* Singh and Puri, J., 1926, 504.

The relative changes of rotatory power in methyl alcohol and acetone are given by $CO_2H > H > CH_3 > Cl$. This corresponds with the relative polarity of the groups as deduced from molecular inductive capacities (Rule, J., 1926, 553).

The molecular rotations of the *p*- and *m*-substituted camphorophenylimides are considerably lower than those of the corresponding acids, whereas in the case of the *o*-substituted derivatives they are of the same magnitude.

Experimental.

Condensation of Camphoric Anhydride with o-*Chloroaniline.*—Equimolecular quantities of these and a little fused sodium acetate were heated together at 145—150° for 4 hours. The product was dissolved in 90% alcohol, decolorised with animal charcoal, precipitated, and extracted with a dilute solution of sodium bicarbonate, which left a very small residue of camphoro-*o*-chlorophenylimide. This crystallised from alcohol in fine, light needles, m. p. 128° (Wootton, *loc. cit.*, gives m. p. 125—126°). It was soluble in acetone, methyl alcohol, and ether, but sparingly soluble in ethyl alcohol (Found: C, 65·6; H, 6·4; Cl, 12·2. Calc., for $C_{16}H_{18}O_2NCl$: C, 65·8; H, 6·2; Cl, 12·1%).

The bicarbonate solution was acidified and the amorphous solid obtained was recrystallised twice from 60% alcohol; it then melted at 165° (Wootton, *loc. cit.*, gives m. p. 139—140°, which is that of a mixture of 2′-chlorocamphoranilic acid and the imide). *2′-Chlorocamphoranilic acid* is soluble in acetone, methyl alcohol, and ethyl alcohol and moderately easily soluble in ether (Found: C, 62·2; H, 6·8; Cl, 11·2; equiv. by titration with NaOH, 311. $C_{16}H_{20}O_3NCl$ requires C, 62·0; H, 6·5; Cl, 11·5%; equiv., 309·5).

Condensation of Camphoric Anhydride with m-*Chloroaniline.*—The procedure was that described above. The alcoholic solution slowly deposited fine, silky needles of camphoro-*m*-chlorophenyl-

imide, which melted at 176° after recrystallisation (Wootton gives m. p. 172—173°). It was soluble in acetone, methyl alcohol, and ether, and sparingly soluble in ethyl alcohol (Found: C, 66·0; H, 6·9; Cl, 12·2%).

The alcoholic filtrate, on being concentrated, gave a further crop of impure imide. The filtrate from this was poured into a large volume of water, and the precipitate of 3′-chlorocamphoranilic acid thus obtained was dissolved in dilute sodium bicarbonate solution, reprecipitated, and crystallised from 60% alcohol, the pure acid separating in thin plates, m. p. 216—217° (Wootton gives m. p. 207—209°). It was soluble in acetone, methyl alcohol, and ethyl alcohol, and very sparingly soluble in ether (Found: C, 61·8; H, 6·85; Cl, 11·9%, equiv., 304).

Condensation of Camphoric Anhydride with p-*Chloroaniline.*—The procedure was that described above, and the solvent absolute alcohol. The solution slowly deposited stout, prismatic needles of camphoro-*p*-chlorophenylimide, which were twice recrystallised from alcohol; they then melted at 165° (Wootton gives m. p. 162—163°). The imide is soluble in acetone, methyl alcohol and ether, and very sparingly soluble in ethyl alcohol (Found: C, 65·5; H, 6·5; Cl, 12·3%).

From the united filtrates a second crop of the imide was obtained, m. p. 164—165°, after recrystallisation from alcohol. 4′-Chlorocamphoranilic acid, isolated in the same way as the *m*-compound, crystallised from alcohol in needles, m. p. 197° (Wootton gives m. p. 192—194°). It was soluble in acetone, methyl alcohol and ethyl alcohol, and sparingly soluble in ether (Found: C, 61·7; H, 6·6; Cl, 11·9%; equiv., 314).

In all the condensations, complete separation of the acid from the imide could be effected by fractional crystallisation from ethyl alcohol, but it was a rather tedious process.

Molecular rotations of the chlorocamphoranilic acids and camphorochlorophenylimides.

CCLXII.—δ-d-*Bornylsemicarbazide and* δ-d-neo*Bornylsemicarbazide.*

By JOHN AUGUSTUS GOODSON.

FOR an investigation, which has so far given negative results, the author has had occasion to prepare a quantity of δ-*d*-bornylsemicarbazide and δ-*d*-*neo*bornylsemicarbazide. The use of such optically active semicarbazides for the resolution of racemic carbonyl compounds has been suggested by various workers and a number of them have been prepared, *e.g.*, camphoryl-ψ-semicarbazide (Forster and Fierz, J., 1905, **87**, 722), δ-α-phenylethylsemicarbazide (Wilson, Hopper, and Crawford, J., 1922, **121**, 866), and δ-menthylsemicarbazide (Wilson and Crawford, J., 1925, **127**, 103), whilst Forster and Attwell attempted to prepare β-bornylsemicarbazide (J., 1904, **85**, 1188), but in no case have these substances so far been used successfully for this purpose. δ-*d*-Bornylsemicarbazide

and δ-*d*-*neo*bornylsemicarbazide were only tried on one racemic ketone, *viz.*, 3-methyl*cyclo*hexanone, and although well-crystallised products were obtained, they did not separate into optical antipodes on fractional crystallisation from two solvents.

EXPERIMENTAL.

Acetone-δ-d-*bornylsemicarbazone*.—To *d*-bornylamine (10 g.) melted by immersion in an oil-bath at 175°, was added acetone-semicarbazone (7·5 g.) a little at a time, and the heating continued for 15 minutes. The cold crystalline product was recrystallised from alcohol, and active *acetone*-δ-d-*bornylsemicarbazone* obtained in anhydrous needles (yield, 76%), m. p. 141—148° (corr.), $[\alpha]_D^{20°}$ + 25·5° (c = 2·04 in dry alcohol) (Found : C, 66·7; H, 10·0; N, 16·5. $C_{14}H_{25}ON_3$ requires C, 66·9; H, 10·0; N, 16·7%).

In order to obtain a good yield, it is necessary to use anhydrous *d*-bornylamine. In a preliminary experiment, *d*-bornylamine containing two molecules of water of crystallisation, obtained by precipitation with sodium hydroxide from a solution of the hydrochloride, was used; a considerable quantity of di-*d*-bornylcarbamide was then produced.

δ-d-*Bornylsemicarbazide Hydrochloride*.—Acetone-δ-*d*-bornylsemicarbazone (85 g.) and 10% hydrochloric acid (850 c.c.) were heated on the water-bath for 1½ hours. δ-*Bornylsemicarbazide hydrochloride* crystallised on cooling and was recrystallised from alcohol after removal of a small quantity of di-*d*-bornylcarbamide by filtration (yield, 94%). The anhydrous substance, m. p. 190—198° (corr.), had $[\alpha]_D^{20}$ + 2·6° (c = 5 in dry alcohol) (Found in air-dried substance : loss at 105° in a vacuum, 14·1. $C_{11}H_{22}ON_3Cl,2H_2O$ requires H_2O, 12·7%. Found in anhydrous substance : C, 53·1; H, 8·9; Cl, 14·2. $C_{11}H_{22}ON_3Cl$ requires C, 53·3; H, 9·0; Cl, 14·3%).

δ-d-*Bornylsemicarbazide*.—δ-*d*-Bornylsemicarbazide hydrochloride (10 g.) dissolved in a little alcohol was treated with 8·5 c.c. of 20% sodium hydroxide solution and poured into water. The base was extracted with chloroform and obtained in needles by addition of light petroleum to the concentrated solution. The substance, dried in a vacuum at 50°, melted at 75° after softening some degrees lower, and had $[\alpha]_D^{20°}$ + 17·0° (c = 5 in dry alcohol). On keeping, it gradually decomposed (Found in dried substance : C, 62·5; H, 10·4. $C_{11}H_{21}ON_3$ requires C, 62·5; H, 10·0%).

δ-*d*-Bornylsemicarbazones of various ketones were prepared by adding the requisite quantity of ketone to a concentrated solution of the base in alcohol.

iso*Pulegone*-δ-d-*bornylsemicarbazone*, prepared from *iso*pulegone

having $\alpha_D^{18^\circ} - 6{\cdot}0^\circ$, crystallised in thick, rhombic plates, m. p. 224—226° (corr.), $[\alpha]_D^{20^\circ} + 9{\cdot}2^\circ$ ($c = 5{\cdot}04$ in chloroform) (Found: C, 72·8; H, 10·1. $C_{21}H_{35}ON_3$ requires C, 73·0; H, 10·2%).

4-*Methyl*cyclo*hexanone*-δ-d-*bornylsemicarbazone* crystallised in clusters of six-sided plates, softening slightly at 145° (corr.), melting at 154° (corr.), and having $[\alpha]_D^{20^\circ} + 27{\cdot}2^\circ$ ($c = 4{\cdot}898$ in dry alcohol) (Found: C, 70·5; H, 10·2. $C_{18}H_{31}ON_3$ requires C, 70·8; H, 10·2%).

3-*Methyl*cyclo*hexanone*-δ-d-*bornylsemicarbazone*, prepared from optically inactive 3-methyl*cyclo*hexanone, melted at 172—177° (corr.) and had $[\alpha]_D^{20^\circ} + 27{\cdot}4^\circ$ ($c = 4{\cdot}85$ in dry alcohol) (Found: C, 70·5; H, 10·1. $C_{18}H_{31}ON_3$ requires C, 70·8; H, 10·2%). Recrystallisation from alcohol or ligroin failed to resolve it into its components, even when seeded with d-3-*methyl*cyclo*hexanone*-δ-d-*bornylsemicarbazone*, m. p. 173—179° (corr.), $[\alpha]_D^{20^\circ} + 7{\cdot}4^\circ$ ($c = 4{\cdot}726$ in dry alcohol) (Found: C, 70·4; H, 10·1. $C_{18}H_{31}ON_3$ requires C, 70·8; H, 10·2%), prepared from *d*-3-methyl*cyclo*hexanone kindly supplied by Dr. Kenyon.

Acetone-δ-d-neo*bornylsemicarbazone*, prepared in the same way as acetone-δ-*d*-bornylsemicarbazone, but at 190° in order to keep the *neo*bornylamine liquid, crystallised from alcohol in anhydrous needles, m. p. 175—179° (corr.), $[\alpha]_D^{20^\circ} - 92{\cdot}1^\circ$ ($c = 2{\cdot}008$ in dry alcohol) (Found: C, 66·6; H, 10·1. $C_{14}H_{25}ON_3$ requires C, 66·9; H, 10·0%).

δ-d-neo*Bornylsemicarbazide hydrochloride* was prepared by hydrolysis of the above acetone derivative with dilute hydrochloric acid. The anhydrous substance melted at 198—202° (corr.) and had $[\alpha]_D^{20^\circ} - 50{\cdot}8^\circ$ ($c = 4{\cdot}982$ in dry alcohol) (Found in air-dried substance: loss at 105° in a vacuum, 5·3. $C_{11}H_{22}ON_3Cl,H_2O$ requires H_2O, 6·8%. Found in substance dried at 105° in a vacuum: Cl, 14·1. $C_{11}H_{22}ON_3Cl$ requires Cl, 14·3%).

δ-*d*-*neo*Bornylsemicarbazones were prepared by adding the requisite quantity of ketone to a concentrated solution of δ-*d*-*neo*-bornylsemicarbazide in alcohol.

4-*Methyl*cyclo*hexanone*-δ-d-neo*bornylsemicarbazone* crystallised in rosettes of needles, m. p. 151—155° (corr.), $[\alpha]_D^{20^\circ} - 91{\cdot}3^\circ$ ($c = 2{\cdot}83$ in dry alcohol) (Found: C, 70·4; H, 10·0. $C_{18}H_{31}ON_3$ requires C, 70·8; H, 10·2%).

3-*Methyl*cyclo*hexanone*-δ-d-neo*bornylsemicarbazone*, prepared from optically inactive 3-methyl*cyclo*hexanone, melted at 157—161° (corr.) and had $[\alpha]_D^{20^\circ} - 91{\cdot}2^\circ$ ($c = 4{\cdot}772$ in dry alcohol) (Found: C, 70·6; H, 10·3. $C_{18}H_{31}ON_3$ requires C, 70·8; H, 10·2). Recrystallisation from alcohol or ligroin failed to resolve it into its components.

The author desires to express his thanks to Mr. R. E. Hedger for assistance in the work and to Dr. Kenyon for supplying the *d*-3-methyl*cyclo*hexanone used.

WELLCOME CHEMICAL RESEARCH LABORATORIES.

[*Received, July 16th*, 1927.]

CCLXIII.—*The Absorption Spectrum of Ergosterol in Relation to the Photosynthetic Formation of Vitamin* D.

By RICHARD ALAN MORTON, ISIDOR MORRIS HEILBRON, and EDWARD DAVID KAMM.

IT has been shown (Heilbron, Kamm, and Morton, *Biochem. J.*, 1927, **21**, 78) that the antirachitic potency developed on irradiation of ordinary cholesterol, either from cod-liver oil or from brain, may be traced to the presence in it of a minute quantity of some foreign substance which exhibits well-defined absorption bands near 293·5 μμ, 281·5μμ, and 270 μμ. These bands disappear on irradiation, concomitantly with the development of antirachitic potency in the product. A similar conclusion was almost simultaneously arrived at by Pohl (*Nach. Ges. Wiss. Göttingen*, 1926), using an entirely different spectroscopic technique (monochromatic light and photo-electric cells). These results are also substantiated by the fact that cholesterol regenerated from its dibromide could not be activated by irradiation with ultra-violet light. Subsequent work developed by using the spectroscopic method rapidly led to the conclusion that ergosterol—or a similar sterol—is the actual pro-vitamin, and this has been fully substantiated by animal tests (Rosenheim and Webster, *Biochem. J.*, 1927, **21**, 127; Windaus and Hess, *Nach. Ges. Wiss. Göttingen*, 1926).

In extension of our earlier work, it became necessary to examine in detail the absorption spectrum of ergosterol, in order to establish an accurate standard of comparison by means of which we could determine the relative richness of various materials in respect of the pro-vitamin.

In agreement with the work of Pohl as briefly reported by Windaus and Hess (*loc. cit.*), our results correspond in a very remarkable degree with the absorption curve found for ordinary cholesterol :

	λ max.	λ max.	λ max.
Cholesterol.....	293 μμ	280 μμ	269 μμ
Ergosterol	293·5 μμ	281·5 μμ	270 μμ

Further, the results indicate that ergosterol is 2—4 × 10^3 times as active as our specially prepared cholesterol (Heilbron, Kamm, and Morton, *loc. cit.*).

We next studied the change in the absorption spectrum brought about by irradiation of ergosterol in alcoholic solution. A solution of 0·05 g. of ergosterol in 250 c.c. of optically pure alcohol was prepared and portions were exposed to the light of a practically *new* (Hewittic) quartz mercury-vapour lamp of the vacuum type. Samples were withdrawn every 15 minutes and the absorption spectrum was determined. For this purpose two Hilger E_3 quartz spectrographs were used alternately, each being fitted with a rotating disc sector photometer. Two series of absorption curves were obtained showing the selective absorption at half-hour intervals. The two sets of curves were reasonably concordant and only one will therefore be described.

1. Ergosterol. Fresh solution not irradiated. Bands at 270 μμ, 281·5 μμ, and 293·5 μμ. Minimum 230 μμ. "ε" max. 10,200. "ε" min. 2,400.

2. Irradiated for 30 minutes. Broad maximum near 275 μμ. "ε" max. 8,500. Minimum near 230 μμ. "ε" min. 3,750. The absorption band is wider in the region 230—265 μμ than the corresponding band for the fresh solution.

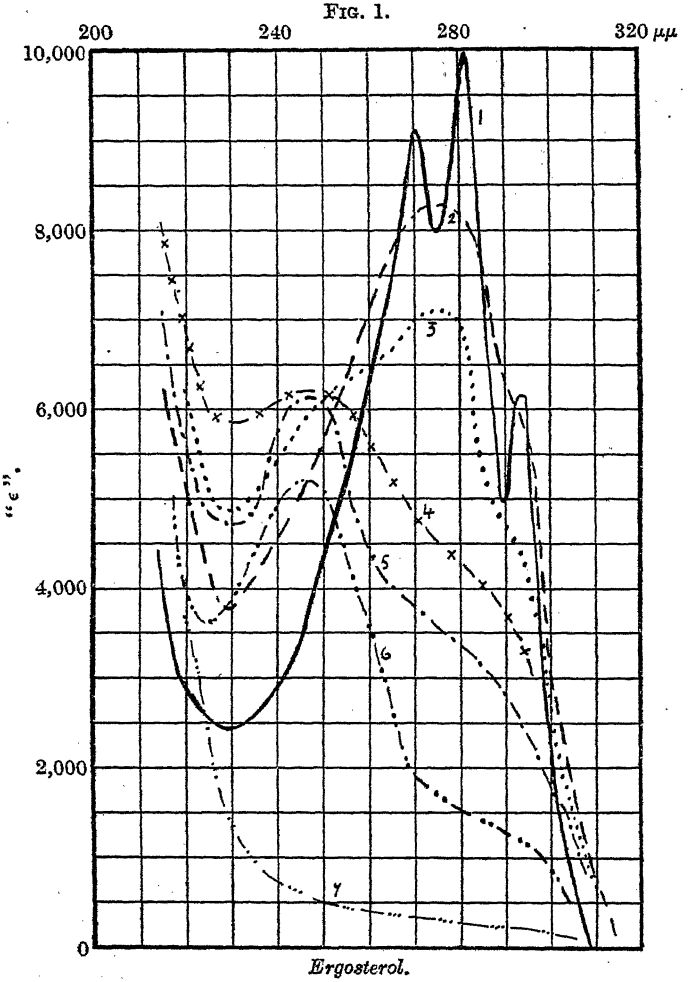
3. Irradiated for 60 minutes. Broad maximum near 275 μμ. "ε" max. 7,150. Minimum near 230 μμ. "ε" min. 4,850. The curve shows a marked step-out in the region 240—260 μμ, indicating the incipient appearance of a band in that region of the spectrum.

4. Irradiated for 90 minutes. The curve shows a new maximum near 247 μμ. "ε" max. 6,300 and a minimum near 230 μμ. "ε" min. 5,800. The persistence of the new band is therefore low. At the same time the absorption curve shows marked absorption over the region 260—300 μμ, indicating that the ergosterol has not entirely disappeared.

5. Irradiated for 120 minutes. The band at 247 μμ has increased in persistence, whilst the absorption over the range 260—300 μμ shows a collateral decrease.

6. Irradiated 150 minutes. The band at 247 μμ is well developed. "ε" max. 5,250, a minimum is shown at 225 μμ, and the persistence is considerable. From 247 μμ—269 μμ the absorption curve is fairly straight, but at 270 μμ a sharp inflexion commences and the curve falls slowly to the limiting position near 310 μμ.

7. Irradiated for 6 hours. The solution is now almost diactinic and all trace of selective absorption has disappeared.



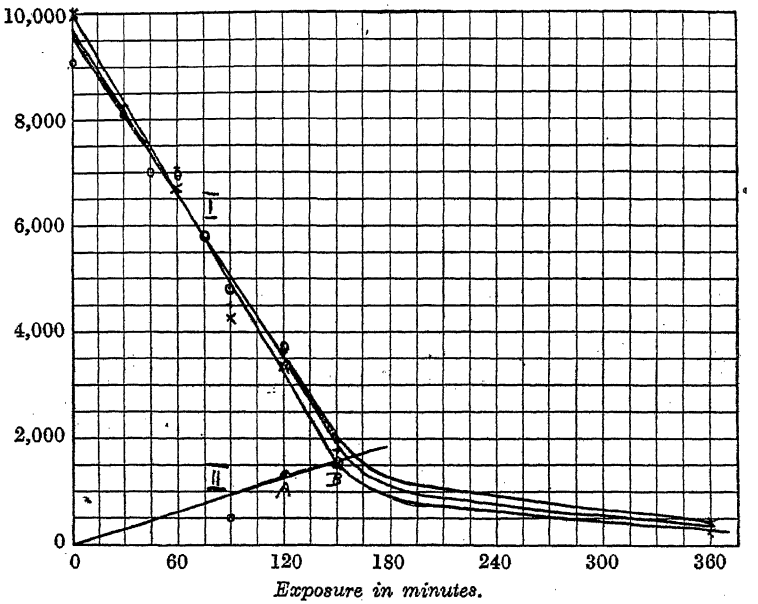
The curves (Fig. 1) show that the reaction

$$\text{ergosterol} \xrightarrow{\text{u.v. light}} \text{vitamin } D \quad . \quad . \quad . \quad . \quad (1)$$

is accompanied by the disappearance of selective absorption in the region 260—300 μμ and by the appearance of a new selective absorp-

tion in the region 230—260 μμ with a maximum at 247 μμ. This new band itself disappears with further irradiation, a fact which is

FIG. 1.



not inconsistent with the view that it is due to vitamin *D*, since it is known that "excessive" irradiation of cod-liver oil induces a loss of vitamin potency.*

* The results of biological experiments have now come to hand and show that the product giving the 247 μμ band at maximum intensity possesses very

When the extinctions at 270—275 μμ and 280 μμ are plotted against time, the result is, within experimental error, a straight line, indicating that the rate of disappearance of ergosterol depends solely on the energy input. By plotting the persistence of the new band against time, a roughly linear relation is likewise obtained (Fig. 2). These results can only mean that the *whole* of the incident energy is absorbed and is photochemically effective, within the absorption band and within the limits of the straight line relationship.

FIG. 2.

I, *extinction coefficients at* 281·5 μμ, 275 μμ, 270 μμ, *ergosterol curves.*
II, *persistence of new band* (*line* AB *produced cuts axes at origin*).

In our experience, the irradiation of thin layers of solid ergosterol is unsatisfactory. Complete disappearance of the original bands is secured only after long exposure and under conditions in which consecutive reactions are not precluded.

The absorption curves indicate a fact of considerable significance, namely, that the irradiation of ergosterol in solution or in the solid state is quite unlikely to give pure vitamin *D* unless special precautions are taken. The existence of a well-marked absorption

high antirachitic potency, whereas the product which has undergone irradiation until this band has disappeared is not effective at the same dosage. The tests were kindly carried out by Messrs. H. Jephcott and A. L. Bacharach, using the method described in their paper (*Biochem. J.*, 1926, **20**, 1351).

band between 225 μμ and 270 μμ characteristic of a photochemically unstable substance, *viz.*, vitamin *D*, means that if photodecomposition of this compound is to be avoided, *these radiations must be screened off*. The most suitable material for transmitting only light of the middle ultra-violet region is the proprietary "Vitaglass." Since, however, the rays between 270 and 293 μμ are absorbed to a considerable extent by vitaglass, very prolonged exposures will be necessary. Rosenheim and Webster (*Biochem. J.*, 1927, **21**, 392) state that "the action of ultra-violet light on ergosterol leads to an obvious physical change and the production of a yellowish resin." The nature of the intramolecular change which gives rise to the vitamin formation is at present unknown. The first step towards solving this problem is the preparation of pure vitamin *D*, and at present the line of attack most clearly indicated is the prevention of its photochemical decomposition by suitable screening.

The present results have a very definite bearing on the problem of the industrial production of vitamin *D*. Anything approaching a satisfactory yield in the reaction (1) requires prolonged irradiation —an expensive process. Screening a quartz mercury-vapour lamp with vitaglass is obviously wasteful, since the large energy emission of the 265 μμ and 253·6 μμ (resonance) lines is detrimental to the stability of vitamin *D*, and must not have access to the solution undergoing irradiation. It would seem, therefore, that the mercury vapour lamp is unsuitable for this particular photochemical reaction.

The alternative light sources are carbon or metal arcs. It is quite feasible to obtain suitably treated carbon arcs with little or no emission on the ultra-violet side of 270 μμ. On the other hand, there can be little doubt that the working cost of mercury vapour lamps is lower than that of carbon or tungsten arcs producing the same intensity of ultra-violet light of all wave-lengths. These considerations show that the photochemical formation of vitamin *D* in good yield presents a formidable problem both to research and to costing. There seems, however, every reason to expect a solution if the experiments are accurately controlled by spectroscopic means.

Some comment is necessary on a statement by Rosenheim and Webster (*Biochem. J.*, 1927, **21**, 395) to the effect that the absorption of ergosterol "extends well into the ultra-violet region of sunlight." The facts appear to be as follows. Dorno found that the limiting detectable ultra-violet wave-lengths of sunlight were: December—February, 3120 Å.; September—November, 3080 Å.; March—May, 3010 Å.; June—August, 2962 Å.; the relative intensities being Jan. 100, April 400, July 1000, October 600.

Only a very small area of the ergosterol absorption is covered by wave-lengths on the long-wave side of 2960 Å., and appreciable

photochemical reaction only appears possible in summer sunlight. This is, of course, in harmony with the seasonal incidence of rickets.

A brief remark on the paper by Hume, Lucas, and Smith (*Biochem. J.*, 1927, **21**, 362) is also necessary. These authors suggest that the mechanism of synthesis of vitamin *D in vivo* is the photochemical transformation of traces of ergosterol or a substance with similar absorption bands. Unfortunately, the transmission of epidermis falls to zero near 296 μμ, so that a direct experimental test is excluded. We propose to investigate the matter further in two ways :

(1) To ascertain spectroscopically whether ergosterol, in solution in a quartz vessel, can be transformed into vitamin *D* by exposure to sunlight.

(2) To ascertain whether an extract containing ergosterol can be prepared from skin by means of solvents.

During the course of this work preliminary attempts were made to ascertain whether the formation of vitamin *D* is due to polymerisation. Determinations of molecular weight by the Rast micro-method failed to establish any such change, but we were not completely satisfied with the conditions under which the determinations were carried out and are repeating and extending the experiments.*

We desire to express our thanks to Mr. W. Doran and Mr. M. N. Leathwood for help in the experimental work, to Mr. F. H. Carr, C.B.E., of British Drug Houses, Ltd., for the ergosterol, and to the Food Investigation Board for a grant which has enabled this research to be carried out.

THE UNIVERSITY, LIVERPOOL. [*Received, May 27th*, 1927.]

CCLXIV.—*Studies in the Coumarin Series. Part I. The Action of the Grignard Reagent upon Substituted Coumarins.*

By ISIDOR MORRIS HEILBRON and DOUGLAS WILLIAM HILL.

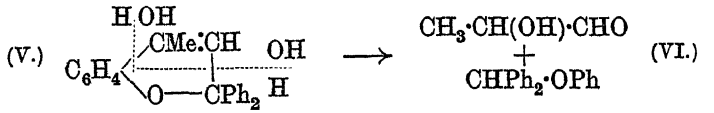
DECKER and FELLENBERG (*Annalen*, 1907, **356**, 281) have shown that the interaction of coumarins and the Grignard reagent leads, under carefully specified conditions, to the production of mono-alkyl- or -aryl-pyrylium salts, and more recently Willstätter and his

* Whilst this paper was in the press, our attention was drawn to a paper by Pohl (*Nach. Ges. Wiss. Göttingen*, Mathematisch-Physikalische Klasse, 1927) in which the absorption curves of ergosterol and vitamin *D* are described. The photoelectric and photographic methods are in substantial agreement.

co-workers (*Ber.*, 1924, **57**, 1938, 1945) have used this reaction for the synthesis of anthocyanidins from 3-methoxycoumarins. On the other hand, Houben (*Ber.*, 1904, **37**, 498) has described the formation of dialkyl and diaryl derivatives of coumarin itself. Whereas magnesium alkyl halides led to the formation of 2 : 2-dialkyl-Δ^3-chromens, magnesium phenyl bromide gave rise to the carbinol (I), the formation of which he attributed to a steric hindrance preventing the loss of water necessary for the production of the 2 : 2-diphenylchromen.

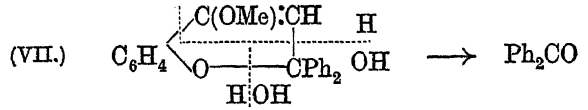
The work described in the present paper was initially undertaken with the intention of synthesising flavylium chlorides containing methoxyl or hydroxyl in the 4-position; the latter would probably readily lose hydrogen chloride and pass into flavones. As, however, only diaryl products were obtained, a detailed investigation of coumarins substituted in the 3- and 4-positions was initiated which has led to the isolation of three distinct types of product. Two of these, differently constituted diarylchromens, are now described; the third, a series of benzopyrylium salts, will form the subject of a subsequent communication. While this work was in progress, a most noteworthy contribution to the subject was published by Löwenbein (*Ber.*, 1924, **57**, 1517), who showed that the supposed diphenyl-*o*-hydroxystyrylcarbinol (I) of Houben is in reality 2 : 4-diphenylchroman-2-ol (II), which readily loses water on heating with glacial acetic acid, yielding 2 : 4-diphenyl-Δ^2-chromen (III).

(I.) $C_6H_4<^{CH:CH\cdot CPh_2\cdot OH}_{OH}$ $\qquad$ $C_6H_4<^{CHPh\cdot CH_2}_{O\text{——}CPh\cdot OH}$ (II.)



In addition to the chromanol, he obtained a second compound which proved to be 2 : 2-diphenyl-Δ^3-chromen (IV).

(III.) $C_6H_4<^{CHPh\cdot CH}_{O\text{——}CPh}$ $\qquad$ $C_6H_4<^{CH:CH}_{O\text{——}CPh_2}$ (IV.)



Löwenbein also examined the 5 : 7-, 4 : 6-, and 4 : 7-dimethylcoumarins, all of which, according to him, yielded the corresponding chromanols analogous to (II).

In the course of our own experiments, the action of magnesium phenyl bromide upon both 3-methyl- and 3-phenyl-coumarin was studied. In each case the corresponding chromanol was isolated, from which the elements of water were readily eliminated on heating with glacial acetic acid, 2 : 4-diphenyl-3-methyl-Δ^2-chromen and 2 : 3 : 4-triphenyl-Δ^2-chromen, respectively, being formed. Since these compounds were prepared, a full description of the latter has been published by Löwenbein and Rosenbaum (*Annalen*, 1926, 448, 223), who have prepared it both from 3-phenylcoumarin and

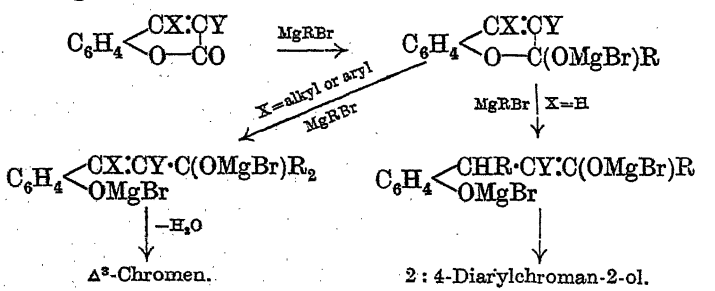
by the interaction of magnesium phenyl bromide upon 2 : 3-diphenylbenzopyrylium perchlorate.*

On the other hand, 4-methyl- and 4-methoxy-coumarins yield 2 : 2-*diphenyl*-4-*methyl*-Δ^3-*chromen* (V) and 4-*methoxy*-2 : 2-*diphenyl*-Δ^3-*chromen* (VII), respectively.

According to Löwenbein (*loc. cit.*), certain Δ^3-chromens are converted into coumarone derivatives of the same empirical formula on boiling with glacial acetic acid. Neither of the above compounds (V and VII) was altered under such conditions. That, however, they are in reality Δ^3-chromens has been definitely established by a study of their products of hydrolysis. 2 : 2-Diphenyl-4-methyl-Δ^3-chromen was refluxed for 24 hours with 50% potassium hydroxide solution; ring scission then occurred with production of *benzhydryl phenyl ether* (VI). With 4-methoxy-2 : 2-diphenyl-Δ^3-chromen, refluxing for 5 hours with 33% potassium hydroxide solution was sufficient to cause complete scission. The product isolated in this case was benzophenone, cleavage occurring in the same manner as found by Baker (J., 1925, **127**, 2349). These results, although not wholly in agreement with Löwenbein's findings in the case of the 4 : 6- and 4 : 7-dimethylcoumarins, harmonise well with the work of Kohler (*Amer. Chem. J.*, 1907, **38**, 511), who has shown that addition of the Grignard reagent to $\alpha\beta$-unsaturated ketones takes place both in the 1 : 2 and in the 1 : 4 positions, the relative amounts of each compound formed being dependent on the nature of the unsaturated compound; *e.g.*, the unsaturated ketone $C_6H_5\cdot CH{:}CH\cdot CO\cdot C_6H_5$ gives mainly 1 : 4 addition (94—96%), whereas $(C_6H_5)_2C{:}CH\cdot CO\cdot C_6H_5$ yields 100% of unsaturated alcohol owing to complete 1 : 2 addition.

Our experiments with coumarins have led us to the definite conclusion that the primary reactions with the Grignard reagent follow a common course, the ultimate formation of a Δ^2- or Δ^3-chromen being influenced solely by the position of the substituent

* Dr. Löwenbein informs me (private communication) that he has also prepared 2 : 4-diphenyl-3-methyl-Δ^2-chromen (m. p. 94°) by the decomposition of 2-phenyl-3-methylbenzopyrylium perchlorate with magnesium phenyl bromide—I. M. H.



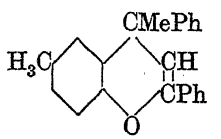
in the pyran ring. Two explanations may be presented to meet the above postulation. In the first place, the primary reaction involving one molecule of the Grignard reagent may result in the production of an αβ-unsaturated ketone (VIII) and the subsequent

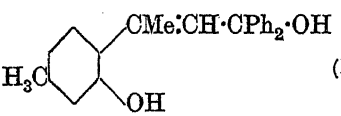
(VIII.) $C_6H_4<^{CX:CH\cdot COR}_{OMgBr}$ $C_6H_4<^{CHR\cdot CH:CR\cdot OH}_{OH}$ (IX.)

reactions would then directly follow the Kohler rule. Where X = hydrogen, 1 : 4 addition would chiefly occur with production of the enol (IX), from which the chromanol (X) would result, as pointed out by Löwenbein (*Ber.*, 1924, **57**, 1517), through intra-

(X.) $C_6H_4<^{CHR\cdot CH_2}_{O\text{——}CR\cdot OH}$ $C_6H_4<^{CX:CH\cdot CR_2\cdot OH}_{OH}$ (XI.)

molecular rearrangement from the keto-form. On the other hand, where X is other than hydrogen, 1 : 2 addition will take place, giving the styrylcarbinol (XI), which will immediately pass into the Δ^3-chromen by loss of a molecule of water. Löwenbein considers, however, that Δ^3-chromen formation occurs directly without opening of the lactone ring, since phenyl *o*-hydroxystyryl ketone yields only 2 : 4-diphenylchroman-2-ol when treated with magnesium phenyl bromide, whereas, as previously mentioned, coumarin gives both the chromanol and the Δ^3-chromen. It will be conceded, however, that the reactions involved with the two compounds are not identical and that the presence of the free *o*-hydroxyl group in the ketone may well favourably influence the 1 : 4 addition. An alternative mechanism differing only in degree from the above, and equally explicable on the Kohler rule, may also be reached by assuming that the first reaction with the Grignard reagent comprises direct addition without ring opening. The course of the subsequent reactions under these conditions is expressed by the following formulæ :





Either explanation provides a perfectly general interpretation of the Δ^2- or Δ^3-diarylchromen formation and meets the problem presented by the 3-substituted coumarins which fail to yield

Δ^3-diarylchromens, a result incompatible with the idea that interaction can occur directly without scission of the lactone ring. The fact that whereas coumarin itself gives both the 1 : 4- and 1 : 2-addition products, whilst the 3-substituted coumarins give only 1 : 4-addition, is also in agreement with Kohler's findings in the case of the unsaturated ketones $C_6H_5 \cdot CH{:}CMe \cdot CO \cdot C_6H_5$ and $C_6H_5 \cdot CH{:}CPh \cdot CO \cdot C_6H_5$.

The complete harmony between our experimental results and these theoretical deductions induced us to re-examine the products obtained from both 4 : 6- and 4 : 7-dimethylcoumarin, which, according to Löwenbein, yielded 2 : 4-diphenylchroman-2-ol derivatives. Working in exact accordance with this author's conditions, we failed to obtain from 4 : 6-dimethylcoumarin any trace of the so-called chromanol, m. p. 110°, but isolated in good yield a substance, m. p. 127°, which corresponded to the compound obtained by Löwenbein by treatment of the chromanol with glacial acetic acid and to which he assigned the structure of 2 : 4-diphenyl-4 : 6-dimethyl-Δ^2-chromen (XII). The main yield from 4 : 7-dimethylcoumarin was a compound, m. p. 86°, apparently identical with the supposed 2 : 4-diphenyl-4 : 7-dimethyl-Δ^2-chromen (m. p. 87°). In addition, a very small yield of a substance, m. p. 146°, was obtained of empirical formula $C_{23}H_{22}O_2$, corresponding to the supposed 2 : 4-diphenyl-4 : 7-dimethylchroman-2-ol of m. p. 144°.

(XII.)

(XIII.)

The fact that chromens were obtained directly from the products of the reaction is in itself some indication that these do not belong to the Δ^2-series, and this we have proved by an examination of their scission products. Benzhydryl *p*-tolyl ether was obtained in good yield from the 4 : 6-dimethyl compound. In the case of 2 : 2-diphenyl-4 : 7-dimethyl-Δ^3-chromen, in addition to benzhydryl *m*-tolyl ether, lactaldehyde, m. p. 105°, was isolated, thus definitely establishing the constitution of these compounds as diaryl-Δ^3-chromens.

The substance, m. p. 146°, is probably the intermediate *diphenyl-2-hydroxy-β : 4-dimethylstyrylcarbinol* (XIII), but the quantity at our disposal did not allow of detailed examination.

We acknowledge our indebtedness to Dr. A. Löwenbein, with whom we have been in communication concerning the mechanism of the changes involved in these reactions, and who has freely given us the advantage of his views.

EXPERIMENTAL.

4-Hydroxy-2 : 2-diphenyl-Δ^3-chromen.—Magnesium phenyl bromide (prepared from bromobenzene, 14·5 g., magnesium turnings, 2·5 g., and ether, 100 c.c.) was added to 4-hydroxycoumarin (5 g.), suspended in benzene (250 c.c.). A solid was rapidly precipitated which did not redissolve after 5 hours' heating under reflux. The reaction mixture was decomposed by ice-cold, dilute hydrochloric acid, unchanged bromobenzene and diphenyl were removed by steam distillation, and the residual solid was separated from unacted-upon 4-hydroxycoumarin by boiling with water, in which the latter was readily soluble. After drying, the *chromen* was crystallised from benzene and then twice from absolute alcohol, from which it separated in colourless needles, m. p. 230—231°. It is strongly acidic and dissolves readily in sodium hydroxide and sodium carbonate solutions; it gives no coloration with ferric chloride (Found: C, 83·9; H, 5·1. $C_{21}H_{16}O_2$ requires C, 84·0; H, 5·3%).

4-Methoxy-2 : 2-diphenyl-Δ^3-chromen (VII).—This was prepared in an analogous manner by the action of magnesium phenyl bromide (from 14 g. of bromobenzene) upon a solution of 4-methoxycoumarin (5 g.) in dry benzene (200 c.c.). The residue left after steam distillation was filtered off, dried, and twice recrystallised from absolute alcohol, the *chromen* being obtained in colourless plates, m. p. 135° (yield, 7 g.) (Found: C, 84·1; H, 5·5. $C_{22}H_{18}O_2$ requires C, 84·1; H, 5·7%). It is readily soluble in the usual organic solvents.

Hydrolysis.—The chromen (2 g.) was heated under reflux with 33% potassium hydroxide solution (25 c.c.) for 5 hours. After dilution with water, the whole was extracted with ether, and the oil isolated from the extract was treated with hydroxylamine. The solid thus obtained, after crystallisation from alcohol, melted at 139° and was shown to be identical with benzophenoneoxime by a mixed melting point with an authentic specimen.

4-Methoxy-2 : 2-dianisyl-Δ^3-chromen, prepared from magnesium *p*-anisyl bromide by the method previously described, crystallised from benzene in colourless needles, m. p. 155° (Found: C, 76·8; H, 6·0. $C_{24}H_{22}O_4$ requires C, 77·0; H, 5·9%).

2 : 2-Diphenyl-4-methyl-Δ^3-chromen (V).—This was prepared by treating a solution of 4-methylcoumarin (10 g.) in benzene (150 c.c.) with magnesium phenyl bromide (bromobenzene, 30 g.) in dry ether (100 c.c.). After boiling under reflux for 4 hours on the water-bath, the whole was steam-distilled and the residue extracted with ether. After removal of the solvent from the dried extract, crystals contaminated with some oily material were obtained. The oil was removed by treatment with a small quantity of alcohol, and the yellow solid recrystallised from benzene and again from glacial

acetic acid; the *chromen* then separated in colourless prisms, m. p. 89° (Found: C, 88·7; H, 6·4. $C_{22}H_{18}O$ requires C, 88·6; H, 6·1%).

Hydrolysis. Isolation of benzhydryl phenyl ether (VI). The above chromen (0·5 g.) was gently boiled under reflux with 50% potassium hydroxide solution (15 c.c.) for 24 hours. After cooling, the reaction mixture was extracted with ether. The oil left after removal of the solvent from the washed and dried extract solidified on standing and then crystallised from a very small volume of light petroleum in colourless needles, m. p. 56°. The compound was insoluble in aqueous sodium hydroxide and gave no colour reaction with ferric chloride (Found: C, 88·0; H, 6·4. $C_{19}H_{16}O$ requires C, 87·8; H, 6·2%).

2 : 2-*Diphenyl*-4 : 6-*dimethyl*-Δ^3-*chromen*.—The Grignard reaction in this case was carried out in a similar manner to that described by Löwenbein (*loc. cit.*) by the slow addition of magnesium phenyl bromide (from bromobenzene, 14 g.) to a hot solution of 4 : 6-dimethylcoumarin (5 g.) in benzene (120 c.c.). The reaction mixture was then heated on the water-bath for ½ hour, decomposed by means of cold ammonium chloride solution, and steam-distilled to remove bromobenzene and diphenyl. The residue, which became solid after 24 hours, was then separated and rubbed with a small quantity of ether, which induced it to crystallise. The product was recrystallised from alcohol, separating in colourless rhombs, m. p. 126°. The ether used to crystallise the residue from the steam distillation deposited more of the same compound (Found: C, 88·3; H, 6·5. $C_{23}H_{20}O$ requires C, 88·4; H, 6·4%).

Hydrolysis. Isolation of benzhydryl p-*tolyl ether*. The chromen (2 g.) was gently boiled under reflux with potassium hydroxide solution (25 g. in 25 c.c. of water) for 24 hours. After cooling, the yellow, alkaline solution, together with some solid material, was extracted with ether, and the extract was well washed with water, dried, and evaporated. The residual solid crystallised from 90% alcohol (animal charcoal) in colourless rhombs, m. p. 96°, which were insoluble in sodium hydroxide solution (Found: C, 87·8; H, 5·9. $C_{20}H_{18}O$ requires C, 87·6; H, 5·8%).

Diphenyl-2-*hydroxy*-β : 4-*dimethylstyrylcarbinol* (XIII).—4 : 7-Dimethylcoumarin was treated with magnesium phenyl bromide as was the 4 : 6-isomeride. The resinous product from the steam distillation was dried between porous tiles and then vigorously scratched with ether, whereupon it crystallised. The crystalline mass so obtained was filtered off and twice recrystallised from 90% alcohol, from which the *carbinol* separated in colourless needles, m. p. 146° (yield, 10%) (Found: C, 83·4; H, 6·4. $C_{23}H_{22}O_2$ requires C, 83·6; H, 6·6%).

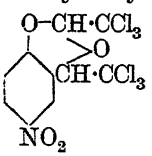
2 : 2-*Diphenyl*-4 : 7-*dimethyl*-Δ^3-*chromen*.—This compound was obtained in two ways : (*a*) The ethereal filtrate after removal of the preceding carbinol deposited, on slow evaporation, a large quantity of a solid, which crystallised from alcohol in colourless needles, m. p. 86° (yield, 75%). (*b*) Diphenyl-2-hydroxy-β : 4-dimethylstyrylcarbinol (1 g.) was heated under reflux for 1 hour with glacial acetic acid (20 c.c.). The gummy residue obtained on dilution with water was crystallised from alcohol, yielding glistening, colourless needles, m. p. 87°, identical with the product in (*a*) (Found : C, 88·3; H, 6·7. $C_{23}H_{20}O$ requires C, 88·4; H, 6·5%).

Isolation of Benzhydryl m-*Tolyl Ether*.—This hydrolysis was carried out in three ways : (*a*) As in previous cases, the chromen (2 g.) was heated for 24 hours with potassium hydroxide solution (25 g. in 25 c.c. of water). The crude product crystallised from alcohol in colourless needles, m. p. 125°. (*b*) The chromen (2 g.) was heated with potassium hydroxide (15 g. in 25 c.c. of water) at 180° in an autoclave for 4 hours. The product was washed with water (200 c.c.), and the solid crystallised twice from 75% alcohol in presence of animal charcoal. It was thus obtained in colourless needles identical with those in (*a*). (*c*) The chromen (1 g.) was fused with potassium hydroxide (10 g.) and, when cold, the mass was dissolved in water and extracted with ether. After purification, the substance described in (*a*) and (*b*) was obtained (Found : C, 87·4; H, 5·9. $C_{20}H_{18}O$ requires C, 87·6; H, 5·8%).

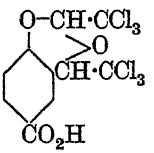
The alkaline solution from (*c*) was rendered acid, and the solution, which contained a small quantity of solid material, was extracted with ether. After removal of the solvent, the residue crystallised from a small volume of methyl alcohol in colourless needles, m. p. 103—105°. It readily reduced Fehling's solution and Tollens's reagent and was identical with lactaldehyde in all respects.

2 : 4-*Diphenyl*-3-*methylchroman*-2-*ol*.—3-Methylcoumarin (10 g.), dissolved in benzene, was heated for 4 hours on the water-bath with magnesium phenyl bromide (3 mols.). The reaction mixture was decomposed with dilute hydrochloric acid and steam-distilled. The non-volatile residue was collected and crystallised from alcohol and finally from benzene, from which the *chromanol* separated in colourless crystals, m. p. 149° (Found : C, 83·9; H, 6·1. $C_{22}H_{20}O_2$ requires C, 83·5; H, 6·3%).

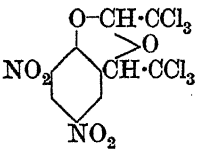
2 : 4-*Diphenyl*-3-*methyl*-Δ^2-*chromen* was prepared by boiling the above chromanol (1·5 g.) with glacial acetic acid (10 c.c.) for 1 hour. The cold solution was diluted with water, and the precipitate crystallised from alcohol, the *chromen* separating in colourless needles, m. p. 91° (Found : C, 88·5; H, 6·2. $C_{22}H_{18}O$ requires C, 88·6; H, 6·1%).



In conclusion, we desire to express our thanks to the Council of the Department of Scientific and Industrial Research for a grant to one of us (D. W. H.) which has enabled this research to be carried out.



THE UNIVERSITY, LIVERPOOL. [*Received, June 8th*, 1927.]

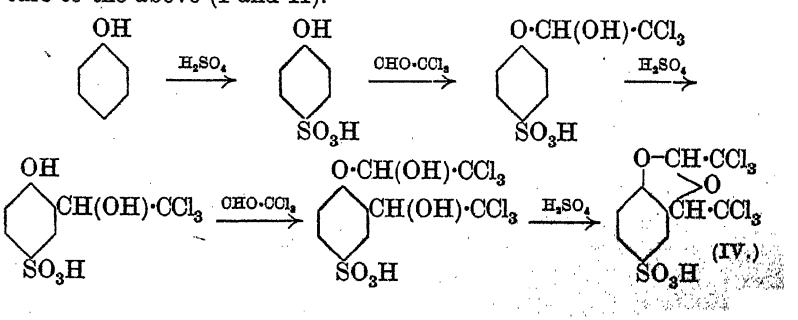


CCLXV.—*The Condensation of Chloral with Phenol.*

By FREDERICK DANIEL CHATTAWAY and ALEXANDER ALLAN MORRIS.

IT has been shown recently (J., 1926, 2720; this vol., p. 685) that in presence of concentrated sulphuric acid, chloral reacts readily with *p*-nitrophenol and with *p*-hydroxybenzoic acid, yielding respectively anhydro-5-nitro- (I) and anhydro-5-carboxy-2-βββ-trichloro-α-hydroxyethoxy-1-βββ-trichloro-α-hydroxyethylbenzene (II)

(I.)



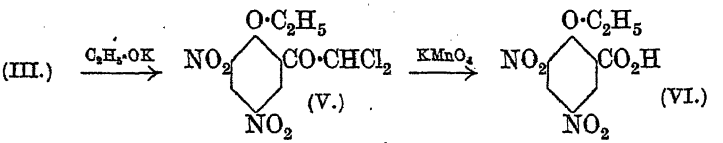
(II.)

(III.)

Chloral appears to condense in this way only with phenols in which the hydrogen in the para-position to the hydroxyl has been replaced by other groups.

When phenol itself is added to chloral suspended in concentrated sulphuric acid, an immediate reaction occurs, and an oily liquid separates which rapidly changes into an opaque, white solid. This readily dissolves in alcohol, giving a colourless solution from which nothing crystallises on cooling. On evaporating off the solvent, a viscid liquid is left which solidifies to a colourless, transparent, resin-like mass, the constitution of which has not yet been determined.

If, however, the phenol is first dissolved in the sulphuric acid, whereby *p*-phenolsulphonic acid is formed, this on addition of chloral slowly reacts, forming a compound (IV) analogous in structure to the above (I and II).



(IV.)

This compound behaves in all respects as a normal sulphonic acid. It is a colourless solid with no definite melting point. It crystallises with three molecules of water, two of which can be removed by heating, and forms well-crystallised salts. When acted upon by phosphorus pentachloride, it forms a *sulphonyl chloride*. This with ethyl and methyl alcohol yields *esters*, with ammonia a *sulphonamide*, and with aniline a *sulphonanilide*.

Its constitution is similar to that of the condensation product (I) yielded by *p*-nitrophenol, since both compounds on nitration yield *anhydro*-3 : 5-*dinitro*-2-ββ*β*-*trichloro*-α-*hydroxyethoxy*-1-ββ*β*-*trichloro*-α-*hydroxyethylbenzene* (III).

The molecules of water are probably attached to the sulphonic residue, the anhydride ring remaining unbroken, since, although only two are removed by heating, yet the ammonium salt is obtained in the anhydrous condition.

The constitution of the acid is further confirmed by the product of the action of alcoholic potash on the dinitro-derivative (III), whereby ωω-*dichloro*-3 : 5-*dinitro*-2-*ethoxyacetophenone* (V) is formed, which on oxidation by potassium permanganate yields 3 : 5-dinitro-2-ethoxybenzoic acid (VI).

Experimental.

Anhydro-2-ββ*β*-*trichloro*-α-*hydroxyethoxy*-1-ββ*β*-*trichloro*-α-*hydroxyethylbenzene*-5-*sulphonic Acid* (IV).—Phenol (100 g.; 1 mol.) was added slowly to 1000 c.c. of well-cooled sulphuric acid (*d* 1·8). After an hour, 400 g. of chloral hydrate (2 mols. + 50 g. excess) were gradually added with constant stirring. The mixture was then kept at the ordinary temperature for 4 days with occasional vigorous shaking. Reaction slowly took place, a bulky, white solid separating in the body of the solution, whilst a solid crust of metachloral formed on the surface. The solid products were filtered off on asbestos, and extracted with boiling water until the filtrate no longer deposited crystals when cooled and strongly acidified. The *sulphonic acid* was thus separated from the metachloral, which was left as a white solid insoluble in boiling water. The filtered aqueous extracts were mixed and evaporated until oily streaks appeared on the surface of the boiling liquid. On cooling, the sulphonic acid separated in viscid oily drops which crystallised into a mass of very thin, lustrous plates (yield, 150 g.). The sulphonic

acid is moderately easily soluble in boiling benzene and separates from this solution in very thin, colourless, lustrous, irregular plates containing three molecules of water (Found: C, 23·75; H, 2·3; Cl, 42·2. $C_{10}H_6O_5Cl_6S,3H_2O$ requires C, 23·8; H, 2·4; Cl, 42·1%).

When heated, the trihydrated acid partly liquefies between 125° and 130°, small prismatic crystals of a monohydrated acid separating.

When heated for ½ hour at 110°, the acid loses two molecules of water, leaving a crystalline aggregate of small, colourless, prismatic crystals of the monohydrated acid (Found: Loss of water at 110°, 7·0. $C_{10}H_6O_5Cl_6S,3H_2O \longrightarrow H_2O$ requires loss of water, 7·1%).

The monohydrated acid is very easily soluble in alcohol and acetone, and very sparingly soluble in boiling benzene and chloroform. It can be recrystallised by dissolving it in boiling acetic acid and adding concentrated hydrochloric acid a little at a time until the solution shows a slight turbidity. On cooling, the acid separates in small, colourless prisms which melt with decomposition between 150° and 166° (Found: C, 25·5; H, 1·7; Cl, 45·3; S, 7·0. $C_{10}H_6O_5Cl_6S,H_2O$ requires C, 25·6; H, 1·7; Cl, 45·4; S, 6·85%).

When moistened with a little cold water, the crystals of the monohydrated acid swell up into an amorphous sticky mass, which on warming gives a clear solution from which the hydrated acid crystallises on addition of a little concentrated hydrochloric acid.

It forms an anhydrous *ammonium* salt which crystallises from a dilute aqueous solution of ammonia in very small, colourless prisms (Found: C, 25·9; H, 2·0; Cl, 45·5. $C_{10}H_9O_5NCl_6S$ requires C, 25·65; H, 1·9; Cl, 45·5%).

Nitration of Anhydro-2-ββδ-trichloro-α-hydroxyethoxy-1-ββδ-trichloro-α-hydroxyethylbenzene-5-sulphonic Acid.—The sulphonic acid (40 g.) was added to a mixture of 150 c.c. of nitric acid (*d* 1·5) and 5 c.c. of concentrated sulphuric acid and heated to boiling. After cooling, the brown solution was poured on crushed ice; the dinitro-compound (III) then separated as a greenish-white solid, which, after drying, was recrystallised from boiling alcohol.

A product similar in every way was obtained when anhydro-5-nitro-2-ββδ-trichloro-α-hydroxyethoxy-1-ββδ-trichloro-α-hydroxyethylbenzene was nitrated in the same manner.

Anhydro-3:5-dinitro-2-ββδ-trichloro-α-hydroxyethoxy-1-ββδ-trichloro-α-hydroxyethylbenzene (III) is easily soluble in boiling acetic acid, alcohol, acetone, and benzene, and crystallises from all these solvents in two polymorphic modifications. On cooling, a solution of the compound in about three times its weight of boiling alcohol the labile modification first separates as slender, silky needles. On allowing these to stand in the mother-liquor, pale yellow rhombohedra of the stable form appear and grow at the expense of the labile form,

which dissolves and finally disappears. Both forms melt at 163° (Found: N, 6·0; Cl, 46·1. $C_{10}H_4O_6N_2Cl_6$ requires N, 6·1; Cl, 46·2%).

The position of the second nitro-group in this compound was established by its behaviour with alcoholic potash. The finely powdered dinitro-compound (25 g.) was gradually added to a solution of 30 g. of potassium hydroxide in 400 c.c. of alcohol, well cooled in a freezing mixture; it dissolved, giving a deep red solution, and chloroform was produced. After about 15 minutes, the liquid was neutralised by hydrochloric acid and the alcohol distilled off in a current of steam; *ωω-dichloro*-3 : 5-*dinitro*-2-*ethoxyacetophenone* (V) then separated as a liquid, which on cooling solidified to a crystalline, yellow mass (17·5 g.). It is readily soluble in boiling alcohol, from which it separates in small, yellow prisms, m. p. 82—84°, which darken when exposed to strong sunlight (Found: N, 8·7; Cl, 22·2. $C_{10}H_8O_6N_2Cl_2$ requires N, 8·7; Cl, 22·0%).

It yields an *osazone*,

$$OEt\cdot C_6H_2(NO_2)_2\cdot C(:N\cdot NH\cdot C_6H_3Cl_2)\cdot CH:N\cdot NH\cdot C_6H_3Cl_2,$$

when heated with an alcoholic solution of 3 : 5-dichlorophenylhydrazine. This compound is very sparingly soluble in boiling chloroform, from which it separates in minute, orange needles, m. p. 224° (Found: N, 14·4; Cl, 24·6. $C_{22}H_{16}O_5N_6Cl_4$ requires N, 14·3; Cl, 24·2%).

Oxidation of ωω-Dichloro-3 : 5-*dinitro*-2-*ethoxyacetophenone by Permanganate.*—ωω-Dichloro-3 : 5-dinitro-2-ethoxyacetophenone (15 g.) was added to a hot aqueous solution of 15 g. of potassium permanganate, and boiled until the oily drops first formed on the addition of the compound disappeared. The deep yellow filtrate from the precipitated manganese dioxide was concentrated, and an excess of hydrochloric acid added; 3 : 5-dinitro-2-ethoxybenzoic acid then separated, m. p. 132·5° (compare Ullmann, *Annalen*, 1909, **336**, 85) (Found: C, 42·6; H, 3·3; N, 10·9. Calc. for $C_9H_8O_7N_2$: C, 42·2; H, 3·1; N, 10·9%).

Anhydro-2-*ββββ-trichloro*-α-*hydroxyethoxy*-1-*ββββ-trichloro*-α-*hydroxyethylbenzene*-5-*sulphonyl Chloride*, $O<\begin{matrix}CH(CCl_3)\cdot O\\CH(CCl_3)\end{matrix}>C_6H_3\cdot SO_2Cl$.—The monohydrated acid (30 g.) and powdered phosphorus pentachloride (55 g.) were heated on the water-bath for 5 minutes, and the viscous pale brown oil formed was poured slowly over crushed ice. The *sulphonyl chloride* separated as a white solid, and crystallised from ether–light petroleum in very slender, colourless needles, m. p. 130·5° (Found: C, 25·5; H, 1·3; Cl, 52·6. $C_{10}H_5O_4Cl_7S$ requires C, 25·6; H, 1·1; Cl, 52·9%).

When boiled with any alcohol it reacts readily and yields the corresponding alkyl sulphonate. The *methyl* ester separates from

boiling methyl alcohol, in which it is moderately easily soluble, in small, highly refracting, colourless prisms, m. p. 150° (Found: C, 28·3; H, 1·7; Cl, 45·7. $C_{11}H_8O_5Cl_6S$ requires C, 28·4; H, 1·7; Cl, 45·8%). The *ethyl* ester separates from boiling ethyl alcohol in small, colourless, elongated, irregular plates, m. p. 143° (Found: C, 29·4; H, 2·2; Cl, 44·5. $C_{12}H_{10}O_5Cl_6S$ requires C, 30·1; H, 2·1; Cl, 44·4%).

The sulphonyl chloride also reacts readily with ammonia and with aniline in boiling alcohol to form a sulphonamide and a sulphonanilide.

Anhydro-2-βββ-*trichloro*-α-*hydroxyethoxy*-1-βββ-*trichloro*-α-*hydroxyethylbenzene*-5-*sulphonamide* separates from boiling alcohol, in which it is readily soluble, in colourless, small, silvery plates, m. p. 207° (Found: N, 3·2; Cl, 47·3. $C_{10}H_7O_4NCl_6S$ requires N, 3·1; Cl, 47·3%).

When dissolved in acetic acid and chlorinated, it yields *anhydro*-2-βββ-*trichloro*-α-*hydroxyethoxy*-1-βββ-*trichloro*-α-*hydroxyethylbenzene*-5-*sulphondichloroamide*, which dissolves easily in chloroform and separates in colourless, slender prisms, m. p. 165—174° (decomp.) (Found: Cl as $\cdot NCl_2$, 13·4. $C_{10}H_5O_4NCl_8S$ requires Cl as NCl_2, 13·7%).

Anhydro-2-βββ-*trichloro*-α-*hydroxyethoxy*-1-βββ-*trichloro*-α-*hydroxyethylbenzene*-5-*sulphonanilide* crystallises from dilute alcohol in very slender, silky, hair-like prisms, m. p. 168·5° (Found: N, 2·7; Cl, 40·5. $C_{16}H_{11}O_4NCl_6S$ requires N, 2·7; Cl, 40·5).

THE QUEEN'S COLLEGE, OXFORD. [*Received June 24th*, 1927.]

NOTES

Co-ordination Compounds of Beryllium and m- *and* p-*Nitrobenzoylacetone.* By HENRY BURGESS.

THE mutarotation of beryllium benzoylcamphor was attributed to an asymmetric arrangement around the beryllium atom by Lowry and Burgess (J., 1924, **125**, 2082), but owing to the occurrence of two asymmetric carbon atoms in the camphor nucleus, rigorous proof of the suggestion could not be obtained. It was proposed to confirm it by using an unsymmetrical β-diketone or β-ketonic ester which contained no asymmetric carbon atom and the basic or acidic group necessary for the resolution. *p*- and *m*-Aminobenzoylacetone and ethyl *p*-nitrobenzylacetoacetate appeared to fulfil these conditions. Owing to the resolution of beryllium benzoylpyruvate by Mills and Gotts (J., 1926, 3121), it was decided to place on record the results already obtained.

p-*Nitrobenzoylacetone.*—Freshly powdered sodamide (10·5 g.) was

slowly added to ethyl *p*-nitrobenzoate (50 g.) and acetone (19·8 c.c.) in dry ether (150 c.c.), cooled to −17°. The mixture immediately became greenish-black and ammonia was evolved. After being kept for 2 hours in the freezing mixture and for 20 hours at room temperature, the product was poured into ice-water, the ether separated, and the aqueous layer extracted twice with chloroform. (From these extractions, 16 g. of ethyl *p*-nitrobenzoate were recovered.) The aqueous layer was filtered through charcoal and acidified, and the resulting precipitate was filtered off and dried. This solid was extracted several times with ether, the ethereal solution was evaporated, and the resulting yellowish-brown crystals were recrystallised from methyl alcohol (yield, 1·5 g.), p-*nitrobenzoylacetone* being obtained in golden-yellow needles, m. p. 112—113·5° (Found: C, 58·1; H, 4·5; N, 6·8. $C_{10}H_9O_4N$ requires C, 57·95; H, 4·4; N, 6·8%). It is readily soluble in ordinary organic solvents except the cold alcohols and is insoluble in water. With caustic soda, it gives a bright yellow solution, and with copper acetate it produces a green precipitate, which is soluble in chloroform.

Beryllium p-*nitrobenzoylacetone* was obtained in nearly theoretical yield by the method described for beryllium benzoylcamphor (*loc. cit.*) (Found: C, 57·6*; H, 3·9*; Be, 2·2*. $C_{20}H_{16}O_8N_2Be$ requires C, 57·0; H, 3·8; Be, 2·1%). It is readily soluble in chloroform and hot benzene, from which it separates in brownish-yellow, compact crystals, m. p. 243—244°. It is sparingly soluble in alcohol and insoluble in water.

m-*Nitrobenzoylacetone*.—Preliminary experiments having shown that benzoylacetone can be recovered quantitatively from concentrated sulphuric acid at room temperature, the following nitration was carried out: A mixture of nitric acid (*d* 1·42; 7 c.c.) and sulphuric acid (*d* 1·84; 24 c.c.) was slowly added to benzoylacetone (15 g.) in sulphuric acid (100 c.c.), mechanically stirred and kept at −11° to −9°. After 15 minutes, the product was poured on ice; the precipitate obtained crystallised from hot methyl alcohol in very pale yellow needles, m. p. 114—115° (*p*-nitrobenzoylacetone depresses the m. p. by 20°) (yield, 47%) (Found: C, 58·1; H, 4·6%). m-*Nitrobenzoylacetone* is easily soluble in ordinary organic solvents except the cold alcohols and ligroin. The yellow coloration with alkalis is less intense than that of the *p*-nitro-derivative. With alcoholic ferric chloride, it gives a wine-red colour.

Beryllium m-*nitrobenzoylacetone*, prepared by the usual method, crystallised from acetone–alcohol in orange-yellow, square plates, m. p. 207—208° (Found: C, 57·3*; H, 3·9*; Be, 2·1%). It is

* Values so marked are the results of micro-estimations carried out by Siegmund Weil, Tübingen.

readily soluble in chloroform and benzene, less soluble in acetone, and slightly soluble in alcohol.

Ethyl Bis-p-*nitrobenzylacetoacetate.*—*p*-Nitrobenzyl bromide was slowly added to an equivalent quantity of ethyl sodioacetoacetate in absolute alcohol, sodium bromide being precipitated. After heating for 2 hours, the alcohol was evaporated, water added, and the precipitate crystallised from acetone–methylated spirit, *ethyl bis*-p-*nitrobenzylacetoacetate* separating in colourless flakes, m. p. 137—139° (Found: C, 60·5, 60·0; H, 5·0, 4·6; N, 6·8, 6·7. $C_{20}H_{20}O_7N_2$ requires C, 60·0; H, 5·0; N, 7·0%). It is readily soluble in acetone, ether, chloroform, and hot benzene, and sparingly soluble in cold alcohol. It gives a coloration neither with caustic soda nor with ferric chloride.

Ethyl p-*Nitrobenzylacetoacetate.*—The mother-liquor from the above compound left an orange-coloured oil on evaporation. This solidified when cooled in the ice-chest, and crystallised from benzene–ligroin in very pale yellow needles, m. p. 43—45° (Found: C, 59·05; H, 5·8. $C_{13}H_{15}O_5N$ requires C, 58·8; H, 5·7%). It is very soluble in all organic solvents except ligroin, in which it is sparingly soluble. With caustic soda, it gives an intense yellowish-orange coloration, and with ferric chloride a deep reddish-purple colour slowly develops. Copper acetate precipitates a green copper derivative, which is soluble in chloroform.

I wish to take this opportunity of expressing my thanks to the Chemical Society for a grant towards the expenses of the research, and also to Professor C. S. Gibson for his helpful criticism and encouragement.—Guy's Hospital Medical School. [*Received, March 21st*, 1927.]

The Reduction of Arsenic Compounds in Acid and in Alkaline Solution by Sodium Hyposulphite (Hydrosulphite). Production of Sodium Arseno-hyposulphite. By Walter Farmer and James Brierley Firth.

In an investigation on the reduction of certain arsenic compounds by sodium hyposulphite, in which a product corresponding to arsenic subsulphide, As_3S, was isolated (J., 1926, 119), it was inferred from preliminary experiments (and existing literature) that two intermediate complex compounds are formed, one of which is a decomposition product of the other.

The Primary Intermediate Complex, Sodium Arseno-hyposulphite, $Na_3As(S_2O_4)_3$.—Preliminary experiments carried out in glass vessels indicated that, in the presence of alcohol, shaking of an alkaline solution of trisodium arsenite containing hyposulphite was followed

by formation of two unstable precipitates, one of which was heavier than the other. Similar heavy precipitates were obtained when concentrated solutions of common sodium arsenate were used.

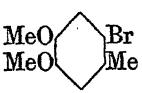
The products adhered to the walls of the vessel, and became viscous when treated with dilute alcoholic potash. In subsequent experiments, quartz containers were employed.

Sodium hyposulphite (2·75 g.) was introduced into a cold solution of 2·75 g. of common sodium arsenate in 3 c.c. of water to which a whirling motion had been imparted. The flask was closed, and the whirling maintained. Dissolution of the last traces of sodium hyposulphite was accompanied by formation of a heavy, granular solid, which settled in increasing quantity when the flask was kept at room temperature. The supernatant liquor was decanted off after 15 minutes, and the granular solid was washed five times by decantation with methylated alcohol and four times with benzene and kept in a quartz dish in a vacuum over sulphuric acid for 24 hours. A creamy-white powder was obtained (yield, 1 g.).

When a small quantity of the product was strongly heated in a Bunsen flame, a brown and a yellow sublimate formed and a garlic odour developed. If cautiously heated, the product first turned brown and, when more strongly heated, gave a brown and a yellow sublimate as before. When a small quantity of the product was treated with dilute hydrochloric acid, sulphur dioxide was evolved, and a brown product similar to that described in the previous paper (*loc. cit.*) formed.

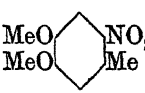
Estimations of the arsenic content of the product, as magnesium pyroarsenate, gave: As, 14·1, 14·1, 14·1, 14·0%. Estimations of hyposulphite by Wilkes's method (*J. Soc. Chem. Ind.*, 1923, **42**, 356T) were based on the view that, in presence of hypoiodous acid, hydrolysis of 1 g.-mol. of arseno-hyposulphurous acid, $H_3As(S_2O_4)_3$, is attended by liberation of 4 g.-mols. of iodine according to the following equations:

(1) $H_3As(S_2O_4)_3 + 3H_2O = H_3AsO_3 + 3H_2S_2O_4$,
(2) $H_3AsO_3 + 2HIO + 3KOH = I_2 + K_3AsO_4 + 4H_2O$,
(3) $3H_2S_2O_4 + 9KIO + 6KOH = 6KHSO_4 + 9KI + 3H_2O$,
(4) $6KHSO_4 + 3KIO + 3KI = 3I_2 + 6K_2SO_4 + 3H_2O$.



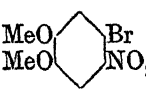
Two samples gave: S_2O_4, 70·9, 70·5 [$Na_3As(S_2O_4)_3$ requires As, 14·2; S_2O_4, 72·7%].

The Secondary Intermediate Complex, Sodium Arseno-thiosulphate, $Na_3As(S_2O_3)_3$.—Standard solutions of potassium hydroxide and hydrochloric acid of the same normality were prepared. 25 C.c. of the standard alkali in which 1 g. of sodium arseno-hyposulphite (1 mol.) and the calculated quantity of sodium sulphite (3 mols.)

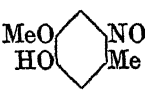


had been dissolved were rapidly added to 25 c.c. of the standard acid containing 2·5 c.c. of concentrated acid. A turbidity developed, followed by precipitation of arsenious sulphide. Decomposition of sodium arseno-hyposulphite in presence of sodium sulphite by this neutralisation method is considered to lead to formation, and rapid decomposition, of sodium arseno-thiosulphate, arsenious sulphide being one of the products (compare Jellinek, *Z. physikal. Chem.*, 1911, **76**, 257; Szilàgyi, *Z. anorg. Chem.*, 1920, **113**, 69).—UNIVERSITY COLLEGE, NOTTINGHAM. [*Received, April 8th*, 1927.]

The Displacement of Bromine accompanying the Nitration of 6-Bromo homoveratrole. By TOM HEAP, THOMAS G. H. JONES, and ROBERT ROBINSON.



JONES and ROBINSON (J., 1917, **111**, 919) described the conversion of 6-bromohomoveratrole (I) into a mononitro-derivative, m. p. 121°, by the action of a mixture of nitric acid and acetic anhydride.



(I.)

(II.)

(III.)

(IV.)

We have, however, been unable to repeat the preparation of the nitro-derivative, since, on several occasions, following the description as closely as possible, the sole product of a sluggish reaction was 6-nitrohomoveratrole (II) (yield, 36%). Although it may be that some variation of the conditions is responsible for this divergence, we think it more likely that the observation of Jones and Robinson was erroneous as the result of contamination of the creosol employed with guaiacol and that the compound isolated was 4-bromo-5-nitroveratrole (III), m. p. 124° (or 121—122°, see below).

It is no longer necessary to employ beechwood tar as a source of creosol, since the pure phenol can be readily obtained from vanillin by Clemmensen's method.

6-Bromohomoveratrole (I).—The reduction of vanillin (100 g.) by means of amalgamated zinc and hydrochloric acid (Oberlin, *Arch. Pharm.*, 1925, **263**, 641) gave creosol (60 g.), b. p. 220—225°/760 mm., which was converted by known methods into homoveratrole, b. p. 218—220°, m. p. 22° (yield, 91%), and then into 6-bromohomoveratrole, b. p. 265—267°, m. p. 31° (yield, 94%). The latter crystallised in truncated octahedra, and, on oxidation with potassium permanganate and boiling dilute aqueous sodium hydroxide for 1½ hours, yielded 6-bromoveratric acid; this, alone or mixed with a specimen obtained by brominating methyl veratrate and hydrolys-

ing the product, melted at 183—184°. When treated with a mixture of acetic anhydride and nitric acid under the conditions prescribed by Jones and Robinson (*loc. cit.*), bromohomoveratrole (20 g.) gave 6-nitrohomoveratrole (8·5 g.), which crystallised in yellow needles from methyl alcohol; m. p. 117—119°, alone or mixed with an authentic specimen (Found: C, 55·0; H, 5·8. Calc. for $C_9H_{11}O_4N$: C, 54·8; H, 5·6%).

6-*Nitro*iso*creosol* (IV).—Cardwell and Robinson (J., 1915, **107**, 256) commented on the fact that 6-nitrohomoveratrole is not readily hydrolysed by alkalis. It is certainly less readily attacked than nitroveratrole, but by following the procedure of Pollecoff and Robinson (J., 1918, **113**, 647) for the preparation of 4-nitroguaiacol an almost theoretical yield of the nitro*iso*creosol was obtained in 73 hours. The substance crystallised from aqueous alcohol in slender, pale yellow needles, m. p. 168—170° (Found: C, 52·6; H, 4·6; N, 7·6. $C_8H_9O_4N$ requires C, 52·5; H, 4·9; N, 7·7%). The *acetyl* derivative crystallised from alcohol in colourless, elongated, hexagonal plates, m. p. 100—101°. On methylation the phenol yielded 6-nitrohomoveratrole, m. p. 117—119°. The conditions applicable for its further nitration to 2 : 6-dinitro*iso*creosol were not ascertained, since the action of nitric acid led to the production of soluble orange-red substances.

6-*Bromoveratric Acid*.—When methyl veratrate is brominated in cold acetic acid solution and the product crystallised, the yield of pure methyl 6-bromoveratrate, m. p. 88—89°, is not satisfactory, and Professor Smiles has suggested to us that methyl 2-bromoveratrate may be produced in the reaction. On treatment with cold nitric acid (*d* 1·42) pure 6-bromoveratric acid, m. p. 183—184°, gave a 50% yield of 4-bromo-5-nitroveratrole, m. p. 121—122°, whilst the crude product gave a 36% yield of this substance under identical conditions. 4-Bromo-5-nitroveratrole, prepared from bromoveratrole, had m. p. 121—122°, and a mixture with the specimen from 6-bromoveratric acid had the same m. p. The matter will be further investigated, our chief concern at the moment being to confirm the recorded m. p.'s of 6-bromoveratric acid and its methyl ester.—THE UNIVERSITY, MANCHESTER. [*Received, July 11th*, 1927.]

CCLXVI.—*The Constitution of Certain Salts and Acids in Solution as determined by Observations of Critical Solution Temperatures.*

By SYDNEY RAYMOND CARTER and NORMAN JOSEPH LANE MEGSON.

DURING the course of investigations on the behaviour of sulphur dioxide towards certain salts in acid solutions, the occurrence of complex formation with hydrogen chloride was frequently suspected. Thus, ferric chloride exhibited a far greater tendency than ferrous chloride to combine with hydrogen chloride (J., 1924, **125**, 1886), whilst cupric chloride only appeared to do so at acid concentrations above 7*N* (J., 1925, **127**, 505). Recent work by one of us (this vol., p. 1918) has indicated pronounced combination between hydrogen chloride and mercuric chloride [see also Abegg, "Handbuch der anorganischen Chemie," 1905, II, (2), 641], whilst the reaction between hydrogen chloride and sulphur dioxide or selenium dioxide is much less marked and probably only evident in high concentrations of acid.

It appeared that a study of the mutual miscibilities of liquids, as developed by Pfeiffer (*Z. physikal. Chem.*, 1892, **9**, 444), Timmermanns (*ibid.*, 1907, **58**, 128), and Patterson and his collaborators (*J. Physical Chem.*, 1925, **29**, 295; J., 1925, **127**, 624, 2544; 1926, 2787, 2791) might afford independent confirmation of such complex formation. We wished, however, to work at higher concentrations, if possible, and therefore it was necessary to test the applicability of the method in such cases, since recorded work has hitherto been restricted to the more dilute solutions.

The elevation of the critical solution temperature (*C.S.T.*) of a known mixture produced by each substance was determined separately and then the elevation due to the mixture of the substance with hydrogen chloride was observed. Any decrease from the theoretical elevation was assumed (when not accounted for by other means) to be due to complex formation. Two systems were employed: (1) water and phenol, and (2) water and *iso*butyric acid. The latter system, having a low *C.S.T.*, allows a considerable elevation before the boiling point is reached, and consequently a wide range of concentrations. It also has the advantage that the end-point is more easily determinable than is the case with phenol.

EXPERIMENTAL.

The determination of the *C.S.T.* was carried out in a test-tube fitted with a thermometer and glass stirrer. The apparatus was closed and provision was made for leading in a current of nitrogen

if required. The temperature was controlled by a water-bath and the *C.S.T.* in the case of *iso*butyric acid was observed by the appearance or disappearance of turbidity, as judged with a constant illuminant behind the tube, whilst for phenol, the apparent disappearance of the thermometer bulb was employed, as recommended by Patterson. Readings obtained in this way were reproducible to $\pm 0{\cdot}02°$.

The *iso*butyric acid with water gave a *C.S.T.* of 18·07° over a range of 26·8—28·6% of acid. Since this value is low compared with some of the values in the literature, a small amount of impurity is evidently present, but as this is probably *n*-butyric acid it is not likely to affect the results which follow.

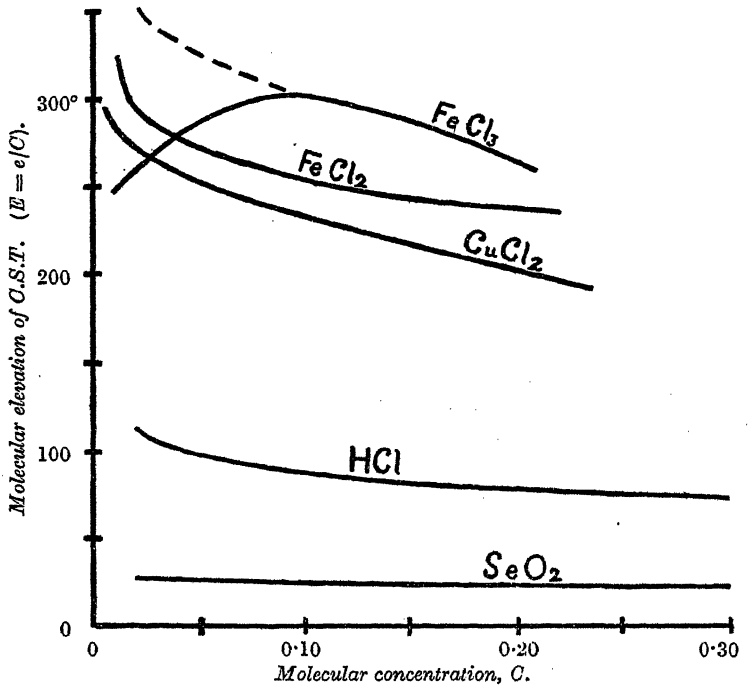
In these results, C is the *molecular* concentration of salt per 1000 g. of total mixture (*i.e.*, water, organic solvent, and solute); e is the elevation of the *C.S.T.* in degrees; and E is the molecular elevation, *i.e.*, $E = e/C$. Table I gives the values of e for given concentrations of the separate constituents in the *iso*butyric acid–water system, as read from smoothed curves.

TABLE I.

C	0·02.	0·04.	0·06.	0·08.	0·10.	0·12.	0·16.	0·20.	0·24.
SeO_2	0·52°	1·00°	1·48°	1·96°	2·40°	2·78°	3·56°	4·30°	5·08°
HCl	2·22	4·00	5·62	7·20	8·62	10·02	12·64	15·20	17·68
$CuCl_2$	5·40	10·28	14·90	19·14	23·00	26·98	33·90	40·22	46·48
$FeCl_2$	5·80	11·04	15·96	20·72	25·14	29·60	38·30	47·10	(55·90)
$FeCl_3$	5·25	10·96	17·60	23·96	30·08	35·76	45·50	(52·90)	—

C	0·30.	0·40.	0·50.	0·60.	0·70.	0·80.	0·90.	1·00.	1·10.
SeO_2	6·24°	8·24°	10·36°	12·80°	14·90°	17·22°	19·60°	21·96°	24·25°
HCl	21·18	26·20	31·50	36·30	40·80	45·10	49·04	52·78	56·20

If these values of e and C be plotted graphically, the curves, with the exception of that of selenium dioxide, deviate from straight lines, giving a curvature which is concave towards the concentration axis. This is in accordance with the decreased ionisation to be expected at the higher concentrations.



Ferric chloride gives a curvature near the origin which is slightly different from the remainder. These effects are much more clearly shown by plotting E against C (see Fig. 1).

For a normal substance such as hydrogen chloride, E increases with diminishing concentration as the result of ionisation. In the case of ferric chloride the increase ceases at $C = 0{\cdot}09$ and E falls rapidly with further dilution. Since hydrolysis begins to be appreciable at about the same stage, it probably affords an explanation (Goodwin, *Z. physikal. Chem.*, 1896, **21**, 15).

An interesting series of curves is obtained by plotting log e against log C. They approximate to parallel straight lines over a fair

range of concentration, the exception being that of ferric chloride, which crosses those of cupric and ferrous chlorides. The straight lines are in accordance with the equation $\log e = m \log C + b$, which gives the relation $e = AC^m$, proposed by Carrington, Hickson, and Patterson (J., 1925, **127**, 2548). The numerical value of the constant in our case gives $m = 0{\cdot}92$ for the system *iso*butyric acid–water, whilst the previous authors obtained $m = 0{\cdot}84$—$0{\cdot}87$ for phenol–water.

FIG. 1.

The regularity of the results obtained on plotting C against e and E, and $\log C$ against $\log e$, as well as of the results for the mixtures still to be described, suggests that the principles developed by Patterson in the more dilute solutions are also valid for the higher concentrations.

Mixtures of Salts with Hydrogen Chloride.

The possibility of complex formation was investigated, the concentration of the salt being kept approximately constant whilst that of the hydrogen chloride was varied over a fairly wide range. The theoretical elevation of the *C.S.T.*, denoted by "Mean e calc.,"

is half the sum of the elevations for *double* the concentration of each constituent, as described by Patterson (J., 1925, **127**, 626). This rule can be applied when the values of e for the salt and hydrogen chloride do not vary considerably, but for differences greater than 20° it is not so accurate.

TABLE II.

SeO_2 + HCl.					$CuCl_2$ + HCl.				
	C.	*e* calc.	Mean *e* calc.	*e* obs.		*C.*	*e* calc.	Mean *e* calc.	*e* obs.
SeO_2	0·681	30·58°	39·70°	39·63°	$CuCl_2$	0·103	41·20°	36·42°	36·75°
HCl	0·438	48·80			HCl	0·241	31·65		
SeO_2	0·347	14·78	26·66	27·87	$CuCl_2$	0·090	37·20	30·47	30·83
HCl	0·312	38·54			HCl	0·168	23·75		
$FeCl_2$ + HCl.									
$FeCl_2$	0·105	48·95	33·30	33·60	$FeCl_2$	0·0716	35·20	36·65	36·29
HCl	0·116	17·65			HCl	0·307	38·10		
$FeCl_2$	0·0703	34·60	31·20	31·08	$FeCl_2$	0·0681	33·80	26·49	26·47
HCl	0·205	27·80			HCl	0·128	19·81		

SO_2 + HCl.				
	C.	*e* calc.	Mean *e* calc.	*e* obs.
SO_2	(0·4)	5·0°	33·0°	34·2°
HCl	0·550	61·0		

No consistent lowering of e is thus observed for the mixtures SeO_2 + HCl, $FeCl_2$ + HCl, and $CuCl_2$ + HCl. The actual concentration of sulphur dioxide was not determined, since the same stock solution was used in making up both the SO_2 and the SO_2 + HCl mixtures for the determination of e. Only a slight increase in e is observed, and in view of the experimental errors involved, this may be interpreted as evidence of no combination between sulphur dioxide and hydrogen chloride at these concentrations.

Ferric Chloride and Hydrogen Chloride.—It was evident that some kind of reaction was taking place. When the ferric chloride alone was in the mixture of *iso*butyric acid and water, it imparted a dark brown colour to the organic layer. On addition of hydrogen chloride, this became lighter, assuming a light yellow colour when the ratio HCl : $FeCl_3$ reached 6 : 1. The concentration of ferric chloride was kept at *ca.* 0·08 whilst that of hydrogen chloride was varied from 0·08 to 0·50, and in these circumstances depressions of e were observed as shown in Table III.

The consistent appreciable decrease in e is evidence of complex formation, and since the greatest percentage decrease occurs when HCl : $FeCl_3$ = 3 : 1, it appears probable that the compound $FeCl_3$,3HCl exists in solution.

The complex ferric compounds which are formed by carboxylic

TABLE III.

0·0766	0·0790	43·65°	13·00°	28·33°	29·36°	+1·03°	—
0·0824	0·1715	46·42	27·40	34·91	33·33	−1·58	4·6
0·0836	0·2446	46·80	31·42	39·11	36·63	−2·48	6·5
0·0844	0·2625	47·20	32·72	39·96	37·08	−2·88	7·5
0·0869	0·2770	48·20	34·10	41·15	37·98	−3·17	8·0
0·0815	0·3145	46·10	37·65	41·87	39·77	−2·10	5·1
0·0764	0·4370	44·00	48·10	46·05	43·51	−2·54	5·7

acids, such as acetic acid, might be expected to explain the anomalous behaviour of ferric chloride in *iso*butyric acid:

$3FeCl_3 + 6CH_3{\cdot}CO_2H + 2H_2O \rightleftharpoons [Fe_3(OH)_2(CH_3{\cdot}CO_2{\cdot})_6]Cl + 8HCl$

(Weinland, " Complex-Verbindungen," 1919, pp. 345 *et seq.*). The brown coloration may then be satisfactorily attributed to the coloured complex, whilst the subsequent addition of hydrochloric acid leads to the repression of complex formation and a consequent fading of colour.

The occurrence of complex formation causes solubility of the ferric chloride in both liquids instead of in the water alone, and this would tend to decrease the *C.S.T.*, especially for higher concentrations of ferric chloride. Since, however, the abnormalities in *C.S.T.* are mainly observed at the lower concentrations of ferric chloride, and in the opposite sense, we consider that the extent of interaction between the ferric chloride and *iso*butyric acid must be relatively small.

For the remaining examples, the phenol–water system was found more convenient.

Mercuric Chloride and Hydrogen Chloride.—Mercuric chloride is soluble both in phenol and in *iso*butyric acid, but the former solvent was found to be more suitable to work with. The *C.S.T.* was depressed and *e* was negative (Table IV).

TABLE IV.

C	0·05	0·10	0·15	0·20	0·25
$-e$ for $HgCl_2$	1·72°	3·58°	5·58°	7·72°	9·85°
$+e$ for HCl.....	3·58	6·50	9·02	11·38	13·60
C	0·30	0·35	0·40	0·50	0·60
$-e$ for $HgCl_2$	12·00°	14·10°	—	—	—
$+e$ for HCl.....	15·80	17·50	19·18	22·20	(24·7)

The graph of log *C* against log *e* for mercuric chloride is a straight line and its slope indicates $m = 1{\cdot}1$. This differs from the normal value, 0·87, for ordinary substances insoluble in phenol.

The concentration of mercuric chloride was kept nearly constant and that of hydrogen chloride varied; the results obtained are given in Table V, and afford an example of the *C.S.T.* being raised by a

TABLE V.

C_{HgCl_2}.	C_{HCl}.	Mean e calc.	e obs.	Increase.
0·248	0·108	−4·2°	− 3·5°	0·7°

0·245	0·250	+1·05	+ 4·79	3·74
0·249	0·278	+1·55	+ 6·81	5·26
0·244	0·456	+6·20	+15·20	9·0
0·244	0·479	+6·65	+15·84	9·2
0·226	0·595	+9·75	+21·66	11·9

mixture. It is raised to an extent greater than would be expected from the simple mixture, and the effect increases with relative increase in the ratio $HCl/HgCl_2$. Since one of the constituents, mercuric chloride, is soluble in the phenol layer, it shows that a complex is being formed which is insoluble in phenol.

Cuprous Chloride and Hydrogen Chloride.—The value "Mean e calc." = (25°) is an approximation and indicates a lower limit, since "e calc." has been estimated by analogy with the chlorides of univalent metals. If cuprous copper exerts a higher valency as in the double formula Cu_2Cl_2 a still higher value would result. In either case, the low value of e obs. is thus in accordance with complex formation.

(Phenol–water system.)

CuCl	0·0836	(15)		

Summary.

The elevation of critical solution temperature has been employed in order to study complex formation in hydrogen chloride solutions.

The values of e for various salts and acids have been determined in the system *iso*butyric acid–water, and for mercuric chloride in the phenol–water system.

Values of e and E obtained for these salts are regular, except in the case of ferric chloride, in which hydrolysis probably occurs.

The constant m approximates to 0·92 in the equation $e = AC^m$ for *iso*butyric acid–water.

No complex formation has been found between hydrogen chloride and sulphur dioxide, selenium dioxide, or ferrous and cupric chlorides, but considerable complex formation occurs between hydrogen chloride and ferric, mercuric, or cuprous chloride in the concentrations used.

The concentrations are considerably higher than those used hitherto, but the principles are still applicable.

CCLXVII.—*The Electronic Structure of Atoms. Part I. The Periodic Classification.*

By J. D. Main Smith.

The outstanding feature of theories of the structure of atoms is their extensive and intimate relationship to the facts of chemistry summarised in the periodic classification of the elements. This relationship consists essentially in referring the periodicity in the properties of elements to a corresponding periodicity in the structural complexity of their atoms. The existence of this correspondence is readily deducible from a multitude of correlated chemical and physical experimental facts, but its precise nature has been variously interpreted, and diverging views have consequently been held as to the electronic structures attributable to the atoms of the elements.

Examination of the arrangement of the elements in the order of atomic weight shows that characteristic types of elements recur at fixed intervals or periods. The number of elements intervening in a period is always 8, 18, or 32. For example, if the noble gases be taken as points of reference, there are 8 elements from helium to neon and from neon to argon, 18 from argon to krypton and from krypton to xenon, and 32 from xenon to radon.

These sets of elements constitute Mendeléev's periods (see Table 1), the first two sets of 8 elements forming the first two "short"

periods, and the remaining sets of more than eight elements forming the "long" periods. The first two long periods of 18 elements fall into two series of eight valency groups, the "even" series consisting of 10 elements (three in Group VIII), and the "odd"

series of 8 elements. The third long period, containing 32 elements, has been a subject of much discussion, but it is now generally agreed that it is divisible into two series or sub-periods like the other long periods, the even series, however, being of 24 elements, from cæsium to platinum, and the odd series as before of eight elements, from gold to the noble gas radon. It is assumed that in this period only one element, eka-iodine, belonging to the halogen group, remains to be discovered.

The Abridged Periodic Classification.

The history of chemical science has demonstrated clearly that the most useful method for the condensation and generalisation of data is that of classification by types. In organic chemistry, the method proceeds according to constitutional types, such as alcohols, ketones, aldehydes, etc., by reference to *structural* features possessed in common by *compounds*. In inorganic and general chemistry, the method proceeds similarly according to constitutional types, by reference to *valency* features possessed in common by *atoms*. The periodic classification is essentially classification by valency types, the elements being arranged into eight groups having valency from one to eight respectively. This supremely important octet classification is somewhat obscured by the detail introduced by the division of the long periods into the unequal sub-periods of the even and odd series. Modifications intended to simplify and increase the chemical utility of the classification must emphasise this octet arrangement. Many of those proposed in recent years, however, have had for their object, not the increase in the chemical utility of classification of detailed knowledge, but the facilitation of mathematical interpretations of atomic structure, and with this in view the number of groups is successively increased from 8 to 18 and 32 in passing from the short to the long periods. In all such systems, the essential chemical features of classification by valency and periodicity of properties are subordinated or suppressed, although the structure of atoms is fundamentally a chemical problem, profoundly interwoven with the periodic classification of the elements. It will be shown that abridgment, rather than expansion, clarifies the classification, and facilitates a more intimate and accurate interpretation of atomic structures, by throwing the chemically important octet arrangement into high relief.

In the classification of the elements by valency types, the 16 light elements from lithium to argon fall naturally into two periods of eight groups with one element per group per period, each period ending with a noble gas. These two periods may, consequently, be regarded as simple or specific types for the heavier elements of

the long periods. Consideration of the properties of these heavier elements shows that, in each long period, only a few elements approximate closely in properties to the simple types of the short

periods, and that in any one period some of these kindred elements appear in the even and some in the odd series. Mendeléev suggested that the elements diverging most from the specific types were in the nature of " transition " elements bridging a gap between the typical elements of each long period, a view adopted later in a modified form by Bohr in his theory of atomic structure. Mendeléev's suggestion is virtually a recognition that the long periods can be short-circuited by excluding the transition elements, leaving an abridged classification constituted solely of elements closely related to the short period types, the periodic classification thus consisting only of simple periods each of eight elements.

In order to effect this short-circuiting or abridgment of the long periods, it is necessary to decide which elements are most closely related to the typical elements of the short periods, the remaining elements being relegated to transition series. In the first long period (see Table 1), it is evident that potassium and the elements from gallium to krypton are more closely related to sodium and the elements from aluminium to argon than are copper and the elements from scandium to nickel, and these last nine elements are therefore definitely transition elements. There remain only calcium and zinc for consideration. As one of the obvious features of the periodic classification is the increase in basicity with increase in atomic weight in each group, the element corresponding to magnesium, the oxide of which is feebly alkaline, should possess a strongly alkaline oxide, the heavier members of the group having still more alkaline

series of 8 elements. The third long period, containing 32 elements, has been a subject of much discussion, but it is now generally agreed that it is divisible into two series or sub-periods like the other long periods, the even series, however, being of 24 elements, from cæsium to platinum, and the odd series as before of eight elements, from gold to the noble gas radon. It is assumed that in this period only one element, eka-iodine, belonging to the halogen group, remains to be discovered.

The Abridged Periodic Classification.

The history of chemical science has demonstrated clearly that the most useful method for the condensation and generalisation of data is that of classification by types. In organic chemistry, the method proceeds according to constitutional types, such as alcohols, ketones, aldehydes, etc., by reference to *structural* features possessed in common by *compounds*. In inorganic and general chemistry, the method proceeds similarly according to constitutional types, by reference to *valency* features possessed in common by *atoms*. The periodic classification is essentially classification by valency types, the elements being arranged into eight groups having valency from one to eight respectively. This supremely important octet classification is somewhat obscured by the detail introduced by the division of the long periods into the unequal sub-periods of the even and odd series. Modifications intended to simplify and increase the chemical utility of the classification must emphasise this octet arrangement. Many of those proposed in recent years, however, have had for their object, not the increase in the chemical utility of classification of detailed knowledge, but the facilitation of mathematical interpretations of atomic structure, and with this in view the number of groups is successively increased from 8 to 18 and 32 in passing from the short to the long periods. In all such systems, the essential chemical features of classification by valency and periodicity of properties are subordinated or suppressed, although the structure of atoms is fundamentally a chemical problem, profoundly interwoven with the periodic classification of the elements. It will be shown that abridgment, rather than expansion, clarifies the classification, and facilitates a more intimate and accurate interpretation of atomic structures, by throwing the chemically important octet arrangement into high relief.

In the classification of the elements by valency types, the 16 light elements from lithium to argon fall naturally into two periods of eight groups with one element per group per period, each period ending with a noble gas. These two periods may, consequently, be regarded as simple or specific types for the heavier elements of

the long periods. Consideration of the properties of these heavier elements shows that, in each long period, only a few elements approximate closely in properties to the simple types of the short

periods, and that in any one period some of these kindred elements appear in the even and some in the odd series. Mendeléev suggested that the elements diverging most from the specific types were in the nature of " transition " elements bridging a gap between the typical elements of each long period, a view adopted later in a modified form by Bohr in his theory of atomic structure. Mendeléev's suggestion is virtually a recognition that the long periods can be short-circuited by excluding the transition elements, leaving an abridged classification constituted solely of elements closely related to the short period types, the periodic classification thus consisting only of simple periods each of eight elements.

In order to effect this short-circuiting or abridgment of the long periods, it is necessary to decide which elements are most closely related to the typical elements of the short periods, the remaining elements being relegated to transition series. In the first long period (see Table 1), it is evident that potassium and the elements from gallium to krypton are more closely related to sodium and the elements from aluminium to argon than are copper and the elements from scandium to nickel, and these last nine elements are therefore definitely transition elements. There remain only calcium and zinc for consideration. As one of the obvious features of the periodic classification is the increase in basicity with increase in atomic weight in each group, the element corresponding to magnesium, the oxide of which is feebly alkaline, should possess a strongly alkaline oxide, the heavier members of the group having still more alkaline

oxides. This circumstance involves that the congeners of beryllium and magnesium are the alkaline-earth metals, calcium, strontium, barium and radium, whilst zinc, cadmium, and mercury are transition elements.

The transition elements of the first long period are consequently the ten elements from scandium to zinc (see Table 3). The remaining eight elements, potassium, calcium, and gallium to krypton, form an abridged period (see Table 2) with one element per periodic group, exhibiting extremely close resemblance to the typical elements of the short periods. Similar considerations apply to the second long period, the transition elements being the ten from yttrium to cadmium (see Table 3). The remaining eight elements, rubidium, strontium, and indium to xenon, form an abridged period with one element per periodic group. In the third long period, consisting of 32 elements, it is similarly possible to allocate the eight elements cæsium, barium, and thallium to radon to the abridged period. The 24 elements from lanthanum to mercury are in consequence relegated to the transition series.

In the fourth long period, the known elements come to an end with uranium in Group VI of the even series. The chemical and physical properties of actinium, thorium, protactinium, and uranium indicate decisively that they are analogues of yttrium, zirconium, etc., and therefore transition elements. The only remaining known element of the period is radium, which resembles barium so closely that it can be separated from it only with difficulty. Radium consequently is an alkaline-earth metal and must be regarded, not as a transition element, but as the Group II representative in the abridged classification. Similarly, eka-cæsium must, as an alkali metal, be postulated as the Group I representative of the abridged classification, not as a transition element. The existence of only one element, actinium, between thorium and radium renders it certain that the transition series of this last long period contains no transition sub-series similar to the anomalous 14 "rare-earth" elements (see p. 2035), and it is consequently probable that, if all the elements of this period were known, they would number only 18 as in the case of the first and second long periods.

There remain for consideration only the two lightest elements, hydrogen and helium. Apart from hydrogen, no element lighter than helium is known, and many considerations, chemical and physical, render it improbable that any other element can exist. If it be admitted that electrons are the sole valency factors, the fact that helium contains only two electrons makes it certain that hydrogen with one electron is the only possible element lighter than helium. Despite the validity and utility of the octet classification,

it is thus impossible to fill more than two of the eight groups of this primitive period. As the unit of valency and of atomic weight, hydrogen may be regarded as the type of all the valent elements and placed at the head of any of the Groups I to VII of the classification, helium being placed at the head of Group VIII as the type of all the non-valent and noble elements. It is not a matter of importance, in the classification of the elements, in which group hydrogen is placed, but from its univalency it may conveniently be placed in Group I *and* alternatively in Group VII.

The modification of the periodic classification derived from the foregoing considerations is shown in Table 2, and consists of a primitive period of two elements, two short periods each of eight elements, three abridged long periods each of eight elements, and a final abridged and incomplete period, or seven periods in all. Examination of these seven abridged periods reveals much greater regularities in the classification than are readily discernible in the extended form. Basicity, for example, *diminishes* regularly in each *period* from strong alkalinity in the first group to strong acidity in the seventh, and *increases* regularly in each *group* from the first to the seventh period. Further, all the elements which possess alkaline oxides are confined to Groups I and II. The alkaline thallous and plumbous oxides are only apparent exceptions to this rule, for in neither case does the metal exhibit the valency characteristic of the periodic group to which it belongs. This disappearance of alkalinity beyond Group II is of fundamental importance in the interpretation of the electronic structures of the atoms of all the elements, in Groups III to VIII no less than in Groups I and II, for, being a measure of electron mobility, it enables a differentiation to be made amongst the various sub-groups of electrons that constitute the exterior of atoms.

Comparison of Groups III and IV with Groups V, VI, and VII brings to light a further regularity relating to basicity. The whole of the elements of Groups III and IV possess amphoteric oxides, their basic tendencies being approximately equal to their acidic tendencies, and, where the elements exhibit lower valency, the lower oxides are never amphoteric but decidedly basic or even alkaline, as in the case of thallous and plumbous oxides. In Groups V to VIII, on the other hand, all the elements yield oxides which are strongly acidic, and, even where the basic properties are in any degree exhibited by the oxides, as in the case of bismuth and antimony, the derived salts are without exception hydrolysed by water to basic salts. Further, where the elements of Groups V to VII exhibit lower valency than that characteristic of the group, even the lower oxides are usually strongly acidic. Groups V to

VIII, moreover, include every known element which is gaseous below a red heat. The elements of Groups III and IV are consequently as sharply differentiated from those of Groups V to VII as from those of Groups I and II. The periodic classification can thus be divided, not only into groups, periods, and even, odd, and transition series, but also into classes of groups; the first class, Groups I and II, contains what may be termed the alkaline elements; the second class, Groups III and IV, the amphoteric elements; and the third class, Groups V, VI, VII, and VIII, the non-basic elements.

Variable Valency.

A further noteworthy feature of the abridged classification is that, without exception, every element exhibiting variable valency possesses valencies which differ by only 2, 4, or 6 units, iodine, for example, having valencies of 7, 5, 3, and 1. Apparent exceptions to this rule may be found in the case of gallium and indium : both metals, though normally tervalent, are stated to yield bivalent salts, while indium is stated to yield univalent salts in addition. The vapour density of indium " dichloride " slightly above its boiling point, however, proves the formula to be In_2Cl_4, not $InCl_2$. The dichloride has therefore no real existence, and it may be regarded as a double salt of the monochloride and trichloride, $InCl,InCl_3$ or $In(InCl_4)$. Gallium " dichloride " boils at 535°, but its vapour density has been recorded only at 1000° where it is normal. If, however, the formula is Ga_2Cl_4 and dissociation occurs on heating to a mixture of GaCl and $GaCl_3$, the vapour density of the mixture will be the same as that of $GaCl_2$. Fused gallium trichloride is a non-electrolyte, like aluminium chloride, whereas the alleged dichloride is a good conductor and readily yields metallic gallium on electrolysis, pointing to the formula $Ga(GaCl_4)$ or Ga_2Cl_4. A similar dimeric " dichloride " is obtained from thallium by mixing the monochloride with the trichloride, and it is definitely known that thallium does not exhibit bivalency. If gallium and indium " dichlorides " are, as suggested, really gallous gallichloride and indous indichloride, respectively, these two metals fall into line with thallium in the same group as possessing only tervalency and univalency, and the apparent exceptions to the rule of variation by two units of valency disappear from the abridged classification.

The Transition Series.

It has been shown, in connexion with the abridgment of the periodic classification, that 10 elements in each of the first two long periods, 24 in the third long period, and four of the six known elements of the last period show very considerable divergence from

the properties of the typical elements of the two short periods, and are to be regarded as transition elements bridging a gap in each long period between elements most closely allied to the typical elements. In the first long period, these ten transition elements, from scandium to zinc, may be arranged in a sub-period or transition series consisting, like the abridged periods, of eight valency groups (see Table 3). The lightest member of the series, scandium, with an

* 14 Elements, 58Ce to 71Lu, relegated to Table 4.

invariable valency of three, naturally falls into Group III, the heaviest member, zinc, with an invariable valency of two, being proper to Group II, the transition period thus commencing with Group III and ending with Group II.

The set of ten transition elements from the second long period correspond so closely in chemical and physical properties to the ten transition elements from the first long period that, without further discussion, they may be allocated to the corresponding eight groups from III to II (see Table 3).

Owing to the fact that there are 24 transition elements in the third long period as against 10 in the other two long periods, no complete analogy exists, but the nine elements from celtium (hafnium) to mercury in this longest transition series present so close a resemblance to the nine elements in the preceding transition series, from zirconium to cadmium, that they may readily be allocated to the seven corresponding periodic groups from IV to II. There remain in this transition series only the 15 elements having atomic weights lying between barium in Group II and celtium (hafnium) in Group IV. These elements from lanthanum to lutecium (known as " rare-earth " elements) have characteristic tervalency, are relatively strong bases, and give rise to basic salts of the type $La(OH)CO_3$, and mixed salts of the type $LaFCO_3$. There can, therefore, be no doubt that these elements are completely analogous to yttrium and scandium, and are proper to Group III. This transition series of 24 elements may be short-circuited or abridged (see Table 3) by the omission of 14 of the 15 " rare-earth " elements in Group III, leaving an abridged transition series of 10

elements corresponding closely in every member to each of the transition series from the first two long periods. It is not a matter of great importance chemically which 14 "rare-earth" elements are relegated to a transition sub-series, but the relegation is of prime importance in the problem of the electronic structures of the atoms of this period. It is consequently necessary to make a decision, on chemical grounds if possible, as to the element presenting the closest resemblance to yttrium and scandium in the two preceding transition series, and to place the other fourteen in a transition sub-series. Scandium and yttrium have no valency higher than three, whilst yttrium (certainly) and scandium (probably) exhibit the valency of two in acetylenic carbides of the form YC_2. Both yield colourless, diamagnetic salts, while yttrium oxide is a stronger base than scandium oxide, the basicity of the former only just falling short of alkalinity. Consequently the element to be placed in Group III of the third transition series should have no higher valency than three, exhibit a valency of two in an acetylenic carbide, and possess colourless, diamagnetic salts and a strongly alkaline oxide. These properties are possessed only by the lightest of these elements, lanthanum, which must, accordingly, be regarded as the Group III representative in the transition series of the third long period, the remaining 14 from cerium to lutecium, being relegated to a transition sub-series (see Table 4). This transition sub-series

	4	4	4					4						

presents no analogy to the transition sub-period or to the main period, for these are real periods consisting of eight groups, whereas the elements of the transition sub-series do not exhibit valency less than two or greater than four, and thus cannot form a period. From time to time it has been proposed to place cerium in Group IV on the grounds of its quadrivalency and the isomorphism of some few of its salts with those of thorium and zirconium. These proposals have lost much of their point since the discovery of celtium (hafnium), properly allocated to Group IV because of its extraordinarily close resemblance to zirconium. It will, moreover, be shown, in discussing the electronic structure of atoms, that the allocation of cerium to Group III and to the transition sub-series on chemical grounds is fully justified, in that the electron responsible

for the increase in the valency of cerium from three to four is probably structurally unrelated to any of the electrons responsible for the quadrivalency of celtium (hafnium) or indeed of any element in either the main or transition periods.

The transition sub-periods (Table 3), based upon the foregoing considerations, comprise two typical periods each of ten elements, an abridged period also of ten elements, and a final incomplete period, all the periods commencing with Group III and ending with Group II.

With the possible exceptions of scandium and zinc (although scandium possesses an acetylenic carbide of the probable formula ScC_2, in which the metal would be bivalent), all the transition elements exhibit variable valency, and this variation can and usually does occur by one unit, instead of by the invariable two units of the abridged classification. With very few exceptions, the transition elements give rise to coloured salts, whereas the elements of the abridged classification form only colourless salts. Unlike the abridged periodic classification, the groups of which are divisible into a class of two alkaline groups, a second class of two amphoteric groups, and a third class of four non-basic groups, the transition classification consists of only one strongly basic group, III, the other seven groups almost without exception comprising only elements with either amphoteric or strongly acidic properties in their highest oxides, although the acidic properties are feeble in Groups I and II.

The Complete Periodic Classification.

On recombining the transition classification (Table 3) with the abridged classification (Table 2), the full periodic classification including the whole of the elements is obtained (Table 1). This table differs from the commonly accepted forms in small but important features. Seven main periods suffice to include all the known elements, a primitive period of two elements, two simple periods each of eight elements, and four complex periods consisting each of two sub-periods. Each period comprises only eight groups, commencing with Group I and ending with Group VIII, the simple periods and the main sub-periods of the long periods terminating with noble gases and the transition sub-periods with noble metals. In order to indicate their close resemblance to the noble metals of Group VIII, the pairs copper and zinc, silver and cadmium, and gold and mercury, are alternatively included also in this group, just as hydrogen is alternatively included in Group VII to indicate its resemblance to the halogen elements.

The transition elements in each long period are shown in heavy type, the arrows between elements of Groups II and III indicating

the position at which the transition elements create a gap between the typical elements of the periods. In order to preserve the symmetry of the octet classification, the 15 rare-earth elements, belonging to Group III and succeeding barium in atomic weight, are represented only by their most typical member, lanthanum, the other 14 being shown in detail in a footnote to the table. In order to facilitate the identification of the typical members of each group, which constitute the abridged classification, they are placed to the left and the transition elements to the right of the columns.

The abridged classification, the transition classification, the transition sub-series, and the complete periodic classification, shown in Tables 1, 2, 3, and 4, respectively, together with the experimental chemical evidence on which they are founded, will form the basis of subsequent papers on the interpretation of chemical evidence in terms of the distribution of electrons in atomic structures. The next paper will show primarily that the octet classification is due to the existence of from one to eight outer electrons in three sub-groups completed to 2, 2, 4 in the inert gases; that the transition classification is due to from one to eight more deeply seated electrons in two sub-groups completed to 4, 6 and forming part of a main group in five sub-groups of 2, 2, 4, 4, 6, completed in Group I; and that the transition sub-series is due to from one to fourteen still more deeply seated electrons completed to 6, 8, and forming part of a main group in seven sub-groups of 2, 2, 4, 4, 6, 6, 8, completed in lutecium. This scheme of atomic structure was first put forward by the author on incomplete evidence on March 9th, 1924 (*J. Soc. Chem. Ind.*, **43**, 323), and is now found to be fully justified in the light of additional evidence chiefly furnished by the foregoing periodic classifications.

The author desires to thank the Research Committees of Birmingham University and the Chemical Society, Gerald W. Kenrick, Esq., W. Byng Kenrick, Esq., Sir William Waters Butler, Bart., and Professor G. T. Morgan, F.R.S., for grants, laboratory facilities, and gifts and loans of rare metals and chemicals in aid of this series of researches.

CCLXVIII.—*Molecular Structure in Solution. Part II. The Refractive Indices and Surface Tensions of Aqueous Solutions of Cobalt Chloride and Hydrochloric Acid.*

By Owen Rhys Howell.

The densities and viscosities of a series of solutions having a fixed concentration of cobalt but increasing concentrations of hydrochloric acid, and also those of an exactly similar series of solutions of the acid alone, have already been determined (this vol., p. 158). It was shown that the differences in the densities of corresponding solutions varied with increasing concentration of acid, the curve exhibiting a point of inflexion. The differences in the viscosities of corresponding solutions also varied, the curve showing a well-defined maximum. The point of inflexion in the one case and the maximum in the other occurred at precisely the same concentration of acid.

The work of Hill and Howell (*Phil. Mag.*, 1924, **48**, 833) suggests that in the red pigments and solutions the cobaltous atom is surrounded by six other atoms or groups, whilst in the blue pigments and solutions it is surrounded by four, and the results outlined above were interpreted by assuming that with increasing concentration of acid, the cobalt atom is thrown out of its association with six molecules of water, $Co(H_2O)_6^{\cdot\cdot}$, into one with four atoms of chlorine, $CoCl_4''$. It was deemed of interest to determine other physical properties of these solutions in order to ascertain whether they also would show similar variations; the refractive indices and surface tensions have therefore been measured.

Experimental.

Determination of Refractive Index.—The measurements were made with a Pulfrich refractometer. In order that the results should be directly comparable with those already obtained for the densities and viscosities, all determinations were made at 20°.

Since all the solutions were acidic, it was impossible to utilise the usual attachment for temperature regulation. The whole instrument was therefore encased by means of asbestos mill-board cut to shape, and the temperature was kept constant to within ± 0·5° by regulating a small gas flame placed inside the case. The cell was covered with a watch-glass to prevent loss of acid.

Measurements were made for the D line with a sodium flame, and for the C, F, and G′ lines with a hydrogen tube. The refractive index of every solution in the series containing acid only was deter-

mined for each of these lines, but this was impossible with the series containing cobalt since these solutions are coloured. Although the red solutions have strong absorption bands in the blue region, with the concentration of cobalt taken the F and G′ lines were transmitted sufficiently well to enable measurements to be made. The refractive index for each of these two lines has therefore been determined for every member of the series of solutions containing cobalt. The blue solutions, however, are much more intense than the red, and with these the C and D lines were completely extinguished. It was therefore possible to determine the refractive index for these two lines only with the solutions at the red end of the series.

Readings could be reproduced to within 1′ even with the faintest lines and to within 0·5′ with strong ones. The values of the refractive index are therefore all correct to the fourth place of decimals and most of them to within 5 units in the fifth place.

Determination of Surface Tension.—The measurements were made with a Traube stalagmometer. The lower capillary and also a long open tube were passed through a rubber stopper fitted into a small bottle. The stalagmometer was filled with the solution, and a little of this was also placed in the bottle in order to saturate with the vapour the atmosphere in which the drops formed. The apparatus was immersed vertically (against a plumb-line) in a glass-fronted thermostat kept at 20° ± 0·01°. The surface tension was calculated from the formula

$$\gamma_{\text{sol.}} = \gamma_{\text{water}} \times n_w/n_s \times d_s,$$

where n_w and n_s are the number of drops given by water and by the solution respectively, and d_s is the relative density of the solution. The value $\gamma_{20°} = 72{\cdot}69$ for water was employed, and the values of the relative density used were those determined in the previous investigation.

It has been shown (Lohnstein, *Z. physikal. Chem.*, 1908, **64**, 686; 1913, **84**, 410; Harkins and Humphery, *J. Amer. Chem. Soc.*, 1916, **38**, 228; Harkins and Brown, *ibid.*, 1919, **41**, 499) that the simple formula for the surface tension requires a correction factor depending on the ratio of the radius of the tip to the linear dimensions of the drop. If r is the radius of the tip and v the volume of the drop, then when $r/v^{\frac{1}{3}}$ lies between 0·76 and 0·95 the correction is practically constant. In a comparative method of determining surface tension the correction factor would then cancel, leaving the equation given above as a true expression.

The diameter of the tip of the stalagmometer used for these experiments was 0·87 cm. The volumes of the largest drops (given

by water) and of the smallest (given by the most concentrated acid solution) were determined by weighing and found to be 0·1268 c.c. and 0·1021 c.c., respectively. The extreme values of the ratio r/v are therefore 0·865 and 0·930. Since these fall within the limits for the constancy of the correction factor, the simple equation used for the calculation is sufficiently accurate.

With the solution yielding the smallest drops, each drop corresponded to 18 divisions on the scale. Since the determinations could be reproduced to within 0·5—1·0 division, the measurements are correct to within about $\pm$ 3 units in the second place of decimals. At least two determinations were made for each solution and the mean was taken.

The tip of the stalagmometer was freed from grease by being dipped in chromic acid solution before each determination and the whole apparatus was similarly cleansed at intervals. The drop number for water was checked from time to time and found to remain quite constant at 55·55 drops.

Materials.—As in the previous investigation, the hydrochloric acid employed was the pure commercial product and the cobalt chloride was Kahlbaum's purest, free from iron and nickel. All the water used was the laboratory distilled water, redistilled with precautions to preclude contamination by dust or grease.

Solutions.—Three stock solutions were prepared: cobalt chloride in water (120 g. of $CoCl_2,6H_2O$ per litre), cobalt chloride in concentrated hydrochloric acid (120 g. of $CoCl_2,6H_2O$ per litre), and hydrochloric acid in water. Their concentrations were adjusted to exactly the same values as those employed in the previous investigation. All the other solutions were prepared from these by dilution in the manner already described (*loc. cit.*).

Note on the Density of Aqueous Hydrochloric Acid.—It was not stated in the previous paper that in preparing the stock solution of hydrochloric acid by diluting the fuming acid, the solutions were cooled in iced water to minimise loss of acid. The stock solution was therefore 10·63*N* at 0° = 32·88% of HCl (by weight). In the present investigation, a solution of the acid having exactly the same density was found by titration against pure sodium carbonate to be 10·48*N* at 18°. The solution therefore contained 32·80% of HCl, a figure in good agreement with that previously found. The densities of the series of solutions prepared by diluting the stock solution were checked and found to agree with those obtained previously to within 1 unit in the fourth place of decimals.

In order to complete the series of values up to the fuming acid, the densities and viscosities of three more concentrated solutions have been determined; these are shown in Table I together with

the true normality of the solution at 18° and the composition by volume and by weight. The concentrations are correct to 0·2%, the densities to within 2 units in the fourth place of decimals and the viscosities to within 0·1%.

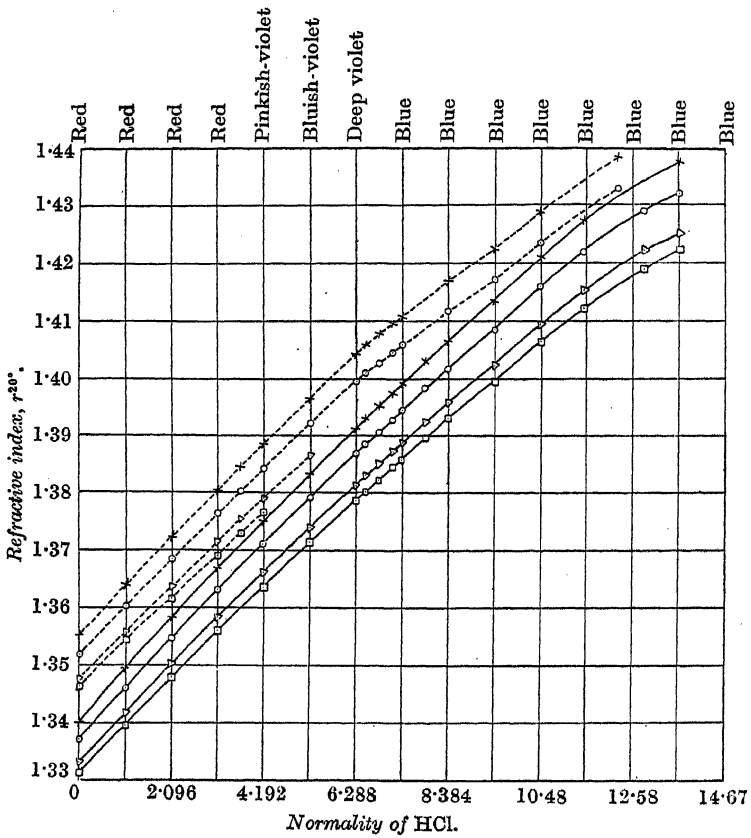
9·432	34·39	29·90	1·1507	1·1487	0·01731
10·48	38·21	32·80	1·1657	1·1637	0·01870
11·48	41·86	35·53	1·1789	1·1768	0·02004
12·83	46·78	39·14	1·1957	1·1935	0·02183
13·38	48·78	40·61	1·2020	1·1998	0·02266

The curve obtained on plotting the densities against the % of HCl by weight is almost a straight line up to 33%, being only very slightly concave to the axis of concentration. The last three values, however, fall below the extended curve, which is in agreement with the values recorded by other observers (Landolt and Bornstein's Tables, 1923, p. 394).

Results.



Refractive Indices.—The values of the refractive indices of the solutions of hydrochloric acid only, measured as already described, are given in Table II, and plotted against the normality of the solution in Fig. 1. It is seen that almost throughout their entire length all four curves exhibit a gradual increase of concavity to the axis of concentration. They fall more rapidly near the end, the values for the two highest concentrations of acid being lower than those anticipated from the general course of the curves. Each of the curves is expressed with very fair accuracy by an equation of the form

$$r_{\text{sol.}} = r_{\text{water}} + xN - yN^2,$$

where N is the normality of the solution and x and y are constants.

Table II. It is seen that the agreement is quite good up to a concentration of $10N$.

The refractive indices of the solutions containing cobalt are given in Table III and plotted against the normality of the acid in Fig. 1 with those for the solutions of acid only. It is seen that the curves are not smooth. There is an obvious break in the continuity, and each curve ultimately tends to become parallel with the corresponding curve for the solutions of acid only.

If the cobalt atom were similarly associated in all these solutions, the refractive index should change regularly with increasing con-

centration of acid, as it does with the solutions of acid alone. Since this is not so, it follows that the cobalt atom undergoes a change in its association as the concentration of acid is increased; a suggestion as to the nature of this change has been given on p. 2039 and its course may be followed by considering the differences of the refractive indices of corresponding solutions. The values

obtained on subtracting the refractive indices of the solutions of hydrochloric acid alone from those of the corresponding solutions containing cobalt are given in Table III and plotted against the normality of the acid in Fig. 3.

The resulting curves are precisely similar to the curve obtained in the previous investigation by plotting the density differences against the concentration of acid. They exhibit well-marked inflexions at the same concentration of acid as the inflexion of the

density-differences curve and as the maximum of the viscosity-differences curve (both of which are reproduced in Fig. 3 for comparison). It is seen that towards the end of its course each curve is flattening out (although not as sharply as the density-differences curve) to become parallel to the axis of concentration, thus indicat-

ing that the change to the $CoCl_4''$ configuration is nearing completion, where further increase in the concentration of acid could no longer affect the state of the cobalt atom.

The refractive index of the blue form is evidently less than that of the red. As the concentration of acid is increased and the change from red to blue proceeds, the curve falls continuously but not regularly. The diminution of the difference of refractive index,

like that of the density difference, takes place at first very gradually and then very rapidly. The suggestion offered to account for this feature in the density-differences curve also explains the same form of the refractive index-differences curve. The $Co(H_2O)_6^{\cdot\cdot}$ ions are progressively converted into $CoCl_4''$ ions, and as these are oppositely charged there is a powerful attraction between them. Evidently this attraction will be a maximum when equal numbers are present in the solution, and it is suggested that this condition obtains at the point of inflexion.

Surface Tensions.—The values of the surface tensions for the two series of solutions are given in Table IV and plotted in Fig. 2. Previous determinations of the surface tension of some aqueous solutions of hydrochloric acid alone have been made by Volkmann (see Landolt and Bornstein's Tables, 1923, p. 238) using the capillary-rise method. The values are in fair agreement with those now reported, which lie on a smooth curve. An equation has not been found to express the whole curve, but if the logarithm of the

* These two values are read from the curve shown in Fig. 2.

difference, Δ, between the surface tension of water and that of each solution be plotted against the concentration of the solution, all the points except the first three lie on a perfectly straight line. The equation to the line is

$$\log \Delta = 0{\cdot}1130N_{18°} - 0{\cdot}5850$$

where $\Delta = \gamma_{water} - \gamma_{sol.}$, and N_{18} is the normality of the solution at 18°. The values of the surface tension calculated from this expression are given in column 5 of Table IV. Comparing them with the observed values in column 4, it is seen that the agreement is within the limits of experimental error.

It was found impossible to get very concordant values of the drop number with the more concentrated acid solutions. They indicate, however, that the surface tensions of these solutions are progressively higher than those anticipated from the general course of the curve. It will be recalled that the densities of these solutions were lower than demanded by the form of the density curve.

The curve for the solutions containing cobalt, on the other hand, obviously consists of two parts, the first (for lower concentrations of acid) being convex to the axis of concentration, and the second (for higher concentrations of acid) being concave to this axis, and eventually becoming parallel to the curve for the solutions of acid alone.

The change in the association of the cobalt atom may again be followed by examining the differences of the surface tensions of the solutions containing cobalt and the corresponding solutions containing acid only. These differences are given in column 6 of Table IV and are plotted against the normality of acid in Fig. 3. It is seen that the curve is again of the same type as the density-differences curve and the refractive index-differences curves, but it differs from these in two important particulars.

The first of these is that the curve falls away rapidly from the initial value, whereas both the density-differences and the refractive index-differences curves fall off gently from the beginning. This characteristic of the surface tension-differences curve is readily explained. It is seen from the values of the surface tensions in Table IV and from the curves in Fig. 2 that the first solution in the series containing cobalt (*i.e.*, aqueous cobalt chloride alone) has a surface tension greater than that of water; so also have the solutions immediately following. That is, the cobalt atom in its red association, $Co(H_2O)_6^{\cdot\cdot}$, *raises* the surface tension of water. It follows from the Gibbs equation that the concentration of this ion in the surface layer is *less* than that in the bulk of the solution.

It is evident from the curves in Fig. 2 that the blue solutions (those having a high concentration of acid) have a surface tension only slightly higher than the corresponding solutions containing acid alone. Assuming that the whole of the acid is " free " in these cobalt solutions, as in the solutions of acid alone, it follows that the cobalt atom in its blue association, $CoCl_4''$, also raises the surface tension of water, but to a far smaller extent than does the

red $Co(H_2O)_6^{\cdot\cdot}$. It is quite probable, however, since the acid is not wholly free but partly bound in the form of these complex ions, that the surface tension of the blue solutions is actually less than that of solutions of acid alone having a concentration equal to that of the "free" acid. In this event, the blue form, $CoCl_4''$, *lowers* the surface tension of water, and in accordance with the Gibbs equation its concentration in the surface layer is *greater* than in the bulk.

Even if the blue form raises the surface tension, it follows that for a given bulk concentration of cobalt, its concentration in the surface layer would be greater than that of the red form. When, therefore, the first introduction of acid to the cobalt solution results in the conversion of some $Co(H_2O)_6^{\cdot\cdot}$ ions into $CoCl_4''$ ions, the same change takes place in the surface layer to a far greater degree. The increase in concentration of the blue form is therefore far greater in the surface layer than in the bulk of the solution. The surface tension, which is a purely surface phenomenon, is a measure of this change, so that the surface tension-differences curve falls rapidly with the initial increases in acid concentration, whereas the density-differences curve and the refractive index-differences curves, indicating the effect in the bulk of the solution, fall away gradually.

The second particular in which the surface tension-differences curve differs from the others is that it exhibits its inflexion at a different concentration of acid. This also is to be expected and is explicable on the same reasoning. It has been suggested that the point of inflexion in the density-differences curve and in the refractive index-differences curves and also the maximum in the viscosity-differences curve occur when the solution contains equal amounts of the two kinds of ions, $Co(H_2O)_6^{\cdot\cdot}$ and $CoCl_4''$, since the attraction between them will then be greatest. It is now suggested that the point of inflexion in the surface tension-differences curve corresponds to the concentration of acid at which the same conditions obtain in the surface layer. Since the blue form accumulates in the surface layer to the exclusion of the red form, it follows that there will be equal amounts of each in the surface layer before this state is reached in the bulk of the solution. The surface tension-differences curve should therefore exhibit inflexion before the corresponding curves for the other properties which are dependent on the conditions in the bulk. It is seen from Fig. 3 that this is so.

It should be noted that although replacement of half the red form by the blue occurs in the surface layer sooner than in the bulk, the complete replacement cannot occur until this change is also

complete in the bulk. So long as any of the red form remains in the solution, a corresponding amount will be present in the surface layer, and it is not until all the red form has been converted in the solution that the same state is reached in the surface layer. The surface tension-differences curve should therefore not flatten out and become parallel to the axis of concentration sooner than the other curves, but at the same concentration of acid. It is seen from Fig. 3 that the curve falls continuously from the point of inflexion and has not become parallel over the range examined, but there are indications that this condition will be reached as with the other curves.

The Colour Change.—In the previous investigation, the colours of the cobalt solutions recorded were those observed by viewing thin layers against a white ground. In the present paper the colours of layers 5 cm. thick viewed in transmitted daylight are given at the head of Fig. 1.

The solutions having an acid concentration up to 3·144*N* are definitely red when examined in either thin or thick layers. Those having a concentration greater than 6·288*N* are green in very thin layers, but definitely blue with no trace of green in thicker layers. This dichroism is very marked.

Whereas these definitely red and blue solutions are clear and "clean," those lying within the limits stated are dull and "muddy" in appearance. In thin layers, the colour is indefinite. Thus the 4·192*N*-solution was previously described as brownish-red; in a thick layer, however, it is pinkish-violet, being definitely reddish with a tinge of blue. The 5·240*N*-solution, which is the most indefinite, was called a dull brown, but would have been better described as a dull amethyst, for even in thin layers it has a distinct blue tinge. In thicker layers the solution is definitely blue with a faint tinge of red. The 6·288*N*-solution is a very deep violet. The change in colour is therefore gradual and extends over a fair range of acid concentration. The 4·192*N*-solution being more red than blue, and the 5·240*N*-solution being more blue than red, the maximum colour change occurs between these concentrations of acid, as indicated at the head of Fig. 3. The 4·716*N*-solution, mid-way in acid concentration between these two, appears to be very nearly half red and half blue.

It was pointed out in the previous investigation that the point of inflexion in the density-differences curve and the maximum in the viscosity-differences curve do not coincide with the maximum change in colour, but at a considerably higher concentration of acid. The same is now seen to be true for the refractive index-differences curve. The colour change therefore takes place before

even half the cobalt has been transformed from the red to the blue association and this is in accordance with the fact already pointed out, that the blue form is far more intense than the red.

It should be noted that the concentration of acid at which the two forms are in equal amount in the surface layer, as indicated by the surface tension-differences curve, also does not correspond to the concentration at which the change of colour occurs.

Summary.

1. The refractive indices and surface tensions of a series of aqueous solutions containing a constant amount of cobalt chloride and increasing amounts of hydrochloric acid have been determined.

2. The same constants of an exactly similar series containing hydrochloric acid alone have also been measured.

3. The differences in the values for corresponding solutions bring to light the effect of the acid on the cobalt in solution.

4. The curve showing the differences in refractive index plotted against the concentration of acid is exactly similar to that of the density differences found in a previous investigation. The point of inflexion in both occurs at the same concentration of acid and is accounted for on the same reasoning.

5. The curve showing the differences in surface tension is also similar, but has a sharp initial fall and exhibits its point of inflexion at a lower concentration of acid. These two differences are wholly explained by the facts (*a*) that the surface tension is a measure of the conditions prevailing in the surface layer while the other properties are a measure of those in the bulk of the solution, and (*b*) that the relative concentrations of the red and the blue cobalt ions in the surface layer are different from those in the bulk under any given conditions.

6. The change in colour of the cobalt solutions with increasing acid concentration is discussed.

The author would express his sincere thanks to Prof. F. L. Pyman, F.R.S., for giving him every facility for prosecuting this work.

CCLXIX.—*Formation and Decomposition of Ketone Cyanohydrins, with Special Reference to some Compounds recently classified as such.*

By ARTHUR LAPWORTH, RICHARD HELMUTH FRED MANSKE, and EDWIN BREW ROBINSON.

IN a recent paper (*Ber.*, 1927, **60**, 586) Houben and Pfankuch described some new nitriles two of which were considered to be the stereoisomeric cyanohydrins of camphor. These workers commented on the remarkable stability of these nitriles, which did not show any tendency to dissociate into hydrogen cyanide and ketone; but having also found that the direct union of hydrogen cyanide and camphor cannot be effected, they concluded that these observations illustrate the rule that "ein Korper, der schwer entsteht, meistens schwer wieder zerfällt" (*loc. cit.*, p. 587).

Houben and Pfankuch described another new nitrile which they regarded as "menthon-cyanohydrin" (*loc. cit.*, p. 599). They did not state specifically that this compound has the same remarkable stability as the supposed camphor cyanohydrins, but, as they were able to purify it (apparently without adopting any special precautions) from boiling ligroin and to hydrolyse it with methyl-alcoholic potassium hydroxide, there can be no doubt that the compound was much more stable than most of the known cyanohydrins of other simple ketones.

Passerini, in a still more recent paper (*Ber.*, 1927, **60**, 1201, 1202), accepts the views of Houben and Pfankuch, but finds that the supposed "menthon-cyanohydrin" described by these authors is converted on hydrolysis with acids into a lactone, and infers that here "das Hydroxyl des Menthon-cyanohydrin in den Menthan-Ring wandert." Such a migration in a saturated compound has no parallel within the knowledge of the present authors.

A long series of measurements of equilibria in systems containing cyanohydrin, hydrogen cyanide and ketone (or aldehyde) in aqueous alcohol has been made in these laboratories during the last 3 years and among the cases studied were those comprising camphor and menthone respectively. It was found that, out of some 60 ketones and aromatic aldehydes examined, only 2, benzophenone and camphor, gave no detectable amounts of cyanohydrin by direct combination with hydrogen cyanide. With the others, a sensibly constant equilibrium condition was attained within 24 to 36 hours at most in aqueous alcohol, if a very small proportion of tripropylamine was present as catalyst. The dissociation constants of the cyanohydrins varied very widely, ratios of extremes observed being

at least 1 : 25,000, and the failure of camphor and benzophenone to yield measurable quantities of cyanohydrin is doubtless to be ascribed to the exceptionally high dissociation constants of the cyanohydrins rather than to catastrophic disappearance of reaction velocity.

It is quite otherwise in the case of menthone, the cyanohydrin * of which is formed quite readily in the cold, the time required in the above conditions to attain a concentration practically identical with the equilibrium value not exceeding 24 hours.

Experiment A illustrates some of these statements: Menthone (11·38 g.), 2 c.c. of ethyl alcohol containing 0·24 g. of tripropylamine, and 5 c.c. of anhydrous hydrogen cyanide dissolved in cold dry methyl alcohol (about 30 c.c.) were mixed and left over-night in a stoppered flask, previous experience having shown that further contraction (initially attendant on combination) is inappreciable after such a period. The vessel was then opened, the contents made up to 50 c.c. with more dried methyl alcohol, and the flask again closed with a waxed stopper and allowed to remain in an ice-chest for 60 hours, a period considerably exceeding that (24—36 hours) which previous experiments, under not wholly dissimilar conditions, had shown to be amply sufficient for the attainment of a practically steady state.† The solution was then analysed by a method based on that of Ultée (*Rec. trav. chim.*, 1909, **28**, 248), which depends on the fact that in presence of mineral acid, silver nitrate in the cold precipitates only cyanidion which is not in combination with the aldehyde or ketone. An aliquot portion of the solution was removed and at once added to excess of standard silver nitrate solution acidified with nitric acid, the whole being shaken, and the silver cyanide removed by filtration. The excess of silver in the filtrate was determined by titration with standard thiocyanate in the usual way. The free hydrogen cyanide present in the original 50 c.c. of solution was thus found to be 1·95 g.

Another portion of the solution was removed and allowed to remain in the cold with five times its bulk of *N*-sodium hydroxide for 45 minutes. The whole was acidified with nitric acid and mixed with excess of standard silver nitrate and the excess of silver was determined as before. The total hydrogen cyanide found in this way was 3·49 g. (comparing favourably with 3·53 g. found in the

* Strictly speaking, as menthone itself is a mixture of two dynamic isomerides, each of which can theoretically give rise to two stereoisomeric addition compounds with hydrogen cyanide, the cyanohydrin formed as above must be a mixture of four isomerides.

† A blank experiment in which the menthone was omitted showed that the total amount of hydrogen cyanide remaining after these manipulations would be approximately 3·53 g. if no combination had taken place.

blank experiment above mentioned). It is probable that a minute but hardly measurable quantity of the sodium derivative of the cyanohydrin remains in equilibrium with menthone and cyanidion in presence of sodium hydroxide:

$$C_{10}H_{18}O + CN' \rightleftharpoons C_{10}H_{18}(CN)\cdot O'.$$

From the titres, it may be deduced (1) that at equilibrium under the conditions specified above, 1 mol. of menthone is converted to the extent of about 0·8 mol. into cyanohydrin, in equilibrium with which 0·2 mol. of unchanged menthone remains with about 1 mol. of uncombined hydrogen cyanide, (2) that menthone cyanohydrin is almost completely converted into menthone and sodium cyanide by cold *N*-sodium hydroxide in not more than 45 minutes, the rapid acidification preventing appreciable recombination.

While the equilibrium may be effectively "frozen" by excess of mineral acid in aqueous or dilute alcoholic solution (as is shown by the failure of silver nitrate to decompose the cyanohydrin in these circumstances), it has not been found possible to separate the cyanohydrin from unchanged menthone owing to the instability of the former. It is quite easy to convert menthone to the extent of 90% into mixed cyanohydrins with excess of anhydrous hydrogen cyanide in presence of a trace of tripropylamine; but when attempts were made to remove hydrogen cyanide at the ordinary temperature by the use of a vacuum, even after adding some excess of hydrogen chloride in ether in the endeavour to stabilise the cyanohydrin, the latter underwent considerable decomposition and in the end constituted only about 30% of the residual oil.

On subjecting the equilibrium mixtures to hydrolytic action of mineral acids, including sulphuric acid, concentrated or dilute, in the cold, no evidence was obtained of the formation of any acid amide or carboxylic acid, and Pinner's method for the conversion of nitriles into imino-ethers in ethereal solution also gave negative results; the nitrile group is, in fact, extremely resistant to cold acid hydrolysts. If the temperature be raised, thermal dissociation occurs and hydrogen cyanide is lost, again before any effective hydrolysis has taken place. With alkalis, as has been demonstrated, the cyanohydrin is almost quantitatively decomposed even in the cold in a short time—probably within a few seconds. The great speed at which equilibrium is reached from either side in systems comprising ketone and cyanohydrin in presence of considerable concentrations of hydroxylion or cyanidion or both is perhaps not generally realised. *Experiment B* is described to illustrate the last point.

B. Cold saturated aqueous potassium cyanide (1 c.c.) at about

20° is shaken in a test-tube with 0·2 c.c. of *cyclo*hexanone which has been purified through the bisulphite compound. The ketone, at first immiscible, very quickly disappears, if the temperature is initially about 15°, a clear solution being formed with rise of temperature; then, as a rule, crystals of the potassium derivative of the cyanohydrin almost at once begin to appear and the whole sets, within about 30 seconds from the beginning of the experiment, to a semi-solid mass.

How little the concentration of *free* hydrogen cyanide affects the addition process may also be observed by repeating the experiment with the previous addition of 0·5 c.c. of 30% aqueous potassium hydroxide to the potassium cyanide. Although the concentration of free hydrogen cyanide due to salt hydrolysis must be reduced thereby many thousand-fold, the same phenomena are observed, while the time taken for setting is not more than doubled. The apparent decrease in speed is doubtless due in the main to the salting-out action of the potassium hydroxide reducing the already small solubility of the *cyclo*hexanone in the aqueous phase.

Observations already mentioned show that menthone cyanohydrin is readily formed and decomposed even in the cold in alkaline media and therefore, if the phenomena just described are not reproduced when menthone is used instead of *cyclo*hexanone, it is not because reaction is indefinitely delayed, but because the dissociation constants of menthone cyanohydrin and of its potassium derivative are much higher than those of *cyclo*hexanone cyanohydrin and of its potassium derivative respectively.* If, therefore, the compound described by Houben and Pfankuch were, in fact, menthone cyanohydrin, then at a very early stage in the alkaline hydrolysis which they carried out (*loc. cit.*, p. 600) equilibrium must have been attained, and this equilibrium should be reached no less rapidly by simply boiling menthone with potassium cyanide and potassium hydroxide in methyl-alcoholic solution, and with similar results on allowing hydrolysis to proceed. *Experiment C* was therefore carried out.

C. Menthone (10 g.) with potassium cyanide (10 g., or 2·5 mols.) and methyl alcohol (100 c.c.) was heated on the steam-bath for 48 hours. (A small portion of the product was removed at this point and worked up for carboxylic acid, but none could be detected.) Potassium hydroxide (25 g.) was next added and the heating was continued for a further 70 hours. On working up the whole for carboxylic acid, 1·9 g. of oily product, sparingly soluble in water but

* The dissociation constants of the two cyanohydrins in aqueous alcoholic solution at the ordinary temperature have been measured by one of us (R. H. F. M.) and found to be roughly in the ratio 72 : 1.

readily soluble in aqueous sodium carbonate, were isolated. Doubtless Houben and Pfankuch would have commented on such a poor yield after so prolonged a period of heating, but they do not mention either. It may be added that on attempting to convert the acid material into amide by the method used by Houben and Pfankuch only a small proportion of the product was soluble in hot ligroin, and even that portion failed to yield any crystalline solid.

Conclusions.—True menthone cyanohydrin, *i.e.*, the mixture of cyanohydrins produced by addition of hydrogen cyanide to ordinary menthone, is readily formed and decomposed reversibly in solutions which are at all alkaline and its properties indicate that Houben and Pfankuch were dealing with quite another compound. The characters ascribed by these workers to the compounds which they describe as camphor cyanohydrins are also at variance with those of all known ketone cyanohydrins.

It is suggested that a transformation of the Wagner type occurs when the nitrogen atom is separated from carbon in the experiments described by Houben and Pfankuch.

THE UNIVERSITY, MANCHESTER. [*Received, July 5th*, 1927.]

CCLXX.—l-*Methylephedrine, an Alkaloid from* Ephedra *Species.*

By SYDNEY SMITH.

THE Chinese drug Ma Huang derived from an *Ephedra* species has become of importance in Western medicine as the source of *l*-ephedrine, an alkaloid which has recently been found to possess a physiological action resembling that of adrenaline. In addition to *l*-ephedrine the drug contains *d*-ψ-ephedrine, and another alkaloid, the subject of the present communication, has now been isolated.

The constitutions of *l*-ephedrine and *d*-ψ-ephedrine

(OH·CHPh·CHMe·NHMe)

have been established beyond doubt by syntheses of the racemic bases and their resolution into the corresponding enantiomorphic forms, two of which are identical with the naturally occurring alkaloids *l*-ephedrine and *d*-ψ-ephedrine. The empirical formula and properties of the new alkaloid suggested that it was probably the *N*-methyl derivative of either *l*-ephedrine or *d*-ψ-ephedrine. The *N*-methyl derivatives were therefore prepared by methylation of the natural bases and it was found that the m. p. and specific rotation of *l*-methylephedrine were identical with those of the new alkaloid. Comparison of the m. p. and specific rotation of the

corresponding hydrochlorides and the methiodides afforded ample confirmation that the new alkaloid is identical with *l*-methylephedrine, $OH{\cdot}CHPh{\cdot}CHMe{\cdot}NMe_2$.

EXPERIMENTAL.

The syrupy alkaloidal residue obtained in the manufacture of ephedrine, freed as completely as possible from *l*-ephedrine and *d*-ψ-ephedrine, was purified by distillation under reduced pressure and neutralised with aqueous oxalic acid and the solution was evaporated to dryness. The residue on extraction with alcohol gave an alcohol-soluble fraction, which was dissolved in water and treated with a saturated aqueous solution of picric acid. The oil which first separated became solid on standing, and subsequent crops separated in a crystalline condition. The picrate was treated with hydrochloric acid and ether, and the resulting solution of the hydrochloride evaporated to dryness. The residue, after several crystallisations from alcohol, gave *l-methylephedrine hydrochloride* in stout, colourless tablets, m. p. 188—189° (corr.) (Found: C, 61·3; H, 8·3; Cl, 16·2. $C_{11}H_{17}ON,HCl$ requires C, 61·2; H, 8·4; Cl, 16·4%). It is readily soluble in water, less soluble in alcohol, and sparingly soluble in acetone. In water solution, it had $[\alpha]_D$ −29·8° ($c = 4{\cdot}6$).

l-Methylephedrine, prepared by addition of concentrated potassium hydroxide solution to a solution of *l*-methylephedrine hydrochloride in water, separated as an oil which rapidly solidified. It crystallised readily from methyl alcohol in stout needles, m. p. 87—88° (corr.). Previously recorded values are 59—62° (Miller, *Arch. Pharm.*, 1902, **240**, 481), 78° (Eberhard, *ibid.*, 1915, **253**, 65), 84° (Nagai, Abstract by Chen and Kao, *J. Amer. Pharm. Assoc.*, 1926, **15**, 632) (Found: C, 73·5; H, 9·4. Calc. for $C_{11}H_{17}ON$: C, 73·7; H, 9·6%). The base can be titrated with standard acid with methyl-red as indicator: 0·7956 g. required 44·4 c.c. of 0·1*N*-sulphuric acid. $C_{11}H_{17}ON$ requires 44·4 c.c. In methyl alcohol it had $[\alpha]_D$ −29·2° ($c = 3{\cdot}0$). When treated with methyl iodide in methyl-alcoholic solution, it gave a *methiodide* which crystallised from alcohol in stout tablets, m. p. 212—213° (corr.) and had $[\alpha]_D$ −21·8° ($c = 2{\cdot}9$) (Found: I, 39·6. $C_{12}H_{20}ONI$ requires I, 39·5%).

Methylation of l-*Ephedrine.*—*l*-Ephedrine (28·4 g.), dissolved in methyl alcohol (28·4 c.c.), was boiled on a water-bath, and methyl iodide (27 g.) in methyl alcohol (27 c.c.) was added slowly. The solution was boiled for 2 hours, concentrated under diminished pressure, and treated with potassium hydroxide solution and ether; 23·6 g. of the methiodide then separated. The alkaline liquor was

extracted with ether and added to the first ethereal extract. After drying over potassium carbonate, the ethereal solution was distilled, the residual base neutralised with aqueous oxalic acid, and successive crops of *l*-ephedrine oxalate, m. p. 249° (corr.), were removed. The final syrupy mother-liquor was treated with excess of potassium hydroxide solution; an oil then separated which rapidly solidified. It melted at 86—87° (corr.) after crystallisation from light petroleum and at 87—88° (corr.) after a further crystallisation from methyl alcohol. When mixed with the alkaloid obtained from Ma Huang, it showed no depression in m. p. (Found: C, 73·7; H, 9·4. Calc. for $C_{11}H_{17}ON$: C, 73·7; H, 9·6%). It had $[\alpha]_D$ −29·5° in methyl alcohol ($c = 4·5$).

The base was dissolved in ether and neutralised with hydrogen chloride. On crystallisation from alcohol the hydrochloride formed colourless tablets, m. p. 188—189° (Found: C, 61·4; H, 8·3; Cl, 16·4. Calc. for $C_{11}H_{17}ON,HCl$: C, 61·2; H, 8·4; Cl, 16·4%). It had $[\alpha]_D$ −29·8° in water ($c = 5·7$). There was no depression of the melting point after admixture with the hydrochloride obtained from Ma Huang.

l-Methylephedrine methiodide crystallises from alcohol in stout tablets, m. p. 212—213° (corr.) (Eberhard, *loc. cit.*, gave m. p. 204°). In aqueous solution it had $[\alpha]_D$ −21·3° ($c = 5·5$) (Found: I, 39·3. Calc. for $C_{12}H_{20}ONI$: I, 39·5%).

l-*Methylephedrine picrate* was prepared by adding a solution of the hydrochloride to a saturated aqueous solution of picric acid. It crystallised readily from alcohol and melted at 144° (corr.) (Found: C, 50·3; H, 4·5. $C_{17}H_{20}O_8N_4$ requires C, 50·0; H, 4·9%).

Methylation of d-*ψ*-*Ephedrine.*—*d*-*ψ*-Ephedrine (56·8 g.), dissolved in methyl alcohol (56·8 c.c.), was boiled on a water-bath, and methyl iodide (56·8 g.) added slowly. The mixture was boiled for 4 hours and treated with potassium hydroxide solution and ether; it then deposited crystals of the methiodide (24·1 g.). The alkaline liquor was extracted with ether and the united ethereal extracts were dried over potassium carbonate. After removal of the ether a crystalline residue (47·6 g.) was obtained which was fractionally crystallised from light petroleum; it then gave as a first crop 6·7 g. of crude *d*-*ψ*-ephedrine, m. p. 113°. Subsequent crops of low-melting base were obtained which were found by titration to consist of nearly pure methylephedrine.

The base was converted into the hydrogen tartrate and purified by recrystallisation from water.

d-*ψ*-*Methylephedrine hydrogen tartrate* crystallises in needles which melt at 84° (corr.) and, after drying in a vacuum over sulphuric acid, at 152° (corr.) (Found in air-dried salt: loss in a vacuum over

H_2SO_4, 10·0. $C_{11}H_{17}ON,C_4H_6O_6,2H_2O$ requires loss, 9·9%. Found in dried salt: C, 54·6; H, 6·9. $C_{11}H_{17}ON,C_4H_6O_6$ requires C, 54·7; H, 7·0%).

d-*ψ*-*Methylephedrine* was prepared by the addition of sodium hydroxide solution to a solution of the hydrogen tartrate in water. The base was extracted with ether and dried over potassium carbonate, and the ether removed by distillation. The residue crystallised readily on cooling and melted at 29—30° (corr.). Emde (*Arch. Pharm.*, 1906, **244**, 246) obtained the base as a thick oily liquid. It was recrystallised from light petroleum at −10°; thereafter it melted at 30° (corr.). d-*ψ*-*Methylephedrine* is readily soluble in the common organic solvents, and somewhat sparingly soluble in water (Found: C, 73·7; H, 9·4. $C_{11}H_{17}ON$ requires C, 73·7; H, 9·6%). In methyl alcohol it had $[\alpha]_D$ +48·1° ($c = 4·7$). It can be titrated with standard acid and methyl-red: 0·6689 g. required for neutralisation 37·2 c.c. of 0·1*N*-sulphuric acid. $C_{11}H_{17}ON$ requires 37·3 c.c.

d-*ψ*-Methylephedrine methiodide crystallises readily from alcohol; m. p. 216—217° (corr.) (Emde, *loc. cit.*, gave m. p. 205°) (Found: I, 39·4. Calc. for $C_{12}H_{20}ONI$: I, 39·5%). In aqueous solution it had $[\alpha]_D$ +34·7° ($c = 2·9$).

d-*ψ*-*Methylephedrine picrate* was prepared by addition of a solution of the hydrochloride to a saturated solution of picric acid in water. It crystallised readily from alcohol and melted at 152—153° (corr.) (Found: C, 50·4; H, 4·9. $C_{17}H_{20}O_8N_4$ requires C, 50·0; H, 4·9%).

The author's thanks are due to Mr. W. Ramsay for assistance in this investigation.

CCLXXI.—*The Use of Titanous Chloride in the Volumetric Estimation of Copper and Iron.*

By WILLIAM GIDLEY EMMETT.

IN the course of a research involving many analyses of cupric chloride solutions, copper was estimated in the solutions by titration with titanous chloride, ferric ammonium sulphate in known quantity and potassium thiocyanate in excess being added as indicator. The method is well known and is described by Knecht and Hibbert ("New Reduction Methods in Volumetric Analysis," 1918) and other workers.

A source of error, apparently hitherto unremarked, lies in the

somewhat rapid decomposition of ferric and cupric thiocyanates by water at the ordinary and at higher temperatures. These reactions were investigated by Philip and Bramley (J., 1913, **103**, 795; 1916, **109**, 597), who showed that the salts were reduced; in the case of the ferric salt, the rate of reduction was diminished by acid when an excess of alkali thiocyanate was present, and greatly increased by a rise in temperature; but the rate of reduction of cupric thiocyanate was not investigated. The results of a brief study of these sources of error, in so far as they concerned the other research, are now reported.

The titrations were carried out according to the technique described by Knecht and Hibbert, carbon dioxide being passed through the flask. A 15% solution of titanous chloride, after being boiled with concentrated hydrochloric acid, was diluted to give an approximately 0·02*N*-solution, and stored in the apparatus depicted (*loc. cit.*). (The diluted solution contained as impurity about 0·00013 g. of iron per c.c. as determined by oxidising 5 c.c. of the original 15% solution with acidified potassium permanganate and titrating the resulting ferric salt with a standardised titanous chloride solution.) A solution of standardised (approx. 0·025*N*) acidified ferric ammonium sulphate was used for checking the titanous chloride solution before and after each series of titrations, a slight but continuous decline in strength being noted.

Decomposition of Ferric Thiocyanate.—Solutions of ferric thiocyanate, prepared by mixing 25 c.c. of ferric chloride solution of known strength with 10 c.c. of 10% potassium thiocyanate (A.R.), containing different quantities of hydrochloric acid were titrated with standard titanous chloride at various intervals after mixing. The results (Table I) show that the decomposition is slight at the

ordinary temperature, and (in agreement with Philip and Bramley) that it is more pronounced at higher temperatures, but is inhibited by acid. Consequently, in analytical work the titration of ferric thiocyanate solutions must be carried out at the ordinary temperature in the presence of free acid and without undue delay after addition of thiocyanate to the ferric salt.

Decomposition of Cupric Thiocyanate.—Titrations with titanous chloride after different intervals were made on portions of 25 c.c. of cupric chloride solution (A.R.) to which had been added as indicator 10 c.c. of 10% potassium thiocyanate (A.R.) and 5 c.c. of the standard ferric solution together with varying amounts of hydrochloric acid. Typical results are given in Table II.

* Since the velocity of change of ferric thiocyanate at the ordinary temperature is seen to be small compared with that of cupric thiocyanate, the total reduction has been ascribed to the latter.

Solutions of cupric chloride containing hydrochloric acid in concentrations from 0·25*N* to 3·3*N*, when titrated at the ordinary temperature with titanous chloride as soon as possible after addition of potassium thiocyanate, gave results which agreed amongst themselves within 0·1%. It is thus seen to be essential in the titration of cupric thiocyanate solutions to observe the same precautions as in the case of ferric thiocyanate.

When solutions of cupric chloride (*ca.* 0·015*N*) and 10% potassium thiocyanate (with or without added acid) were mixed and kept for 10 minutes or more before titration with titanous chloride, sharp end-points were not obtained; after the red colour of the ferric thiocyanate indicator had yielded to a colourless solution holding a pale grey precipitate, it developed again in a few seconds. Further addition of a drop of titanous chloride caused decoloration followed by renewed appearance of colour, and so on. The phenomenon is ascribed to the precipitation of cupric thiocyanate from the solution while awaiting titration, black acicular crystals having been observed under such conditions; in the course of the titration the precipitate slowly redissolves and reacts at the end to re-form ferric thiocyanate.

This supplies another reason why titration of cupric thiocyanate solutions should be done without loss of time.

By following Knecht and Hibbert's method with the addition of the precautions mentioned, analyses with an error of less than 0·2% were easily obtained. The titanous chloride solutions were standardised against a solution of cupric chloride (A.R.) in which the chlorine had been determined gravimetrically as silver chloride and/or the copper as cuprous thiocyanate.

A more convenient method of preparing a standard copper solution consists in dissolving a known weight of electrolytic copper in a solution of sodium peroxide in hydrochloric acid. About 5 g. of sodium peroxide are added to about 20 c.c. water and the solution is acidified with concentrated hydrochloric acid, being kept cool meanwhile. About 1 g. of pure copper turnings is added and dissolves in about ½ hour. The solution is then boiled under reflux to decompose all hydrogen peroxide (or to drive off dissolved chlorine), and diluted to a convenient volume. This method gave results from 0·1 to 0·2% lower than that previously described, probably on account of the presence of traces of iron in the sodium peroxide used.

The use of ferrous ammonium sulphate as a primary standard has been adversely criticised by the U.S. Bureau of Standards (Circular No. 26, 1921, 11) and by Thornton and Wood (*Ind. Eng. Chem.*, 1927, **19**, 150), and the author's results are in agreement with this.

The reduction of solutions of cupric thiocyanate on standing gives a ready explanation of Tomiček's observation (*Rec. trav. chim.*, 1924, **43**, 798) that when copper sulphate solutions were titrated by the potentiometric method in the presence of an excess of potassium thiocyanate large divergences from the expected figures were obtained; his suggestion that the thiocyanate is changed to sulphide, the copper salt being thereby fixed, is probably incorrect.

Highly erratic results were also recorded by Mach and Lederle (*Landw. Versuchs-Stat.*, 1914, **84**, 142) when titrating mixtures of ferric chloride and cupric sulphate in the presence of potassium thiocyanate, the ascertained copper content of cupric sulphate crystals varying from 25·08 to 18·26% with increasing concentration of ferric salt, whilst analysis by the electrolytic method gave 25·52% copper. These vagaries may perhaps also be ascribed to decomposition of the thiocyanates prior to titration, or alternatively to precipitation of cupric thiocyanate from the solutions.

The author desires to express his indebtedness to Dr. S. R. Carter for valuable assistance in the course of the work.

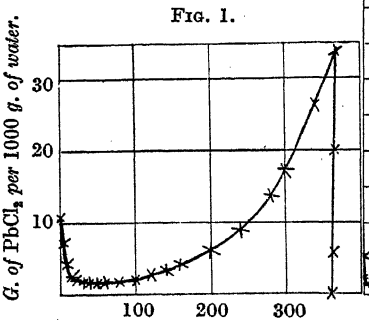
CCLXXII.—*Studies of Equilibria in the Systems Sodium Chloride–Lead Chloride–Water, Lithium Chloride–Lead Chloride–Water.*

By GEORGE E. R. DEACON.

THE purpose of this work was the investigation of those complex salts, if any, formed by lead chloride with sodium or lithium chloride, which are capable of existence in contact with aqueous solutions at 25°, and to obtain the isothermal diagrams for these systems.

The method used was the same as that described by Burrage

FIG. 1.



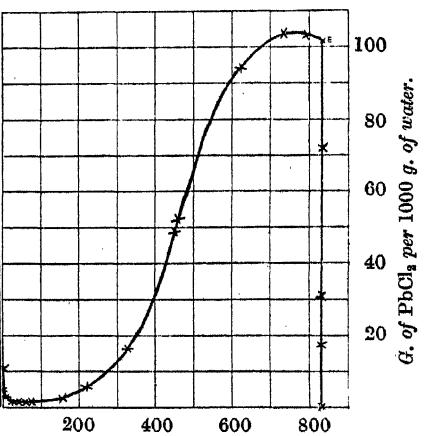


FIG. 2.

(J., 1926, 1703). The lead was estimated gravimetrically as chromate and the total chloride as silver chloride, water being found by difference. The analytical results for the liquid and wet solid phases were plotted on triangular diagrams according to Schreinemakers's method of residues; they exhibit the nature of the results more clearly, however, when plotted as in Figs. 1 and 2.

Lead Chloride–Sodium Chloride–Water.

Previous work on this system has led to conflicting results. (Mme.) Demassieux (*Ann. Chim.*, 1923, **20**, 233) studied the system at 100°, 50°, and 13°, and found that no double compounds existed. Kendall and Sloan (*J. Amer. Chem. Soc.*, 1925, **47**, 2306), working at 25°, describe the compound $2PbCl_2,NaCl$. The present investigation shows the absence of any such compound, the solid phases being lead chloride and sodium chloride only.

TABLE I (see Fig. 1).

Composition of the equilibrium solutions at 25° for the system $NaCl$–$PbCl_2$–H_2O. (Concentrations are expressed as g. per 1000 g. of water.)

NaCl.	$PbCl_2$.	Solid phase.	NaCl.	$PbCl_2$.	Solid phase.

Lead Chloride–Lithium Chloride–Water.

This system has been investigated at 50° by Demassieux (*loc. cit.*), and some measurements have also been made at 25° by Kendall and Sloan (*loc. cit.*), who claimed the existence of the salt $LiCl,2PbCl_2$. The present work shows the absence of this salt at 25°, and that of Demassieux shows that no compound is formed at 50°.

The system is singular in that the decrease in solubility of the lead chloride to 1·39 g. and the subsequent increase to 103·5 g. are followed by a slight decrease in solubility to 101·6 g. before the eutectic point is reached. The curve undergoes a break at the eutectic point, and a second solid phase $LiCl,H_2O$ separates. The separation of the monohydrate is in agreement with the work of Bogorodsky (*J. Russ. Phys. Chem. Soc.*, 1893, **25**, 316), who describes this hydrate as the stable form between 12·5° and 98°.

TABLE II (see Fig. 2).

Treis (*Jahrb. Min. Beil.-Bd.*, 1914, **37**, 766), investigating the binary systems $PbCl_2$–XCl (where X = Li, Na, K, or Rb), found that whilst potassium gave two double compounds, and rubidium three, no combination was obtained between lithium or sodium chloride and lead chloride. Double salts are also formed between potassium and lead chlorides in aqueous solution (Burrage, *loc. cit.*).

Summary.

1. Equilibria existing at 25° in the systems NaCl–$PbCl_2$–H_2O, and LiCl–$PbCl_2$–H_2O have been investigated over the whole range of concentrations.

2. At this temperature, no double salts are capable of existence in either system.

The author desires to thank Professor Allmand, under whose direction this work was carried out during the session 1926—1927.

UNIVERSITY OF LONDON,
KING'S COLLEGE. [*Received, July 9th*, 1927.]

CCLXXIII.—*Ferric Thiocyanate.*

By KENNETH CLAUDE BAILEY.

IT is generally assumed that the blood-red substance produced by the interaction of ferric chloride and potassium thiocyanate, and extracted by ether from its aqueous solution, is ferric thiocyanate. Kruss and Moraht (*Ber.*, 1889, **22**, 2054) obtained double salts, to which they attributed the formulæ $9KSCN,Fe(SCN)_3,4H_2O$ and $3KSCN,Fe(SCN)_3,nH_2O$, by crystallisation from aqueous mixtures, but these salts were decomposed by moist ether, and could not account for the colour extracted by that solvent.

Clarens's suggestion (*Bull. Soc. chim.*, 1923, **33**, 988) that the substance obtained in presence of an excess of ferric chloride is a dithiocyanate has been combated by the author (*Proc. Roy. Irish Acad.*, 1924, **37**, *B*, 2, 6).

Tarugi stated (*Gazzetta*, 1904, **34**, ii, 326; *Annali Chim. Appl.*, 1925, **15**, 416; 1926, **16**, 281) that the red compound was a per oxidised ferrous salt, $FeHC_3N_3S_3O_3$, but his conclusions from hi earlier work were disputed by Bongiovanni (*Gazzetta*, 1907, **37**, i, 472). Although Tarugi reaffirmed these conclusions in his later work, it was deemed desirable to repeat his experiments and examine point by point the most striking arguments which he adduced in support of his formula.

According to his directions, therefore, an excess of freshly prepared ferric hydroxide was dissolved in aqueous thiocyanic acid, the solution saturated with sodium chloride and extracted with ether, and the extract filtered and dried, where desirable, over anhydrous sodium sulphate. The results obtained were identical with those given by an ethereal extract of ferric chloride and potassium thiocyanate (excess).

(1) A little of the fresh ethereal solution was added to water, and then gave a deep blue colour with potassium ferrocyanide and only a yellow colour with ferricyanide (Tarugi obtained a greenish colour and a blue colour, respectively). After being kept for some time, the solution gave a blue colour with ferricyanide, showing slow reduction of part of the iron to the ferrous condition.

(2) When dilute nitric acid was added to a strong solution of potassium thiocyanate, and the mixture shaken with ether, a red extract was obtained which was strongly acid. This result can hardly be attributed to oxidation as asserted by Tarugi, for a similar extract was obtained when hydrochloric acid was substituted for nitric acid, and the substance extracted was almost certainly thiocyanic acid (compare Bailey, *loc. cit.*; Werner and Bailey, J., 1926, 2970).

(3) A solution of ferric sulphate was prepared containing 5·58 g. per litre of iron and excess of acid. If no excess acidity had been present, 30 c.c. of $N/10$-sodium hydroxide should have sufficed to precipitate all the iron in 10 c.c. and give a neutral solution. About 69 c.c. were actually needed; 10 c.c. of the ferric solution contained, therefore, the equivalent of about 39 c.c. of $N/10$-acid in excess. When similar titrations were performed with solutions containing potassium thiocyanate and potassium oxalate, very indefinite results were obtained by the use of phenolphthalein, the indicator employed by Tarugi. Neutral litmus paper gave consistent results and was employed throughout.

Another source of error lay in the fact that the iron was not completely precipitated from solutions containing thiocyanate and oxalate until a fair excess of alkali was present, and there was a danger of adsorption of the alkali by the precipitated hydroxide. To avoid this, the solution was boiled, and 68 c.c. of $N/10$-alkali were added. The solution was filtered, the filter-paper washed, and further alkali added to ensure complete precipitation. The solution was again filtered, and the solution and washings were back-titrated with $N/10$-sulphuric acid. This procedure was followed even in the case of the plain ferric sulphate solution, to ensure uniformity of results, for each filtration necessarily incurs loss. The following results were obtained:

10 C.c. of ferric sulphate solution required 69·1 c.c. of $N/10$-sodium hydroxide.

10 C.c. of ferric sulphate solution + 60 c.c. of $N/10$-potassium thiocyanate (*i.e.*, 6 mols.) required 69·3 c.c.

10 C.c. of ferric sulphate solution + excess of concentrated potassium thiocyanate + potassium oxalate until solution was pale yellow required 69·1 c.c.

No increase in free acidity due to the reduction of iron to the ferrous condition was observed, and the only plausible explanation of Tarugi's statement, that such increase occurs, is that an error was introduced by the use of phenolphthalein, or by adsorption of sodium hydroxide by the precipitate.

Tarugi suggested that the decolorisation of the red solution by potassium oxalate was due to reduction of the red peroxidised compound by the oxalate. If this were the case, an amount of potassium oxalate equivalent to the original red compound should be oxidised during the reaction.

Quantitative estimations showed that no oxalate disappeared during the operation, and that twenty times as much oxalate was necessary for approximate decolorisation as should have sufficed for reduction of the peroxidised compound supposed to be present. This result was consistent with the disappearance of the red colour by double decomposition, but not with reduction of a peroxidised compound at the expense of the oxalate.

(4) Some fresh, red, ethereal solution was decolorised by potassium oxalate. Ammonia was added and the precipitate was quickly filtered off, washed with air-free water, and dissolved in hydrochloric acid; the solution gave an intense blue colour and precipitate with ferrocyanide, but only a greenish-yellow solution with ferricyanide. Tarugi's result (that the iron is precipitated in the ferrous condition) is only intelligible on the supposition that the ferric oxalate solution was exposed to sunlight, which would probably cause formation of some ferrous oxalate.

(5) Some of the ethereal solution was treated with oxalate, calcium chloride, and ammonia, as directed by Tarugi. The precipitate, as before, contained ferric iron and no ferrous iron. To the neutralised filtrate one drop of very dilute ferric chloride solution was added. A red colour, readily extracted by ether, was produced. Tarugi obtained a red colour not extracted by ether. This result may be easily explained. If the solutions employed are fairly dilute, the filtrate is a very dilute solution of thiocyanate, and even one drop of concentrated ferric chloride produces an excess of the latter reagent. The red colour is then only extracted with diffi-

culty. By using concentrated solutions of the other reagents and a dilute solution of ferric chloride, a mixture is obtained in which the thiocyanate is in excess, and the colour is readily extracted (see Durand and Bailey, *Bull. Soc. chim.*, 1923, **33**, 653; Bailey, *loc. cit.*).

(6) To water freed from air by boiling, some ammonia was added in a separating funnel, and red ethereal solution till the funnel was quite full. After shaking, the precipitate was allowed to subside, and had the typical appearance of ferric hydroxide; it was rapidly and repeatedly washed with air-free water, and dissolved in a little acid. The resulting solution gave no blue colour with ferricyanide. The supernatant liquid was tested for thiocyanate as under (5), with similar results.

(7) The ethereal solution gave a blue colour with benzidine, but a similar result was obtained with ferric chloride and benzidine. This reaction, therefore, does not prove the peroxidised nature of the red compound.

(8) An attempt was made to crystallise the red compound from its ethereal solution, dried over anhydrous sodium sulphate. This solution, however, when kept in a desiccator, changed in composition even before depositing solid, and a solution which originally gave only a yellow colour with ferricyanide soon gave a blue colour, showing conversion of iron into the ferrous state. After the solution had evaporated almost completely, the residue remained moist for about a week. This red liquid was acid in reaction, and doubtless contained free thiocyanic acid. A large proportion of the iron in the solid residue, although not all, was in the ferrous condition.

Philip and Bramley (J., 1913, **103**, 795) observed reduction of ferric thiocyanate in aqueous solution:

$$8Fe(CNS)_3 + 6H_2O = 8Fe(CNS)_2 + 7HCNS + CO_2 + H_2SO_4 + NH_3.$$

It seems possible that a similar reduction of ferric thiocyanate to ferrous thiocyanate with production of thiocyanic acid is taking place here. In view of the undoubted and rapid alteration of the red product, it seems unlikely that an analysis of any substance crystallised from the ethereal solution in a desiccator (Tarugi found Fe, 20·59; S, 34·37. Calc. for $FeHC_3N_3S_3O_3$: Fe, 20·07; S, 34·40%) can give results sufficiently trustworthy to establish a formula such as that proposed by Tarugi.

Summary.

Many of the experiments described by Tarugi have been carefully repeated. No evidence was obtained to support his conclusion that the red compound formed by dissolving ferric hydroxide in an

aqueous solution of thiocyanic acid is $FeHC_3N_3S_3O_3$. The results all indicate that the compound is ferric thiocyanate.

The author wishes to express his gratitude to Professor E. A. Werner for the helpful interest which he has taken in this work.

TRINITY COLLEGE, DUBLIN. [*Received, June 21st*, 1927.]

CCLXXIV.—*The Inflammation of Mixtures of the Paraffins and Air in a Closed Spherical Vessel.*

By GEORGE BARTON MAXWELL and RICHARD VERNON WHEELER.

IN a previous paper on the inflammation of mixtures of methane and air in a closed spherical vessel (J., 1918, **113**, 840), ignition being at the centre, it was recorded that the maximum pressures developed were about 10% less than the calculated values. For the calculations, the degree of dissociation of the products when inflammation had spread through the vessel was determined by analyses of samples rapidly withdrawn at the moment of attainment of maximum pressure; and Langen's values for specific heats were used. Close agreement between results obtained for mixtures of the same composition, inflamed within spheres of 4 and 16 litres capacity, showed that losses due to conduction of heat could not entirely account for the low experimental values, which were ascribed mainly to radiation losses. Experiments by Tizard and Pye (Empire Motor Fuels Committee, Report, 1923—24) with internal-combustion engines, gave surprisingly high results for the pressures produced on explosion of mixtures of heptane and air, the observed pressures being but little less than those calculated. Either the heat loss during the inflammation of heptane is considerably less than with methane, or the method of calculating explosion-temperatures used by Tizard and Pye gave low values.

The work herein described was undertaken to elucidate this matter and to study the factors which influence the rate of inflammation of hydrocarbons. The hydrocarbons used were the first five members of the paraffin series. Save that the pressure-gauge was fitted with a stronger spring than in the earlier determinations, the explosion-vessel (a 4-litre sphere) and the method of experiment were as described previously (*loc. cit.*). To ensure strictly comparable results throughout the series, the experiments with methane and ethane (see J., 1919, **115**, 81) were repeated. The pressures measured were slightly higher than in the earlier records, but the results, given in the tables that follow, did not otherwise differ

materially. Each table of observed results is followed by calculations of the maximum temperatures attainable and the theoretical maximum pressures for a number of mixtures. The method of calculation, which is explained in the experimental portion of the paper, was based on that used by Tizard and Pye (*loc. cit.*), whose data we have employed. The theoretical composition of the products of combustion of each mixture, and the ratios of the number of molecules present at the moment of maximum temperature to the initial number ("molecular ratios") are also recorded. All the mixtures were at an initial temperature and pressure of 15° and 1 atmosphere, and were ignited at the centre of the sphere.

The Pressures developed.—Comparison between the observed and the calculated pressures is made in Fig. 1. Both experiment and calculation show the maximum pressure to be given in each instance by a mixture containing an excess of hydrocarbon over that required for complete combustion. The amounts of these "displacements" are recorded in Table VI, together with the observed and calculated maximum pressures and the amounts of "lost pressure" expressed as % of the calculated values.

The close agreement in composition between the observed and calculated maximum-pressure mixtures leads to the conclusion that

TABLE VI.

Compositions of Mixtures giving Maximum Pressures. Lost Pressures, %.

	Theoretical mixture for complete combustion, %.	Mixture giving maximum press., %.		Maximum press.		Lost press., %.
		Calc.	Obs.	Calc.	Obs.

Pentane	2·55	3·00	2·95	9·07	8·85	2·45

the " displacements " are the effects of dissociation on the explosion-temperatures and " molecular ratios," for which allowance was made in the calculations.

The " lost pressure " may be due to loss of heat by conduction and radiation or to incomplete combustion. It was shown in a previous paper (*loc. cit.*) that, in mixtures of methane and air containing between 7·5 and 12·5% of methane, a loss of heat by conduction of 2—3% can be presumed during the attainment of uniformity of temperature after inflammation. Such a loss may be assumed also with the other hydrocarbons. It is not easy to obtain a comparison of radiation losses during combustion of each hydrocarbon from the calculated compositions of the products. The intensities of radiation from steam and from carbon dioxide have been determined by Julius (" Die Licht- und Warmestrahlung verbrannter Gase," Berlin, 1890) and R. von Helmholtz (" Die Licht- und Warmestrahlung verbrennender Gase," Berlin, 1890), but the most trustworthy figures seem to be those recorded by Haslam, Lovell, and Hunneman (*Ind. Eng. Chem.*, 1925, **17**, 272), who estimated (by measuring the radiation from flames of methane and carbon monoxide, the theoretical amount of primary air being used with each) that the intensity of radiation from steam was about 1·7 times that from carbon dioxide. If these results be accepted, a comparison can be made of the relative " radiating powers " of the mixtures of carbon dioxide and steam in the products of combustion of the different hydrocarbons. Such a comparison is made in Table VII. The figures in columns 2 and 3 give the relative numbers of molecules of carbon dioxide and steam calculated to be present in the products of combustion of each maximum-pressure mixture at the moment of maximum pressure. These values were obtained from Tables I—V by multiplying the respective volume percentages by the corresponding molecular ratio.

The radiating power thus decreases from the methane to the pentane mixture, which is in accord with the decrease in " lost

TABLE VII.

Relative Radiating Powers of Products of Combustion of Maximum-Pressure Mixtures.

pressure" (Table VI). It must be borne in mind, however, that the calculated maximum explosion-temperature rises from the methane to the pentane mixture, which would offset the decreasing H_2O/CO_2 ratio because of the difference in the mean wave-lengths of the radiations. It is, on the whole, improbable that differences in radiation loss account entirely for the differences in "lost pressure."

A more probable explanation lies in errors in the values for specific heats (Bjerrum, *Z. Elektrochem.*, 1911, **17**, 731; 1912, **18**, 101) on which our calculations, as also Tizard and Pye's, were based. Recent work by Womersley (*Proc. Roy. Soc.*, 1921, *A*, **100**, 483) suggests that Bjerrum's values for steam at high temperatures were much too low. Womersley's results extend only to 2000°, and for calculations of explosion-temperatures higher than this figure extrapolated values must be used. A few calculations are recorded in Table VIII, and if they are compared with those given in Table I, it will be seen that the composition of the mixture for which the calculated pressure is greatest (10% methane) is unchanged, but that the value for the pressure, 7·59 as compared with 8·17 atm., is considerably lower when Womersley's figures are used. The calculated pressure is, in fact, very near that found

TABLE VIII.

Calculated Maximum Temperatures and Pressures on Explosion of Methane–Air Mixtures.

(Based on Womersley's values for the specific heat of steam.)

CH_4 in original mixture,	Products of combustion * at moment of maximum temperature, %.						"Molecular ratio."	Maximum temp.	Press. rise, atm.

* CH_4 = nil.

experimentally (7·38 atm.). No doubt the true value for the mean specific heat of steam over the range 100—2000° lies between

Bjerrum's (8·42 cals. per g.-mol.) and Womersley's (11·69). If so, calculations of maximum explosion-temperatures based on Bjerrum's figures would be too high, and the amount of the error would increase with the amount of steam in the products of combustion. Values for the amounts of steam in the products of combustion of unit volume of the maximum-pressure mixture for each hydrocarbon at the moment of maximum pressure are given in Table VII, from which it appears that over-estimation of loss of pressure would be greatest with methane and least with pentane (see Table VI).

There may also be error in the values (from Nernst, *Z. anorg. Chem.*, 1905, **45**, 130; and Bjerrum, *Z. physikal. Chem.*, 1912, **79**, 513) used in estimating the amount of dissociation of carbon dioxide and steam. In this connexion, it is of value to compare the analyses of samples of the gases rapidly withdrawn from the explosion-vessel at the moment of maximum pressure with methane–air mixtures (J., 1918, **113**, 840) with the calculated compositions of the products of combustion of similar mixtures (Table IX).

* "Calc. = nil."

There is an indication from these results that the extent of the dissociation of carbon dioxide has been over-estimated in the calculations, for the experimental values for the amounts of this gas in the products of combustion at the moment of maximum pressure are consistently high. In part, the discrepancy might be due to recombination during cooling of the samples (which was, however, very rapid), but this is not likely in view of the close agreement of the observed and calculated figures for hydrogen. Further, Fig. 1 shows that the discrepancy between observed and calculated pressures is greatest for mixtures containing an excess of combustible gas, a result which can be attributed to over-estimation of the "molecular ratios" in the calculations. It would thus seem that the decrease in "lost pressure" in passing from methane to pentane

(Table VI) may be more apparent than real. It is probable that the unexpectedly close agreement between calculated and observed engine efficiencies with heptane as fuel, recorded by Tizard and Pye, was also due to errors in the data on which the calculations were based.*

The Rate of Development of Pressure.—With a given hydrocarbon, it is apparent that the main factor controlling the mean rate of pressure development on explosion of its mixtures with air is the mean temperature of explosion. This is clear from Fig. 2, in which the effect of variation in composition of the mixtures on the rate of development of pressure is shown graphically for each hydro-

FIG. 2.

carbon, together with the calculated explosion-temperatures. Table X has been compiled from Fig. 2, and makes comparison between the observed "maximum-speed" mixtures and the calculated "maximum-temperature" mixtures. The "maximum-speed" mixture for each gas is that in which the time from ignition to the attainment of maximum pressure is least.

As a corollary to the observation that, under the conditions of these experiments, the mean rate of pressure development with a given paraffin is determined by the mean explosion-temperature, it follows that the "displacement" of the maximum-speed mixture

* Fenning and Tizard have recently published a paper on the dissociation of carbon dioxide at high temperatures (*Proc. Roy. Soc.*, 1927, *A*, **115**, 318) which confirms our conclusion. (Added July 10th, 1927.)

TABLE X.

Composition of Maximum-speed and Maximum-temperature Mixtures.

	Hydrocarbon in maximum-speed mixture (obs.), %.	Hydrocarbon in maximum-temperature mixture (calc.), %.	Mean temp. (calc.).	Time (obs.) from ignition to maximum-pressure (sec.).

Pentane	2·90	2·8	2380	0·057

is due to the same cause, dissociation, as displaces the calculated maximum-temperature mixture.

In this connexion, it is of interest to compare the results recorded in Table X with Mason's determinations (J., 1923, **123**, 210) regarding the mixture of each of the paraffins with air which gave the maximum speed of uniform movement of flame. Mason's results are summarised in Table XI. There is general agreement between the compositions of the maximum-speed mixtures under the two

TABLE XI.

Uniform Movement in Paraffin–Air Mixtures.

	Maximum-speed Mixtures. (Mason.)	
Paraffin.	Maximum-speed mixture, %.	Speed of uniform movement (5-cm. diam. tube) (cm. per sec.).
Methane	9·65	91
Ethane	6·05	127
Propane	4·45	114
Butane	3·65	113
Pentane	2·90	115

different conditions of experiment, and the order of speed of flame in the series of mixtures is the same. This is in accord with our recent observation (this vol., p. 297) that the generalisation known as " the law of speeds," first formulated with respect to the uniform movement of flame, applies also to the rate of spread of flame within a closed sphere.

EXPERIMENTAL.

The explosion-vessel and its fittings have been described in J., 1918, **113**, 854. Ignition of the mixtures was at the centre of the vessel by a secondary discharge from a " 10-inch " induction-coil at a 1 cm. gap between pointed copper electrodes, the current through the primary circuit being 10 amps. and the trembler of the coil being locked.

The pressure-gauge was calibrated by compressed air at intervals during the series of experiments against a standard Bourdon gauge. The mean of the calibrations, which checked well amongst themselves, showed a deflexion of the manometer stylus of 1 cm. for a pressure increase of 7·85 atm.

The hydrocarbons were obtained as follows: Methane, from a blower of fire-damp in S. Wales; ethane, (*a*) by the action of water on zinc ethyl, or (*b*) from a cylinder of the compressed gas obtained (from America) by the fractionation of natural gas; propane and butane, by the action of the zinc–copper couple on the corresponding alkyl iodide in alcoholic solution; pentane, from a petroleum distillate, b. p. 35—40°. Each gas, after purification by washing with suitable solvents, was twice liquefied, the middle-boiling fraction only being retained. The ratios C/A (C = contraction on explosion analysis; A = subsequent absorption by potassium hydroxide solution) were: Methane, 1·995; ethane, (*a*) 1·253, and (*b*) 1·245; propane, 1·003; butane, 0·878; pentane, 0·804.

Each gas mixture was prepared in a 20-litre glass gas-holder over a dilute solution of potassium hydroxide and was analysed before use. Before an experiment, the explosion-vessel was exhausted of air to within a few mm. of mercury, filled with the mixture required, re-exhausted and filled again.

Calculation of Explosion Temperatures and Pressures.—The explosive mixtures were assumed to be saturated with water vapour at 15° and the analyses (which take no account of water vapour) were adjusted accordingly. The analytical figures were then proportional to the numbers of molecules of each constituent present in unit volume, and to their partial pressures.

In unit volume of the products of explosion, the numbers of molecules of the constituents can be expressed by $a\ CO_2 + b\ CO + c\ H_2O + d\ H_2 + e\ O_2 + f\ N_2$.

The ratio of the total number of molecules per unit volume at the moment of maximum temperature to the total number in unit volume of the original mixture (the "molecular ratio," M) is $(a + b + c + d + e + f)/1$. The partial pressure of, say, carbon dioxide at the moment of maximum temperature is aP_e/M, whilst $P_e = MT_e/T_i$, where P_e is the explosion-pressure in atmospheres, and T_e and T_i are the explosion-temperature and the initial temperature in °K. For example, in a mixture of pentane and air containing in unit volume: C_5H_{12}, 0·0246; O_2, 0·2005; H_2O, 0·0170; N_2, 0·7579, there are only five unknowns, for the number of molecules of nitrogen, f, can be regarded as remaining constant. Five independent relationships are therefore required to determine them. By equating the carbon, oxygen, and hydro-

gen before and after explosion, the following relationships are obtained:

$$a + b = 5 \times 0{\cdot}0246 = 0{\cdot}1230 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad \text{(i)}$$

$$2a + b + c + 2e = 2 \times 0{\cdot}2005 + 0{\cdot}0170 = 0{\cdot}418 \quad . \quad \text{(ii)}$$

$$c + d \qquad = 6 \times 0{\cdot}0246 + 0{\cdot}0170 = 0{\cdot}1646 \; . \quad \text{(iii)}$$

The equilibrium constants, K_1 and K_2, can be obtained from Nernst's data, thus:

$$K_1 = \frac{P^2_{CO} \times P_{O_2}}{P^2_{CO_2}} = \frac{b^2 e}{a^2} \cdot \frac{T_e}{T_i}; \text{ whence } \frac{b^2}{a^2} e = K_1 \frac{T_i}{T_e} \quad . \quad . \quad \text{(iv)}$$

$$\text{and } K_2 = \frac{P_{CO} \times P_{H_2O}}{P_{CO_2} \times P_{H_2}} = \frac{bc}{ad}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad \text{(v)}$$

Expressions (iv) and (v) involve the explosion-temperature, T_e. A value for this is assumed and the equations are then solved. The simplest method of solution is to attribute different values to one of the unknowns, say e, until the relationship $bc/ad = K_2$ is satisfied.

From the solutions of the equations the rise in temperature can be calculated, since it represents the ratio between the thermal energy released on explosion of unit volume of the mixture and the thermal capacity of the products of explosion of unit volume. In the pentane–air mixture chosen as an example, the thermal energy released is that from 0·0246 g.-mol. of pentane less the calorific value of b g.-mol. of carbon monoxide and d g.-mol. of hydrogen. The thermal capacity of the products = amount of each constituent multiplied by its mean specific heat between 15° and the assumed explosion-temperature.

If the explosion-temperature so calculated does not agree within 5° of the predicted value, a fresh calculation is made with a new value for T_e. In the example given, the value for T_e finally chosen was 2618° K. and the calculated value then was 2623° K. The latter was accordingly taken as representing the maximum explosion-temperature. The molecular ratio was found to be 1·0645, so that the explosion-pressure, P_e, was $(2623/288) \times 1{\cdot}0645 = 9{\cdot}7$ atm. The pressure rise above atmospheric was therefore 8·70 atm.

The experiments described in this paper have been carried out for the Safety in Mines Research Board, to whom our thanks are due for permission to publish the results.

CCLXXV.—*The Reduction of Nitro-compounds by Aromatic Ketols. Part I. Some* p-*Azoxy-compounds.*

By HUGH BRYAN NISBET.

THAT benzoin and its analogues may reduce Fehling's solution has been known for a long time, but the possibility of reducing nitro-groups by means of these agents has not hitherto been investigated. It has now been found that benzoin, anisoin, and furoin, in hot alcoholic solution in the presence of a trace of sodium methoxide or ethoxide, may be successfully used for the reduction of nitro-groups to azoxy-groups :

$$2R{\cdot}NO_2 + 3R{\cdot}CH(OH){\cdot}CO{\cdot}R = R_2N_2O + 3R{\cdot}CO{\cdot}CO{\cdot}R + 3H_2O.$$

The reduction is particularly successful in the case of *p*-nitro-compounds such as the *p*-nitrobenzylideneanilines, *p*-nitrobenzonitrile, the *p*-nitrocinnamic esters, and the *p*-nitrostilbenes, since the azoxy-compounds formed are, in general, sparingly soluble substances and may be readily separated from the 1 : 2-diketone to which the ketol is oxidised in the course of the reaction. The reduction proceeds very quickly, in some cases with ebullition of the solvent, and in a very short time the *p*-azoxy-compounds separate from solution. The 1 : 2-diketone may be recovered in each case from the mother-liquor.

With benzoin as reducing agent, 60—70% yields of *p*-azoxybenzylideneanilines can be obtained from the corresponding *p*-nitrobenzylideneanilines. *p*-Azoxybenzylideneaniline so obtained is identical with that obtained by reducing *p*-nitrobenzylideneaniline with alkali sulphides (*Chem. Zentr.*, 1900, ii, 612) or with alcoholic potash (Alway, *Ber.*, 1902, **35**, 2436), by treating *p*-nitrobenzyl chloride with caustic potash (Alway, *loc. cit.*), or by condensing *p*-azoxybenzaldehyde with aniline (Alway, *Amer. Chem. J.*, 1902, **28**, 43). *p*-Azoxybenzylidene-*p*-toluidine prepared by this method is identical with the compound prepared by reducing *p*-nitrobenzylidene-*p*-toluidine with alkali sulphides (*Chem. Zentr.*, 1900, ii, 612) or by the condensation of *p*-azoxybenzaldehyde with *p*-toluidine (Alway, *Ber.*, 1902, **35**, 2437). *p*-Nitrobenzylidene-*p*-aminoacetophenone is reduced by benzoin to *p*-azoxybenzylidene-*p*-aminoacetophenone.

Japp and Miller (J., 1893, **63**, 474) showed that benzoin and benzonitrile in the presence of concentrated sulphuric acid condense to form triphenyloxazole ; but *p*-nitrobenzonitrile is reduced by benzoin to *p*-azoxybenzonitrile.

By this method of reduction the esters of *p*-azoxycinnamic acid can be prepared directly from the esters of *p*-nitrocinnamic acid.

and the azoxy-acid can be obtained by hydrolysis. The yields of the reduction products are good, usually 70%, and the reaction proceeds very quickly, whereas the reduction of the nitro-acid electrolytically (Marie, *Comp. rend.*, 1905, **140**, 1248) or by sodium arsenite (Vorländer, *Ber.*, 1906, **39**, 806) and the formation of the esters of the azoxy-acid through the silver salt (Vorländer, *loc. cit.*) are all tedious methods.

p-Nitrostilbenes also are easily reduced by this method to *p*-azoxystilbenes, which may be obtained in excellent yield. The table gives the *p*-azoxystilbenes prepared by this method, the approximate yield, usually the average of two experiments, and the molecular weights of those compounds which are sufficiently soluble in 2 : 4-dinitrotoluene to allow of the determination by the cryoscopic method in that solvent (Auwers, *Z. physikal. Chem.*, 1899, **30**, 310).

Azoxy-compounds.	Yield.	*M*, found.	*M*, calc.
p-Azoxystilbene	70%	396	402
p-Azoxy-2-nitrostilbene	70%	487	492
p-Azoxy-2 : 3′-dinitrostilbene	45%	—	—
p-Azoxy-2 : 6-dinitrostilbene	Small	—	—
p-Azoxy-2-nitro-4′-methoxystilbene	70%	512	552
p-Azoxy-2-nitro-3′ : 4′-methylenedioxystilbene	65%	586	580
p-Azoxy-2 : 6-dinitro-4′-methoxystilbene	45%	—	—
p-Azoxy-2-nitro-4′-dimethylaminostilbene	42%	—	—

Anisoin and furoin were substituted for benzoin in the reduction of 2 : 4-dinitrostilbene and gave approximately the same yield of the same azoxy-compound. The mother-liquors yielded anisil and furil, respectively. In all the reductions in which benzoin was used, benzil was recovered from the mother-liquors.

Experimental.

Preparation of Nitrostilbenes.—A modification of Bishop and Brady's method (J., 1922, **121**, 2367) was used. A solution of the polynitrotoluene and the aromatic aldehyde in molecular proportion and 1 c.c. of piperidine in a small quantity of benzene is boiled under reflux until the reaction is complete, the time varying from 1 to 6 hours. The benzene is then allowed to evaporate and the crystalline mass is washed with benzene–light petroleum and recrystallised from glacial acetic acid. 2 : 4-Dinitro-4′-methoxystilbene, 75% yield, m. p. 163° (compare Pfeiffer, *Annalen*, 1916, **411**, 91). 2 : 4 : 3′-Trinitrostilbene, 50% yield, m. p. 182—183° (compare Pfeiffer, *loc. cit.*). 2 : 4 : 4′-*Trinitrostilbene*, from 2 : 4-dinitrotoluene (9 g.) and *p*-nitrobenzaldehyde (7·5 g.). Yield, 12 g. Dark orange needles, m. p. 234—235° (Found : C, 53·9; H, 3·0. $C_{14}H_9O_6N_3$ requires C, 53·3; H, 2·9%). 2 : 4-*Dinitro*-3′ : 4′-*methylenedioxystilbene* from 2 : 4-dinitrotoluene (9 g.) and piperonal

(7·5 g.). Yield, 12 g. Orange-red, squat crystals, m. p. 178—180° (Found: C, 56·9; H, 3·3. $C_{15}H_{10}O_6N_2$ requires C, 57·3; H, 3·2%). 2 : 4 : 6-*Trinitro-4'-methoxystilbene*, from 2 : 4 : 6-trinitrotoluene (11 g.) and anisaldehyde (7 g.). Yield, 9·3 g. Brown needles, m. p. 167—168° (Found: C, 51·8; H, 3·3. $C_{15}H_{11}O_7N_3$ requires C, 52·2; H, 3·2%). 2 : 4-*Dinitro-4'-dimethylaminostilbene*, from 2 : 4-dinitrotoluene (9 g.) and *p*-dimethylaminobenzaldehyde (7 g.). Yield, 11 g. Small, black, lustrous plates, m. p. 181° (Found: N, 12·8. $C_{16}H_{15}O_4N_3$ requires N, 12·8%). The base forms a *chloroplatinate*, yellowish-brown needles, m. p. 211° [Found: Pt, 18·8. $(C_{16}H_{15}O_4N_3)_2,H_2PtCl_6$ requires Pt, 18·9%].

Preparation of Azoxy-compounds. General Method and Remarks.—The nitro-compound is dissolved in the smallest possible quantity of boiling alcohol, sufficient ketol for the reduction of somewhat less than the whole of the nitro-compound is added, and then a few drops of 6% alcoholic sodium methoxide or ethoxide. The solution goes dark, but soon begins to clear and a yellow or an orange precipitate settles out. After cooling a little, this is collected, dried, and recrystallised from xylene. The azoxy-compounds so obtained are, in general, yellow or bronze-yellow, and are very slightly soluble in the common solvents, slightly soluble in boiling xylene, and more soluble in boiling pyridine. If too much reducing agent be added, the reduction products are sometimes red, probably due to the formation of traces of azo-compounds.

The constitutions of the *p*-azoxystilbenes follow from the analytical figures and the molecular-weight determinations, and from their analogy to the other compounds described in this paper. That it is the *p*-nitro-group which is reduced in stilbenes containing more than one nitro-group may be safely assumed, since it has been proved already that other alkaline reducing agents, *e.g.*, ammonium sulphide, attack the *p*-nitro-group first (Thiele and Escales, *Ber.*, 1901, **34**, 2846). The insolubility of the *p*-azoxystilbenes which have been prepared so far by this method has rendered the examination of further reduction products impossible.

p-*Azoxybenzylideneaniline*, $(C_6H_5{\cdot}N{:}CH{\cdot}C_6H_4)_2N_2O$. *p*-Nitrobenzylideneaniline (8 g.) and benzoin (8 g.) gave an almost immediate separation of yellow flakes which, recrystallised from xylene, sintered at 185° and melted and decomposed at 226°. Yield, 5 g. (Found: C, 77·2; H, 5·2; N, 13·8. Calc.: C, 77·2; H, 4·95; N, 13·8%). The compound was completely identified by treating it with 27% nitric acid; *p*-azoxybenzaldehyde, m. p. 190°, and aniline were obtained (compare Alway, *Amer. Chem. J.*, 1902, **28**, 43). The *p*-azoxybenzaldehyde recondensed with aniline to give *p*-azoxybenzylideneaniline which, when mixed with the product

obtained by using benzoin as reducing agent, did not alter its melting point.

p-*Azoxybenzylidene*-p-*toluidine*, $(C_7H_7N{:}CH{\cdot}C_6H_4)_2N_2O$. *p*-Nitrobenzylidene-*p*-toluidine (2·5 g.) and benzoin (2·1 g.) gave an immediate separation of yellow flakes, which were recrystallised from boiling xylene. M.p. 217° (decomp.; sintering at 189—190°). Yield, 1·7 g. (Found: C, 77·9; H, 5·9; N, 12·5. Calc.: C, 77·7; H, 5·55; N, 12·9%).

p-*Azoxybenzylidene*-p-*aminoacetophenone*,

$$(CH_3{\cdot}CO{\cdot}C_6H_4{\cdot}N{:}CH{\cdot}C_6H_4)_2N_2O.$$

p-Nitrobenzylidene-*p*-aminoacetophenone (2·7 g.) and benzoin (2·1 g.) gave an immediate separation of yellow flakes. Recrystallised from xylene, the substance sintered at 187° and melted and decomposed at 217°. Yield, 1·8 g. (Found: C, 73·4; H, 5·15; N, 11·3; *M*, cryoscopic in 2 : 4-dinitrotoluene, 486. $C_{30}H_{24}O_3N_4$ requires C, 73·8; H, 4·9; N, 11·6%; *M*, 488).

p-*Azoxybenzonitrile*.—*p*-Nitrobenzonitrile was prepared by Sandmeyer's method (*Ber.*, 1885, **18**, 1492), but was isolated, not by sublimation, but by extracting the cuprocyanide reaction mixture several times with much boiling water; it was deposited in flakes on cooling and recrystallised from alcohol (yield, 8·2 g. from 13·8 g. of *p*-nitroaniline).

p-Nitrobenzonitrile (6 g.) and benzoin (8·5 g.) were dissolved in 100 c.c. of alcohol, and a few drops of 6% alcoholic sodium ethoxide added. p-*Azoxybenzonitrile* soon began to separate and after cooling it was collected and recrystallised from boiling toluene (yield, 5 g.); m. p. 221° (Found: C, 67·9; H, 3·5; N, 22·5; *M*, cryoscopic in 2 : 4-dinitrotoluene, 247. $C_{14}H_8ON_4$ requires C, 67·7; H, 3·2; N, 22·5%; *M*, 248).

Esters of p-*azoxycinnamic acid*. Ethyl *p*-nitrocinnamate (3 g.) and benzoin (3 g.) gave ethyl *p*-azoxycinnamate (2·1 g.), which crystallised from xylene in yellow, flocculent needles, m. p. 240°, sintering at 140° (Found: C, 67·1; H, 5·5; N, 7·1. Calc.: C, 67·1; H, 5·5; N, 7·2%).

Methyl *p*-nitrocinnamate (2 g.) and benzoin (2 g.) gave 1·4 g. of methyl *p*-azoxycinnamate, which crystallised from xylene in yellow, flocculent needles, m. p. 246°, sintering at 220° (Found: C, 65·8; H, 4·8; N, 7·35. Calc.: C, 65·6; H, 4·9; N, 7·6%).

p-Azoxycinnamic acid was obtained, by hydrolysis of either of the esters, as a yellow, amorphous solid insoluble in the common organic solvents but soluble in alkali; it decomposed at a high temperature (Found: C, 64·2; H, 4·3; N, 7·8. Calc.: C, 63·9; H, 4·1; N, 8·2%).

p-*Azoxystilbene*, $(C_6H_5{\cdot}CH{:}CH{\cdot}C_6H_4)_2N_2O$. 4-Nitrostilbene (1·7 g.)

and benzoin (1·6 g.), treated according to the general method, gave a green solution which in a short time turned yellow and deposited a yellow, flocculent precipitate. This, after recrystallisation from xylene, sintered at 259° and melted and decomposed at 271—272° (Found: C, 83·2; H, 5·6; N, 6·9; *M*, 396. $C_{28}H_{22}ON_2$ requires C, 83·5; H, 5·5; N, 6·9%; *M*, 402).

p-*Azoxy*-2-*nitrostilbene*. Reduction of 2 : 4-dinitrostilbene (Bishop and Brady, J., 1922, **121**, 2367) (2·6 g.) with benzoin (2·1 g.), anisoin (2·6 g.), or furoin (1·9 g.) gave 1·8 g., 1·75 g., or 1·8 g., respectively, of the p-*azoxy*-compound, which crystallised from xylene in orange plates, m. p. 208—210° (Found: C, 68·2; H, 4·2; N, 11·4; *M*, 487. $C_{28}H_{20}O_5N_4$ requires C, 68·3; H, 4·1; N, 11·3%; *M*, 492). Anisil, m. p. 133°, and furil, m. p. 162°, were obtained from their respective mother-liquors.

p-*Azoxy*-2 : 3′-*dinitrostilbene*. 2 : 4 : 3′-Trinitrostilbene (1·6 g.) and benzoin (1·1 g.) gave 0·75 g. of the reduction compound, which crystallised from xylene in yellow flakes, m. p. 212° (Found: C, 58·1; H, 3·4; N, 14·4. $C_{28}H_{18}O_9N_6$ requires C, 57·7; H, 3·1; N, 14·4%).

p-*Azoxy*-2 : 4′-*dinitrostilbene*. Only traces of this reduction compound could be isolated, since it was difficult to find a suitable solvent for the nitrostilbene.

p-*Azoxy*-2 : 6-*dinitrostilbene*. 2 : 4 : 6-Trinitrostilbene (Bishop and Brady, *loc. cit.*) (3·2 g.) and benzoin (2·1 g.) gave on standing over-night a small yield of a solid which, recrystallised from glacial acetic acid, had m. p. 270° (Found: N, 14·6. $C_{28}H_{18}O_9N_6$ requires N, 14·4%).

p-*Azoxy*-2-*nitro*-4′-*methoxystilbene*. 2 : 4-Dinitro-4′-methoxystilbene (3·1 g.) and benzoin (2·1 g.) gave 2·2 g. of the *azoxy*-compound, which is only slightly soluble in boiling xylene and is an orange-red, microcrystalline powder, m. p. 208° (Found: C, 65·8, 64·75, 64·75; H, 4·7, 4·5, 4·6; N, 10·0; *M*, 512. $C_{30}H_{24}O_7N_4$ requires C, 65·2; H, 4·3; N, 10·1%; *M*, 552).

p-*Azoxy*-2-*nitro*-3′ : 4′-*methylenedioxystilbene*. 2 : 4-Dinitro-3′ : 4′-methylenedioxystilbene (2·8 g.) and benzoin (2·1 g.) gave 1·7 g. of the p-*azoxy*-compound which, recrystallised from xylene, formed a red, microcrystalline solid, m. p. 230° (Found: C, 62·1; H, 4·0; N, 9·4; *M*, 586. $C_{30}H_{20}O_9N_4$ requires C, 62·0; H, 3·5; N, 9·6%; *M*, 580).

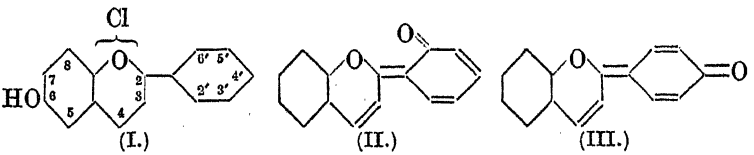
p-*Azoxy*-2 : 6-*dinitro*-4′-*methoxystilbene*. 2 : 4 : 6-Trinitro-4′-methoxystilbene (2·8 g.) and benzoin (2·1 g.) gave 1·25 g. of the p-*azoxy*-compound, which forms bronze plates from xylene. It changes colour at 252° and melts with decomposition at 297° (Found: C, 55·6; H, 3·6; N, 13·2. $C_{30}H_{22}O_{11}N_6$ requires C, 55·9; H, 3·4; N, 13·06%).

p-*Azoxy*-2-*nitro*-4'-*dimethylaminostilbene*. 2:4-Dinitro-4'-dimethylaminostilbene (1·5 g.) and benzoin (1 g.) gave black, flaky crystals of the p-*azoxy*-compound which were washed with hot alcohol. The compound is so slightly soluble in boiling xylene that it cannot be recrystallised from that solvent. The substance without further purification remained unchanged at 305° (Found: N, 14·3. $C_{32}H_{30}O_5N_6$ requires N, 14·5%). The compound is soluble in hot concentrated hydrochloric acid, but the hydrochloride is readily hydrolysed on addition of water. Two attempts to prepare a chloroplatinate failed owing to the almost colloidal nature of the hydrochloric acid solution.

The mother-liquors from each of the above reductions in which benzoin was used yielded benzil, m. p. 95°, on standing or when poured into water and the needles so obtained were recrystallised from alcohol. The compound was identified by its characteristic reaction with alcoholic potash and by its oxidation to benzoic acid, m. p. 122°, by means of alkaline permanganate.

The investigation is being continued with a view to establishing the generality of this method of reducing nitro- to azoxy-groups and determining its value as a method of preparing azoxy-compounds.

In concluding this part of the work, the author desires to thank Professor A. Archibald Boon for his kind interest and for providing the facilities which have rendered this research possible.

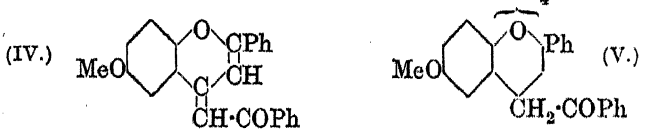


HERIOT-WATT COLLEGE, EDINBURGH. [*Received, June 20th*, 1927.]

CCLXXVI.—*A Synthesis of Pyrylium Salts of Anthocyanidin Type. Part XIII. Some Monohydroxyflavylium Salts.*

By FRANK MOUATT IRVINE and ROBERT ROBINSON.

IT was thought that a study of some of the simpler hydroxyflavylium salts might throw light on the effects produced by hydroxy-groups in different positions in the three nuclei, especially from the point of view of anhydro-base and pseudo-base formation. Solutions of 3-hydroxyflavylium chloride have been obtained by demethylation of the methyl ether (Pratt and Robinson, J., 1923, **123**, 748), but this salt showed such a strong tendency to pass into the pseudo-base that it could not be isolated in a pure condition. It dissolves in sulphuric acid to a solution that exhibits intense plum-coloured fluorescence. 6-Hydroxyflavylium chloride (I) is less readily



hydrolysed, but also yields a colourless pseudo-base, a quinonoid anhydro-base not being possible without the postulation of " bridge-bonds." This is merely one more example among many which

(I.) (II.) (III.)

show that aromatic structures assume a bridge-phase with the greatest reluctance. In the cases of 2′- and 4′-hydroxyflavylium salts, anhydro-bases of the types (II) and (III) are possible. Actually the anhydro-bases derived from 2′-hydroxyflavylium chloride and 2′-hydroxy-8-methoxyflavylium chloride are violet substances that could not be isolated owing to their marked tendency to pass into pseudo-bases by hydration. Thus the quinones are not formed by dehydration of pyranols, but are directly obtained from the kations of the pyrylium salts by removal of a proton under the influence of anions. The colour-base from 4′-hydroxyflavylium chloride is apparently a quinhydrone having the composition $C_{15}H_{10}O_2,C_{15}H_{12}O_3,2H_2O$; by analogy with the suggestions of Schneider and Meyer (*Ber.*, 1921, **54**, 1484) it may be named *4′-hydroxyflavanhydrone*. The molecular weight of the anhydrous compound corresponded with this formula, and similar results were obtained in the study of *4′-hydroxy-8-methoxyflavanhydrone*.

Incidentally *6-methoxy-4-phenacylideneflavene* (IV) has been examined and found to yield a *hydroferrichloride* (V) which is readily hydrolysed by water.

(IV.) (V.)

Moreover, the carbonyl group in (IV) is inactive, so that the resemblance to the pyrones is complete, the system −O−C=C−C=O being extended to −O−C=C−C=C−C=O. Probably the phenacylideneflavenes are dipoles and anhydronium bases in the sense in which that expression was used by Armit and Robinson (J., 1925, **127**, 1607). In view of the remarkable rearrangement of the anhydro-base from 2 : 6-diphenyl-4-*o*-hydroxyphenylpyrylium chloride to phenacylideneflavene (Dilthey and Floret, *Annalen*, 1924, **440**, 95), alternative formulæ for the latter substance would appear to require consideration. However, Dilthey and Floret have excluded

possibilities based on the triphenylpyrylium skeleton on the ground that phenacylideneflavene gives a small quantity of flavone when oxidised by permanganate.

EXPERIMENTAL.

8-Methoxyflavylium Chloride.—Under slightly modified conditions, the direct condensation of *o*-vanillin, acetophenone, and hydrogen chloride in acetic acid solution (Roberts and Robinson, J., 1924, **125**, 209) gave a 70% yield of the flavylium salt, which crystallised from dilute hydrochloric acid in brown needles which blackened at 170° and melted at 190° (decomp.) (Found in material dried in a vacuum: C, 66·2; H, 5·2. $C_{16}H_{13}O_2Cl,H_2O$ requires C, 66·1; H, 5·1%). The *iodide* crystallises from dilute, colourless hydriodic acid in puce-coloured needles, m. p. 134°. All attempts to demethylate these salts were unsuccessful.

Phenyl 2-Hydroxy-5-methoxystyryl Ketone.—2-Hydroxy-5-methoxybenzaldehyde (5·1 g.; 1 mol.) and acetophenone (4 g.; 1 mol.) in ethyl alcohol (30 c.c.) were mixed with a warm solution of potassium hydroxide (13 g.; 7 mols.) in water (13 c.c.) and left in a warm place over-night. The solution was poured into water (400 c.c.), kept for an hour until the waxy precipitate (A) had solidified, and then filtered. The filtrate and washings were acidified with 50% acetic acid and the chalkone was collected and dried (yield, 4·25 g. or 50%). It crystallised from benzene or from 50% alcohol in clusters of fine, golden-yellow needles, m. p. 104° (Found: C, 75·5; H, 5·4. $C_{16}H_{14}O_3$ requires C, 75·6; H, 5·5%).

The residue (A) was thrice recrystallised from alcohol; it formed stellate clumps of short, white needles, m. p. 125° (Found: C, 77·0; H, 6·0. $C_{24}H_{22}O_4$ requires C, 77·0; H, 5·9%). The yield (2·6 g.) of this *2-hydroxy-5-methoxybenzylidenediacetophenone* was 40% of that theoretically possible. A larger percentage was formed when the temperature during the alkaline condensation was higher; but it was not found possible, by varying the molecular proportion of the alkali employed, to obtain a higher yield of the chalkone.

6-Methoxyflavylium Salts.—Phenyl 2-hydroxy-5-methoxystyryl ketone was converted into 6-methoxyflavylium chloride by means of hydrogen chloride in acetic acid solution. The reaction proceeded to completion in the cold, passing through the red ketone-hydrochloride stage. The flavylium salt partly crystallised and was partly precipitated by the addition of ether. It was collected and dried to constant weight in a vacuum (Found: C, 62·3; H, 5·5. $C_{16}H_{13}O_2Cl,2H_2O$ requires C, 62·2; H, 5·5%). The salt crystallised from 5% hydrochloric acid in dark greenish-brown, shining needles, m. p. 97°. Its yellow solution in concentrated sulphuric acid

exhibited a weak green fluorescence, but the orange-yellow alcoholic solution was non-fluorescent. The *ferrichloride* crystallised from acetic acid in glistening, brown platelets with green nuance, m. p. 203° (Found: C, 44·0; H, 3·2; Fe, 12·7. $C_{16}H_{13}O_2Cl_4Fe$ requires C, 44·1; H, 3·0; Fe, 12·9%). The *iodide* crystallised from alcohol in almost black, microscopic needles, m. p. 143°, whilst the *periodide* had m. p. 86—87°. The *perchlorate* crystallised from 60% methyl alcohol in short, dark brown needles, m. p. about 200° (decomp.).

6-*Hydroxyflavylium Salts.*—The demethylation required rather careful control. A mixture of 6-methoxyflavylium chloride dihydrate (8·8 g.), phenol (40 g.), and hydriodic acid (*d* 1·74; 150 c.c.) was heated in a glycerol-bath at 110°, until the effluent stream of carbon dioxide no longer contained methyl iodide (45 minutes). The mixture was diluted with an equal volume of water and of ether, cooled in ice, and filtered; the black crystals (6·4 g.) had a green lustre. After the ethereal layer had been separated, the remainder (about 3·6 g.) of the iodide, mixed with periodide, could be recovered by evaporating the filtrate under reduced pressure in an atmosphere of hydrogen. The demethylated product (7 g.) was dissolved in the minimum volume of hot alcohol (700 c.c.) and concentrated hydrochloric acid (200 c.c.), and freshly precipitated silver chloride (from 7 g. of silver nitrate) added. The mixture was gently boiled during 5 minutes while being stirred; it was then filtered hot, and the residue washed with hot ethyl-alcoholic hydrochloric acid. The filtrate and washings were concentrated to a small volume and cooled, and the 6-*hydroxyflavylium chloride* was collected; it crystallised from alcohol or from 15% hydrochloric acid in orange needles. The chloride was very readily hydrolysed by water, and the pseudo-base was also formed when sodium acetate was added. The *ferrichloride* crystallised from glacial acetic acid in short, reddish-brown needles, m. p. 198° (Found: C, 43·1; H, 2·7; Fe, 13·2. $C_{15}H_{11}O_2Cl_4Fe$ requires C, 42·8; H, 2·6; Fe, 13·3%). The *chloroaurate* formed golden-brown needles which on heating turned grey at 180° but did not melt. 6-Hydroxyflavylium salts give, in concentrated sulphuric acid, orange solutions with a green fluorescence.

4′-*Hydroxyflavylium Salts.*—*p*-Methoxyacetophenone was condensed with salicylaldehyde to form *p*-methoxyphenyl *o*-hydroxystyryl ketone as described by Kostanecki and Zwayer (*Ber.*, 1908, **41**, 1337) and the yield of the pure, recrystallised product was 81%. The chalkone (13·8 g.) was dissolved in a mixture of glacial acetic acid (50 c.c.) and concentrated hydrochloric acid (25 c.c.) by saturating this with hydrogen chloride, and the solution after an hour was gently warmed for 15 minutes and poured into water. An

excess of potassium iodide was added to the filtered solution of the flavylium chloride and an orange precipitate of the anhydrous *4'-methoxyflavylium iodide* was formed (yield, 89%). This salt (17·2 g.) was gently refluxed for ½ hour with hydriodic acid (300 c.c.; *d* 1·74) and phenol (70 g.) in an atmosphere of carbon dioxide. On cooling, crystals (9·4 g.) separated which were pure enough for the next operation; for analysis, they were recrystallised from methyl alcohol, being thus obtained in dark purple prisms (Found: C, 29·8; H, 2·0; I, 62·7. $C_{15}H_{11}O_2I_3$ requires C, 29·8; H, 1·8; I, 63·1%). *4'-Hydroxyflavylium periodide* melts at 208—209° and decomposes suddenly at 285°; when pressed on glass, it has a beetle-green lustre. Freshly precipitated silver chloride (from 2·85 g. of silver nitrate) was added to a solution of the periodide (2 g.) in a hot mixture of methyl alcohol (125 c.c.) and 7·5% hydrochloric acid (100 c.c.), and the whole was boiled for 15 minutes and filtered. The filtrate and washings were concentrated and, on cooling, red needles separated (yield, 80%). This product was crystallised several times from dilute hydrochloric acid in order to remove traces of inorganic impurities which were tenaciously held. The clusters of fine, orange-red needles, after drying over sulphuric acid and potassium hydroxide, darkened at 135° and melted at 142° (decomp.) (Found: C, 61·2, 61·0; H, 5·1, 5·3. $C_{15}H_{11}O_2Cl,2H_2O$ requires C, 61·1; H, 5·1%). This salt dissolves in water or alcohol to an orange solution which becomes yellow on the addition of a drop of dilute hydrochloric acid or red with weakly alkaline reagents. The orange solution in concentrated sulphuric acid exhibits a green fluorescence. The *chloroaurate* crystallises in golden-orange needles, m. p. 177°.

4'-Hydroxyflavanhydrone.—A solution of 4'-hydroxyflavylium chloride in water was covered with benzene, and excess of sodium acetate added; on shaking, a portion of the violet-red substance was dissolved by the benzene, which was separated, dried with potassium carbonate, and filtered. The dark violet solid which remained on removal of the solvent could not be crystallised (Found: C, 72·0; H, 5·7; loss on heating at 110°/15 mm., 7·4. $C_{30}H_{22}O_5,2H_2O$ requires C, 72·3; H, 5·2; H_2O, 7·2%. Found in dried material: C, 77·6; H, 4·9; *M*, by micro-Rast, 472. $C_{30}H_{22}O_5$ requires C, 77·9; H, 4·8%; *M*, 462). On further heating, the deep red substance gradually sintered and was completely molten at 200°. The red solution in pyridine became colourless in a few seconds, probably as the result of the formation of the benzopyran ether (compare Dilthey, *J. pr. Chem.*, 1917, **95**, 113, 117). This flavanhydrone showed no tendency to combine with methyl iodide.

4'-Hydroxy-8-methoxyflavylium Salts.—The method of Nencki and

Stoeber (*Ber.*, 1897, **30**, 1769) for the preparation of *p*-hydroxyacetophenone only gives a 10% yield and the product is difficult to purify. The following modification is much more satisfactory: Powdered anhydrous ferric chloride (81 g.) was added to a solution of phenol (63 g.) in carbon disulphide (48 c.c.), and acetyl chloride (95 c.c.) was then introduced drop by drop with shaking. When the addition was complete, the mixture was shaken during 5 minutes and the carbon disulphide and acetyl chloride were then carefully removed by distillation. The residue was decomposed by water and rendered alkaline with sodium hydroxide, the solution decanted from the ferric hydroxide, which was washed by decantation, and the crude *p*-hydroxyacetophenone precipitated by acidification. After crystallisation from water, 30 g. (yield, 33%), m. p. 110°, were obtained. p-*Acetoxyacetophenone*, m. p. 54°, crystallises from alcohol and was obtained in 80% yield on agitating an aqueous solution of sodium *p*-acetylphenoxide (1 mol.) with acetic anhydride (1 mol.).

A stream of hydrogen chloride was passed through a solution of *o*-vanillin (1·1 g.) and *p*-hydroxyacetophenone (1 g.) in formic acid (10 c.c.) for 1 hour, and the mixture kept until next day. The orange solid precipitated on the addition of ether crystallised from 10% hydrochloric acid (60 c.c.) in brick-red needles (1·6 g.) (Found in material dried in a vacuum: C, 62·3; H, 4·8. $C_{16}H_{13}O_5Cl,H_2O$ requires C, 62·6; H, 4·9%). This salt darkens at 170° and melts at 190° (decomp.); it dissolves in water to a yellow solution exhibiting a weak green fluorescence. The *ferrichloride* crystallised from acetic acid in reddish-brown needles, m. p. 217°, and the *periodide* crystallised in chocolate-coloured needles, m. p. 170—173° (decomp.), after darkening at 140°. The ruby benzene solution of the anhydro-base, prepared in the usual manner, was dried with potassium carbonate and, on removal of the solvent from the filtered solution, a deep purplish-red solid residue was obtained, which was dried in a vacuum (Found: C, 73·7; H, 5·4. $C_{32}H_{26}O_7$ requires C, 73·6; H, 5·0%). The molecular weight could not be determined by Rast's method and no solvent was found to be suitable for recrystallisation; in several solvents, for example, acetone and nitrobenzene, it gave bottle-green solutions. On heating, this 4′-*hydroxy*-8-*methoxyflavanhydrone* gradually sintered and decomposed at 206°.

2′-*Hydroxyflavylium Ferrichloride*.—The condensation of salicylaldehyde with *o*-hydroxyacetophenone (Fries and Pfaffendorf, *Ber.*, 1910, **43**, 215), under conditions similar to those mentioned below, gave a bright scarlet, very sparingly soluble solid, which is not a flavylium salt and is apparently of complex constitution.

The hydroxyl group in the ketonic component was therefore protected by acetylation (compare Friedländer and Neudorfer, *Ber.*, 1897, **30**, 1080; Lesser and Gad, *Ber.*, 1926, **59**, 233). A solution of *o*-acetoxyacetophenone (0·9 g.) and salicylaldehyde (0·6 g.) in formic acid (6 c.c.) was saturated with hydrogen chloride during 3 hours, and next day the red solid, which was precipitated on the addition of ether, was collected and extracted with 17% hydrochloric acid (60 c.c.), leaving a considerable residue. A *ferrichloride* prepared from the filtered solution crystallised from acetic acid in tufts of brown needles, m. p. 125° (Found: C, 42·6; H, 2·7; Fe, 13·3. $C_{15}H_{11}O_2Cl_4Fe$ requires C, 42·8; H, 2·6; Fe, 13·3%). The orange solution in sulphuric acid exhibits a weak green fluorescence. The solution of the ferrichloride in dilute hydrochloric acid gave, with a large excess of sodium carbonate solution, quickly added, a transient purple colour. The colourless filtrate from the ferric hydroxide apparently contained pseudo-base in solution, for on acidification it turned bright yellow, and then, on addition of a large excess of sodium carbonate, the purple colour flashed out, but the solution became almost instantaneously colourless. The purple colour was formed only if the sodium carbonate was added quickly and in large excess.

2′-*Hydroxy*-8-*methoxyflavylium Salts*.—Several attempts to prepare 2′-hydroxy-8-methoxyflavylium chloride by condensing *o*-vanillin (1 mol.) and *o*-acetoxyacetophenone (1 mol.) in anhydrous formic acid with hydrogen chloride failed during the recrystallisation from hot dilute hydrochloric acid (in order to remove the acetyl group in the 2′-position), probably because some complex substance, not a pyrylium salt, was formed in this case also. The use of unacetylated *o*-hydroxyacetophenone led to better results in this instance. A solution of *o*-hydroxyacetophenone (1·4 g.) and *o*-vanillin (1·5 g.) in formic acid (6 c.c.) was saturated with hydrogen chloride for 1·5 hours and on the following day ether precipitated a reddish-brown solid, which crystallised from methyl alcohol in long, red needles; these darkened above 100° and had m. p. 188° (decomp.) (Found: C, 66·3; H, 4·7. $C_{16}H_{13}O_5Cl$ requires C, 66·5; H, 4·5%). This salt dissolved in sulphuric acid to an orange solution exhibiting a weak green fluorescence. When water was added to the solid chloride or to its solution in alcohol, the pseudo-base was obtained; this dissolved with difficulty in dilute hydrochloric acid. Sodium acetate, added in excess to an acid solution of this salt, produced the violet colour-base, which could be extracted by benzene; the colour of the violet solution, however, soon faded. Again, when the colour-base was quickly separated, the filtrate was always found to contain pseudo-base. This remarkable ease of

hydration of the anhydro-base derived from a flavenol has not previously been observed in the absence of a substituent in position 3.

6-*Methoxyphenacylideneflavene* (V).—Following the details given by Feuerstein and Kostanecki (*Ber.*, 1898, **31**, 710) in the case of the parent substance, 2-hydroxy-5-methoxybenzylidenediacetophenone (7·5 g.) was converted into acetophenone (1·1 g.), *phenyl* β-2-*hydroxy*-5-*methoxyphenylethyl ketone* (2·3 g.), and 6-*methoxyphenacylideneflavene* (3·8 g.). The last compound crystallised from alcohol or benzene in yellow, feathery clusters of fine needles, m. p. 146° (Found: C, 80·7, 80·8; H, 5·0, 5·0; MeO, 8·8. $C_{24}H_{18}O_3$ requires C, 81·4; H, 5·1; MeO, 8·8%). In the micro-Zeisel determination, the mixture required to be heated almost twice as long as usual. The solution in cold sulphuric acid was yellowish-orange and non-fluorescent, and on warming a transitory purple colour appeared, succeeded by a ruby one.

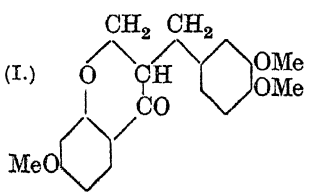
Pure 6-methoxyphenacylideneflavene (1·8 g.) was suspended in acetic acid (10 c.c.), and a stream of dry hydrogen chloride passed during 3 minutes; on shaking, all the solid dissolved to a red solution. The addition of a solution of anhydrous ferric chloride (0·8 g.) in glacial acetic acid (5 c.c.) produced an immediate red precipitate, which soon became brownish-orange and crystalline. After keeping for an hour, the flask being stoppered, the solid was collected and dried over sulphuric acid and potassium hydroxide (yield, 2·54 g. or 92%) (Found: C, 52·0; H, 3·5; Fe, 10·0; MeO, 5·8. $C_{24}H_{19}O_3Cl_4Fe$ requires C, 52·1; H, 3·4; Fe, 10·1; MeO, 5·6%).

6-*Methoxy*-4-*phenacylflavylium ferrichloride* forms microscopic, elongated prisms which melt, with blackening, at 170° (on slow heating). It is sparingly soluble in water to an orange solution which slowly deposits 6-methoxyphenacylideneflavene; this hydrolysis is, however, very rapid in presence of alcohol. The ferrichloride gives an orange, non-fluorescent solution in sulphuric acid.

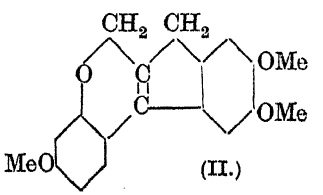
6-Methoxyphenacylideneflavene (1 mol.) did not react when refluxed in benzene solution for ½ hour with magnesium phenyl bromide (1 mol. prepared in ether).

The *phenyl* β-2-*hydroxy*-5-*methoxyphenylethyl ketone* was a brown syrup with a strong green reflex. Although its hydroxyl group could not be acetylated or benzoylated, its carbonyl group was reactive, and the *semicarbazone* and p-*nitrophenylhydrazone* were readily prepared. The former crystallised from alcohol in white, elongated prisms, m. p. 184° (Found: C, 65·1; H, 6·5; N, 13·5. $C_{17}H_{19}O_3N_3$ requires C, 65·2; H, 6·1; N, 13·4%), and the latter separated from alcohol in microscopic, orange needles, m. p. 163—

165°. The ketone itself could not be crystallised. The same hydrochalkone was obtained, also as a syrup, and identified as the semicarbazone, m. p. 184° (alone or mixed), by the catalytic reduction of phenyl 2-hydroxy-5-methoxystyryl ketone with a palladium catalyst.



THE UNIVERSITY, MANCHESTER. [*Received, June 28th*, 1927.]

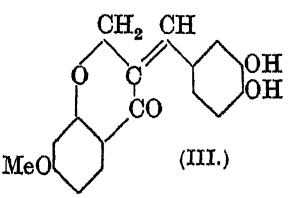


CCLXXVII.—*Experiments on the Synthesis of Brazilin and Hæmatoxylin and their Derivatives. Part II. A Synthesis of Deoxytrimethylbrazilone and of* iso*Brazilein Ferrichloride Trimethyl Ether.*

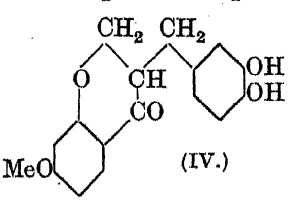
By WILLIAM HENRY PERKIN, jun., JNANENDRA NATH RÂY, and ROBERT ROBINSON.

IN Part I of this investigation (J., 1926, 941) it was explained that our object in attempting the preparation of 3-homoveratryl-7-methoxychromanone (I) was to examine its behaviour towards dehydrating agents, which should convert it into the indene derivative (II), a near relative of *O*-trimethylbrazilin.

(I.)



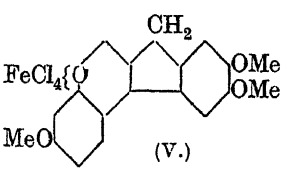
(II.)



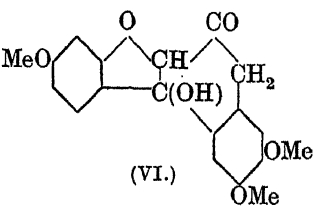
Considerable progress in this direction has since been made and we had hoped to be able to defer publication until our experiments on the final stages of the synthesis of trimethylbrazilin were completed; an interim report has, however, become necessary as the result of a communication received on June 7th from Professor P. Pfeiffer and we therefore submit at once an account of the stage already reached in our work. Professor Pfeiffer's letter mentions results similar in many respects to those which we have obtained and in view of this duplication of research we wish to direct attention to the clear statement of our position which we thought it wise to make at the time of publication of Part I of this series (*loc. cit.*, p. 942) and which it is unnecessary to repeat. The reduction of veratrylidene-7-methoxychromanone by means of hydrogen in presence of palladium yielded (*loc. cit.*, p. 946) 3-homoveratryl-7-methoxychroman, m. p. 96°, instead of the expected ketone (I), which, however, Pfeiffer and Emmer (*Ber.*, 1920, **53**, 945) claimed

to have obtained when they employed platinum as the catalyst. The ketone was stated to melt at 89° and in Part I we expressed some doubt in regard to the accuracy of the interpretation of their results. Since, however, we had not repeated these experiments, our remarks were guarded and summarised in the statement (p. 947): "We do not go so far as to assert that the products of hydrogenation of veratrylidenemethoxychromanone in presence of platinum and of palladium are identical, although we think it probable that this will prove to be the case." The suggestion so expressed was, however, not correct, as the experiments mentioned below indicate, and Professor Pfeiffer informs us that he has re-examined his substance and proved that it is a ketone by the preparation of its oxime. Although we were unable to accomplish satisfactorily the reduction of veratrylidenemethoxychromanone to a related saturated ketone, the formation of the saturated ketone (IV) from 3 : 4-dihydroxybenzylidene-7-methoxychromanone (III) proceeds smoothly under these conditions.

This substance (III) was obtained by the condensation of protocatechualdehyde with 7-methoxychromanone (a new and improved method for the preparation of which is described on p. 2097) in acetic acid solution by means of hydrogen chloride. On methylation in the usual manner, (IV) yields the ketone (I), which has m. p. 92°, and the whole of the substance which we have used in this investigation was prepared in this way. Subsequently the same compound was isolated in poor yield from the products of the partial hydrogenation of veratrylidenemethoxychromanone in presence of palladium.



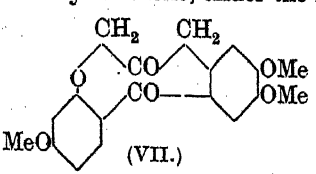
(III.)



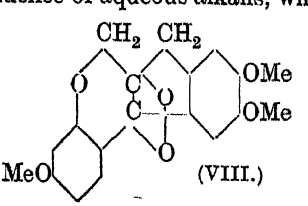
(IV.)

On treatment with phosphoric anhydride in boiling benzene the dehydration of (I) to (II) was effected, and the first indication of its structure and of the fact that it contains the brazilin skeleton was provided by the oxidation of the crude substance to *iso*brazilein ferrichloride trimethyl ether (V) (Engels, Perkin, and Robinson, J., 1908, **93**, 1121; Crabtree and Robinson, J., 1918, **113**, 859), a process effected by means of ferric chloride in acetic acid solution. The salt was identified by comparison with an authentic specimen prepared from brazilein. Later, the compound (II) was obtained from (I) in a pure condition by the dehydrating action of phosphoric anhydride and identified by direct comparison with deoxytrimethyl-

brazilone, $C_{19}H_{18}O_4$, a substance obtained by the reduction of trimethylbrazilone, $C_{19}H_{18}O_6$, with phenylhydrazine (Gilbody and Perkin, J., 1902, **81**, 1046). Deoxytrimethylbrazilone, prepared from brazilin, was also found to yield the *iso*brazilein derivative in the manner described above. Professor Pfeiffer's letter directs attention to the possibility that his dehydration product of the ketone (I) may be deoxytrimethylbrazilone and that the pyrylium salt which it yields on oxidation with ferric chloride may be *iso*-brazilein ferrichloride trimethyl ether. The synthetical proof that deoxytrimethylbrazilone has the constitution (II) and contains the brazilin skeleton necessitates a view of the nature of trimethylbrazilone differing somewhat from that expressed in the formula (VI) (Perkin and Robinson, J., 1908, **93**, 948). It was then suggested that the oxidation of trimethylbrazilin with chromic acid leads to the disruption of the bond common to the chroman and hydrindene nuclei and to the production of a diketone (VII) which passes into (VI) by an intramolecular aldol condensation. In harmony with the conclusions drawn by Professor J. F. Thorpe and his collaborators from extensive researches on ring-chain and intra-annular tautomerism (VI) and (VII) might be regarded as tautomerides.



(V.)



(VI.)

Bearing in mind the phenomena encountered by Willstätter in his study of the *o*-quinones and by Schönberg among the benzils (compare *Annual Reports*, 1922, 109), we might also postulate the peroxidic phase (VIII), the complete tautomeric system being (VI) $\rightleftharpoons$ (VII) $\rightleftharpoons$ (VIII). The phase (VI) must be, at least, an intermediate in the formation of the β-naphthol derivative, α-anhydrotrimethylbrazilone, under the influence of aqueous alkalis, whilst

(VII.)

(VIII.)

VIII) offers an explanation of the remarkable behaviour with phenylhydrazine. Nevertheless, (VI) and (VIII) can only be

related through (VII) and the last seems to be the most satisfactory single expression of the whole character of trimethylbrazilone which it is possible to select. In this phase, some coherence of the carbonyl groups may be manifested as the result of the dipolar character of these groups.

Further evidence bearing on this aspect of the chemistry of brazilin will, it is hoped, be discussed in a future communication and it is proposed to extend the synthetical work indicated above to the analogous hæmatoxylin derivatives. Naturally we are also engaged in attempts to convert deoxytrimethylbrazilone into trimethylbrazilin.

EXPERIMENTAL.

7-Methoxychromanone.—The following method of preparation of this substance is much more convenient than any of those hitherto described. A solution of β-*m*-methoxyphenoxypropionic acid (14 g.) in 80% sulphuric acid (100 c.c.) was heated to 60° during an hour, then at 60—80° for an hour, and finally at 80—90° for a third hour. The ketone was isolated by means of ether in the usual manner from the diluted mixture and freed from acids. The crude product crystallised when dry and weighed 7—8 g. (yield, about 60%). Several new substances which have been prepared in the course of our work may be mentioned here. *Ethyl* β-m-*methoxyphenoxypropionate,* $MeO\cdot C_6H_4\cdot O\cdot CH_2\cdot CH_2\cdot CO_2Et$, obtained by esterification of the acid with boiling ethyl-alcoholic sulphuric acid, crystallises from aqueous alcohol in plates, m. p. 45° (Found: C, 63·8; H, 7·3. $C_{12}H_{16}O_4$ requires C, 64·3; H, 7·1%). This ester could not be condensed with veratraldehyde. *Veratrylidene-7-methoxychromanone dibromide,* prepared in cold carbon tetrachloride solution, has m. p. 137—138° (Found: C, 46·2; H, 3·6. $C_{19}H_{18}O_5Br_2$ requires C, 46·8; H, 3·7%) and yields veratrylidenemethoxychromanone on treatment with zinc dust and acetic acid.

Veratrylidenemethoxychromanone yields an *oxamino-oxime* when treated with hydroxylamine hydrochloride (3 mols.) and sodium acetate in boiling alcoholic solution. The colourless substance crystallises from alcohol in prismatic needles (Found: C, 61·0; H, 5·8; N, 7·0. $C_{19}H_{22}O_6N_2$ requires C, 61·0; H, 5·9; N, 7·5%).

3-(3′ : 4′-Dihydroxybenzylidene)-7-methoxychromanone (III).—An ice-cold solution of 7-methoxychromanone (5 g.) and protocatechualdehyde (5 g.) in acetic acid (30 c.c.) was saturated with hydrogen chloride and set aside. Next day, the garnet crystals which had separated were collected and decomposed by trituration with water at 0°. The substance crystallised from aqueous alcohol (charcoal) in brownish-yellow, microscopic needles, m. p. 212° (Found: C, 68·5; H, 4·8. $C_{17}H_{14}O_5$ requires C, 68·4; H, 4·7%).

The alcoholic solution develops a green coloration on the addition of ferric chloride. Aqueous alkaline solutions are deep crimson to blood-red according to the concentration. Methylation by means of methyl sulphate and sodium hydroxide yields veratrylidene-methoxychromanone, m. p. 141°.

3-(3′ : 4′-*Dihydroxybenzyl*)-7-*methoxychromanone* (IV).—A solution of dihydroxybenzylidenemethoxychromanone (1·5 g.) in alcohol (100 c.c.) to which palladous chloride (15 c.c. of 0·5% aqueous solution) had been added was stirred with hydrogen; 60 c.c. of the gas were absorbed at 15° in 28 minutes. The nearly colourless liquid was filtered and concentrated; the reduction product, then precipitated on dilution with water, crystallised from aqueous alcohol (about 20%) in rectangular plates, m. p. 138° (Found: C, 68·0; H, 5·7. $C_{17}H_{16}O_5$ requires C, 68·0; H, 5·3%). Ferric chloride added to an alcoholic solution of this substance produces a green coloration changing to crimson on keeping. The cherry-red solution in sulphuric acid soon acquires a yellowish-green fluorescence and on addition of water a fluorescent orange solution is obtained. The action of hydrogen chloride on this ketone in glacial acetic acid solution yielded, together with other products, a crystalline *substance*, m. p. 139° (mixed, 118—124°), the investigation of which is not yet complete.

3-*Homoveratryl*-7-*methoxychromanone* (I).—(A) The dihydric phenol described in the last section was methylated in methyl-alcoholic solution by means of methyl sulphate and potassium hydroxide in the usual manner; the product crystallised from aqueous alcohol and then from aqueous acetone in glistening, rectangular plates, m. p. 92° (Found: C, 70·1; H, 6·3. Calc. for $C_{19}H_{20}O_5$: C, 69·6; H, 6·1%). The substance is insoluble in aqueous alkalis and gives no coloration with ferric chloride in alcoholic solution.

(B) When veratrylidenemethoxychromanone was reduced in acetic acid solution by means of the calculated volume of hydrogen in presence of palladium the greater part of the unsaturated ketone was recovered unchanged, whilst an unlimited reduction gave homoveratrylmethoxychroman, m. p. 96°, as previously described (*loc. cit.*). Under the following conditions, however, the dihydro-derivative could be isolated, although in poor yield. A solution of veratrylidenemethoxychromanone (1·4 g.) in pure acetic acid (100 c.c.) to which palladous chloride (20 c.c. of 0·5% solution) had been added was agitated with hydrogen at 18°; 50 c.c. were absorbed in 12 minutes, and a further 50 c.c. in 50 minutes, after which absorption of a third equal volume occurred at 40—45°. The filtered solution was concentrated under diminished pressure

to 35 c.c., and water (10 c.c.) added, causing the precipitation of unchanged material, which was crystallised from alcohol (0·7 g., m. p. 141°). The acetic acid and alcoholic filtrates were diluted with water and the precipitated material was fractionally crystallised from aqueous alcohol and aqueous acetone. About 0·1 g. of a substance crystallising in glistening, rectangular plates, m. p. 92°, was isolated. The m. p. of a mixture with the ketone prepared as described under (A) was 92°, whilst a mixture with homoveratrylmethoxychroman, m. p. 96°, melted at 71—86°. A minute amount of the chroman derivative, m. p. 96°, was isolated from the mother-liquors.

Deoxytrimethylbrazilone (II).—There are indications that 3-homoveratrylmethoxychromanone may be dehydrated by means of a variety of condensing agents, *e.g.*, zinc chloride, stannic chloride, phosphoryl chloride, etc., in that the products are partly oxidised in acid solution to *iso*brazilein salts, the fluorescence of which is so characteristic. Phosphoric anhydride (30 g.) was added to a solution of the ketone (3·5 g.) in benzene (150 c.c.), and the solution gently boiled for 10 minutes. The dark mass was decomposed by the addition of ice, the mixture was heated and agitated, the benzene layer, separated from the strongly fluorescent aqueous solution, was washed with water and aqueous sodium hydroxide, dried with potassium carbonate (charcoal), and filtered, and the solvent was removed in a vacuum. The residue (R) was dissolved in alcohol, and the solution concentrated; the substance which separated on keeping crystallised from alcohol as a satiny mass of colourless sheaves of needles, m. p. 166—171°. This substance was found by direct comparison to be identical with deoxytrimethylbrazilone prepared by the method of Gilbody and Perkin (*loc. cit.*). This and also a mixture of the two specimens had m. p. 166—171°. The colour reactions and solubilities described by Gilbody and Perkin were identical in the cases of the synthetical specimen and that derived from brazilin. Some more details regarding the characteristic reactions of this substance may be given. The solution in an excess of nitric acid is intense eosin-red rather than purple (Gilbody and Perkin) and on dilution with water gives a clear red solution exhibiting very bright yellowish-green fluorescence. The more blue-toned red solution results, however, if the volume of nitric acid employed is greatly diminished, and dilution with water then gives the purple precipitate mentioned by Gilbody and Perkin. A benzene solution was treated with dilute nitric acid (1 vol., *d* 1·42, and 2 vols. of water); a crimson colour then appeared in both layers accompanied by intense yellowish-green fluorescence. On shaking, an orange substance separated from the benzene layer, the colour of which

faded. An acetic acid solution treated with a trace of bromine becomes intense crimson and the usual fluorescence is almost absent; on boiling, the colour changes to orange and dark green fluorescence appears. This becomes brilliant on dilution with alcohol and is of the *iso*brazilein type. Iodine, in most solvents, gives a similar reaction. Bromine, in an acetone solution containing hydrobromic acid, however, immediately oxidises the chromene to the pyrylium bromide, which separates in orange needles. The substance was recognised by conversion into the ferrichloride, identical with the product obtained by the method given below.

iso*Brazilein Ferrichloride Trimethyl Ether* (V).—A characteristic property of deoxytrimethylbrazilone is the ease with which it is oxidised in acid solution with formation of the *iso*brazilein salts and a convenient method is provided by the use of ferric chloride in acetic acid solution. The deoxytrimethylbrazilone was dissolved in warm acetic acid, the solution cooled, and anhydrous ferric chloride introduced; the ferrichloride soon separated as a crimson mass of needles that appeared orange by transmitted light. In some cases, and especially if cooling was used, a deep crimson ferrichloride separated in slender needles and the solution remained red. This was an intermediate product and, on gently warming, the solution became orange and the brownish-orange *iso*brazilein ferrichloride trimethyl ether separated at once. In this form the substance was practically pure and after one crystallisation from acetic acid was identified by careful comparison with a specimen obtained from pure tetramethyldihydrobrazileinol (Engels, Perkin, and Robinson, *loc. cit.*). At a much earlier stage of the investigation, the residue (R) mentioned in the last section was submitted to similar treatment; the ferrichloride so obtained crystallised from glacial acetic acid in slender, orange needles and was directly compared with an exceptionally pure specimen of *iso*brazilein ferrichloride trimethyl ether, with the result that no differences could be detected. The comparison was made in almost the same manner as that instituted by Crabtree and Robinson (*loc. cit.*) with a similar purpose in view and in all cases the properties of the specimens were examined side by side. It is not considered necessary to reproduce the account of these properties, since important variations from the description were not observed.

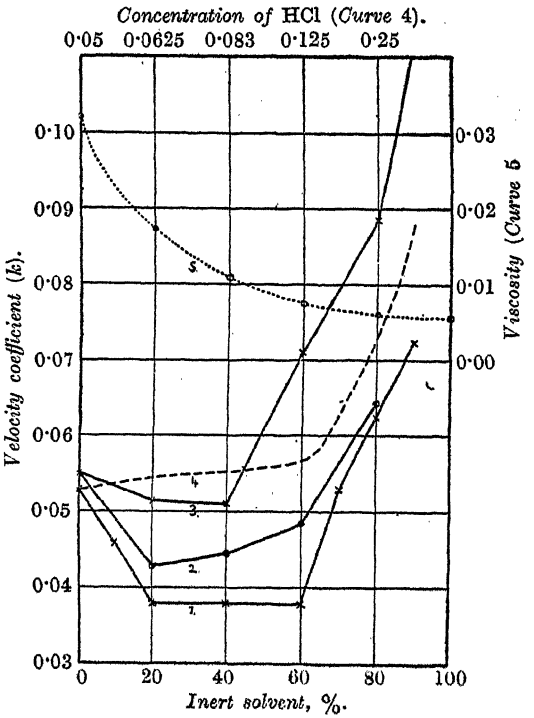
CCLXXVIII.—*Esterification in Mixed Solvents.*

By BALWANT WASUDEO BHIDE and HERBERT EDMESTON WATSON.

PREVIOUS experiments (Bhide and Sudborough, *J. Indian Inst. Sci.*, 1925, **8A**, 89) have shown that the equation $(r - a) \log a/(a - x) - x = kt$ suggested by Goldschmidt and Udby (*Z. physikal. Chem.*, 1907, **60**, 728) gives satisfactory values for the velocity coefficient k in numerous cases of esterification of organic acids with ethyl alcohol, and thus allows for the effect of the water formed during the reaction. The question as to the actual catalytic agent is, however, still obscure. Of the theories which have been put forward (compare Lapworth, J., 1911, **99**, 1427; Rice *et al.*, *J. Amer. Chem. Soc.*, 1923, **45**, 2808; 1924, **46**, 2405; 1925, **47**, 379), that of Goldschmidt (*Z. physikal. Chem.*, 1913, **81**, 30; 1920, **94**, 233), according to which both the hydrogen ions and the undissociated molecules are assumed to act as catalysts, has given satisfactory results in explaining the enolisation of acetone, the decomposition of diazoacetates, and the esterification of certain acids with methyl and ethyl alcohols, for a range in concentration of the catalyst from 0·05 to 0·2*N*. As the degree of dissociation between these limits only changes by approximately 10%, the relative effects of the ions and molecules cannot be determined with great accuracy.

In order to study the question through a greater range of ionic concentration, it was decided to examine the effects obtained in the presence of non-dissociating solvents. Kailan (*Z. physikal. Chem.*, 1914, **88**, 63) has shown that the velocity coefficient for the esterification of benzoic acid by ethyl alcohol is largely increased when benzene is added, but he has not worked with solutions containing more than 75% of benzene.

In the present experiments, mixtures of *iso*amyl alcohol with benzene or ligroin have been used. As acids, suberic and *n*-butyric were selected on account of their convenient rates of esterification. The former is moderately easily soluble in *iso*amyl alcohol (5·15 g. per 100 g. of solvent), but almost insoluble in benzene and ligroin. The latter is miscible in all proportions with all three solvents.



EXPERIMENTAL.

The *iso*amyl alcohol was very carefully purified and dried, the final drying agent being anhydrous copper sulphate, as metallic calcium was found to give rise to traces of ammonia which increased the conductivity. At 30°, it had d 0·8026 and specific conductivity 2×10^{-7} mho. The suberic acid had m. p. 140°; *n*-butyric

acid, b. p. 156—157°/685 mm.; and benzene, $d_4^{30°}$ 0·8658. The ligroin dried over sodium had b. p. 80—90°/685 mm., and did not decolorise bromine. Throughout the preparation and subsequent use of these materials, the utmost care was taken to exclude moisture.

The composition of mixtures is given as % by vol., and density determinations showed that the change of volume on mixing was negligible.

FIG. 1.

Curve 1. *Suberic acid–benzene.* 2. n-*Butyric acid–benzene.* 3. n-*Butyric acid–ligroin.* 4. *Suberic acid–*iso*amyl alcohol with varying* HCl. 5. *Viscosity:* iso*amyl alcohol–benzene.*

Several determinations of the viscosity and conductivity of the solutions were made in order to ascertain whether these properties could be correlated with the velocity coefficients.

Viscosity measurements were made with an Ostwald viscometer at 30° ± 0·05° and the results are in Table I and Fig. 1 (Curve 5).

When hydrogen chloride is dissolved in *iso*amyl alcohol, the viscosity increases regularly with the concentration, rising from 0·0321 for the pure alcohol to 0·0354 for a 0·142*N*-solution.

TABLE I.

Viscosity of mixtures of *iso*amyl alcohol and benzene.

Benzene, %.	Time of flow (secs.).	$d_4^{20°}$.	η.	Benzene, %.	Time of flow (secs.).	d_4^{30}.	η.
0	419·0	0·8026	0·0321	60	95·0	0·8397	0·00760
20	222·4	0·8147	0·0173	80	76·4	0·8525	0·00621
40	137·4	0·8266	0·0108	100	68·0	0·8658	0·00562

Conductivity measurements of solutions of hydrogen chloride in the anhydrous solvents were made, but were rendered difficult by the large decrease in conductivity caused by traces of water. Table II shows the effect of water upon the equivalent conductivity (Λ) of a 0·1*N*-solution of hydrogen chloride in *iso*amyl alcohol;

TABLE II.

Conductivity of 0·1*N*-*iso*amyl alcohol solutions of HCl containing water.

H_2O (mols./litre)	0·0	0·078	0·163	0·203	0·248	0·31	0·62	1·05
Λ	2·18	1·62	1·494	1·491	1·490	1·64	1·99	2·33

it will be observed that the conductivity drops rapidly to a minimum and then steadily rises. Analogous results have been obtained by Goldschmidt (*Z. physikal. Chem.*, 1915, **89**, 129) in the case of ethyl alcohol. Consistent results could only be obtained by making a fresh solution in the conductivity cell itself for each determination.

Table III gives the results obtained for *iso*amyl alcohol alone and for 20 and 40% benzene solutions.

TABLE III.

Conductivity of HCl in *iso*amyl alcohol.

HCl (*N*)	0·00565	0·0166	0·0216	0·0303	0·055	0·071	0·086	0·110	0·164
Λ	2·42	2·33	2·28	2·21	2·18	2·16	2·15	2·20	2·27

Conductivity of HCl in *iso*amyl alcohol containing 20% of benzene.

HCl (*N*)	0·0133	0·0250	0·0385	0·0425	0·0675	0·0773
Λ	1·040	0·917	0·883	0·886	0·923	0·958

Conductivity of HCl in *iso*amyl alcohol containing 40% of benzene.

HCl (*N*)	0·0171	0·0196	0·0308	0·0443	0·074	0·103	0·132
100Λ	1·43	1·36	1·27	1·33	1·53	1·83	2·22

In all these solutions Λ has a minimum value. Godlewski (*J. Chim. physique*, 1905, **3**, 432) has observed a similar minimum for the case of acetic acid in amyl alcohol.

The conductivities of solutions with a higher proportion of benzene were very low, *e.g.*, 0·088*N*-hydrogen chloride in 60% benzene solution had an equivalent conductivity of $7·1 \times 10^{-4}$ mho.

Reaction Velocity.

The rate of esterification was measured in the manner previously described (Bhide and Sudborough, *loc. cit.*) at 30° ± 0·01°. At this temperature the concentration of a 0·05*N*-solution of hydrogen chloride in *iso*amyl alcohol remained unchanged for more than 48 hours. As the reaction with suberic acid was practically complete in 7 hours, no complication was produced by reaction between the alcohol and hydrogen chloride.

According to Goldschmidt the value of r in his formula is constant for any one alcohol. It may be calculated by taking a series of readings during the course of an esterification and solving for k and r from two of the simultaneous equations so obtained. In the present case, r was determined from esterification experiments with both suberic and acetic acids, and the mean value 0·11 was found to yield values of k which were in good agreement with each other in every experiment, so that it is not necessary to give detailed results. The final values for the velocity coefficients are in all cases the mean of at least two concordant determinations.

Preliminary experiments showed that the velocity coefficient was not proportional to the concentration of catalyst but became relatively greater as the concentration increased. In all subsequent experiments the concentration of hydrogen chloride was kept as near to 0·05*N* as possible.

Table IV shows the extent of this variation for the esterification of 0·1*N*-suberic acid by *iso*amyl alcohol. The coefficients given are calculated for 0·05*N* catalyst on the assumption that the velocity coefficient is proportional to the concentration of catalyst.

TABLE IV.

Change in velocity coefficient with catalyst concentration.

HCl (*N*)	0·0045	0·012	0·050	0·100	0·220	0·464
k for 0·05*N*-HCl	0·036	0·045	0·053	0·056	0·071	0·086

Goldschmidt and Udby's formula was found not to give a constant for the highest concentration of acid, the value of k increasing with time. The figure 0·086 in the table is the initial value.

Table V shows the velocity coefficients for 0·1*N*-suberic and *n*-butyric acids in mixtures of *iso*amyl alcohol and benzene with 0·05*N*-hydrogen chloride as catalyst.

As has been pointed out by Kailan (*loc. cit.*), the quantity k, although constant in any one experiment, is not proportional to the true velocity coefficient when the composition of the solvent is altered. The general equation for a second-order reaction may be written $dx/dt = k_1Cc$, where C and c are the concentrations of

TABLE V.

Velocity coefficients of 0·1*N*-suberic and *n*-butyric acids.

	Suberic acid.		*n*-Butyric acid.

the reacting substances. When one of these substances is used as solvent, as in the present case, C may be regarded as constant throughout the reaction, and k_1C may be replaced by k. The latter is the velocity coefficient of Goldschmidt and Udby's equation. The true velocity coefficient $k_1 = k/C$. If C is changed by the addition of a second solvent, this fact must be taken into account when calculating k_1. In Table V, C has been taken as unity for the pure solvent.

Fig. 1 shows diagrammatically the values of k in Table V and also the results for 0·1*N*-*n*-butyric acid in mixtures of *iso*amyl alcohol and ligroin. The curves are similar in shape and appear to exhibit breaks, but this cannot be confirmed without a large number of fresh determinations. The experimental points have been joined merely to show the general trend.

Discussion of Results.

The most striking feature of these results is the large increase in the value of k_1 as the alcohol is diluted with the neutral solvent. The values of k, on the other hand, although decreasing at first and then rising, do not fluctuate to such an extent. This suggests that the method by which k_1 has been calculated from k is inaccurate, or that there is some compensating factor which has not been taken into account, for it seems unlikely that the reactivity should increase more than ten times on the addition of a second solvent.

While the assumption that the reaction velocity is proportional to the concentration of the alcohol is probably correct in the case of an uncatalysed reaction, it does not follow that the same is true in the presence of a catalyst. In the latter case, it is quite possible that the catalyst is mainly associated with the alcohol, a certain proportion of the complexes (whether ionic or molecular) being in the active condition. If a neutral solvent, particularly one in which the catalyst is comparatively insoluble, is now added, the

relation between alcohol and catalyst may be only slightly changed. In other words, the velocity may depend upon the ratio of catalyst molecules to alcohol molecules.

Consider 50 c.c. of a 0·1*N*-solution of suberic acid in 0·1*N*-amyl-alcoholic hydrogen chloride. The velocity coefficient according to Table IV is 0·056 × 2, corresponding with the presence of a certain number of active complexes. If 50 c.c. of benzene, containing the necessary amount of suberic acid to keep the concentration constant, are now added, and it is supposed that the total number of these complexes does not alter, the number in 50 c.c. will be half the original number and the velocity coefficient will be 0·056, and not 0·053 as might be expected from the fact that the catalyst concentration is now 0·05*N*. Similarly for a 10% amyl alcohol solution, the velocity coefficient for 0·05*N* catalyst would be 0·1 times its value for 0·5*N* catalyst, or approximately 0·09. This is qualitatively in agreement with observation, as may be seen in Fig. 1: curve 4 represents the figures in Table IV for the variation of velocity coefficient with acid concentration, plotted in such a way that they show the velocity coefficient calculated as above for each mixed solvent, *i.e.*, corrected so as to show the concentration with reference to the amyl alcohol. The general shape of the later part of this curve has a distinct resemblance to the corresponding portions of the esterification curves.

If this hypothesis be correct, k represents the velocity coefficient, and not k_1.

The present results show that reaction can take place rapidly in the absence of any appreciable number of ions, but they do not afford information as to the relative effect of ions and molecules.

It has so far not been possible to explain either the diminution in k on adding small quantities of benzene, or the minimum in the conductivity curves. Attempts have been made to measure the hydrogen-ion concentration, but so far they have not been successful.

It is evident that much further work is required before more definite conclusions can be drawn, and the experiments are being continued.

Summary.

1. The velocity coefficients of esterification of suberic and *n*-butyric acids in mixtures of *iso*amyl alcohol with benzene and ligroin have been measured in the presence of hydrogen chloride as catalyst.

2. Goldschmidt and Udby's formula has been found to yield satisfactorily constant coefficients.

3. The coefficients increase very considerably on addition of

the neutral solvents, the relation between the value of the coefficient and the composition of the solution being approximately hyperbolic. A possible explanation is that the velocity depends upon the ratio of catalyst to alcohol molecules, and not upon the concentration of catalyst in the whole solution.

4. Conductivity and viscosity measurements have also been made, and it is shown that the ionisation of the catalyst is a negligible factor in determining the velocity. The conductivity of the solutions in which the reaction took place most readily was very low.

BANGALORE.

[*Received, March 24th*, 1927.]

CCLXXIX.—*Acid and Salt Effects in Catalysed Reactions. Part X. The Hydrolysis of Ethyl Acetate with Acetic Acid as Catalyst.*

By HARRY MEDFORTH DAWSON and WILLIAM LOWSON.

IN presence of a strong acid, the rate of hydrolysis of ethyl acetate in dilute aqueous solution is determined by the difference between two reaction velocities which are proportional, respectively, to the concentration of the unhydrolysed ester and to the square of the concentration of the hydrolysed ester.

The integration of the differential equation, which takes account of the two opposed reactions, leads to a formula of very complicated type (compare Harned and Pfanstiel, *J. Amer. Chem. Soc.*, 1922, **44**, 2193), and on this account it is customary to consider the reaction as non-reversible and to replace the total initial concentration of the ester by that corresponding with the ester which has been hydrolysed when the state of equilibrium is reached.

Since the experiments to be described by us are concerned, *inter alia*, with the determination of an accurate value for the catalytic coefficient of the hydrogen ion, it has seemed necessary to inquire to what extent and under what conditions the neglect of the reverse reaction affords a constant which may be taken as a measure of the true hydrolytic coefficient k_r in the equation for the reversible charge. The latter may be written

$$dx/dt = k_r(w - x)(a - x) - k'_r x^2,$$

in which w represents the molar concentration of water and a that of the total ester in the original solution.

Since under the conditions of the experiments to be described x may be neglected in comparison with w, and k'_r may be replaced

by $K_e k_r$, where K_e is the equilibrium constant, the above equation assumes the form

$$dx/dt = k_r\{w(a - x) - K_e x^2\} \quad . \quad . \quad . \quad . \quad (1)$$

The two simplified equations which have been compared with this are

$$dx/dt = k_0 w(a - x) \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

and

$$dx/dt = k_e w(a_e - x) \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

in which k_0 refers to the velocity expressed in terms of the total ester concentration, and k_e is the coefficient obtained by using the concentration of ester, a_e, which has been hydrolysed at the attainment of equilibrium.

In so far as (2) and (3) may be supposed to represent correctly the reaction velocity at different stages, the three values of dx/dt may be equated. From (1) and (2) we thus obtain

$$k_0/k_r = 1 - K_e x^2/w(a - x) \quad . \quad . \quad . \quad . \quad . \quad (4)$$

and from (1) and (3)

$$k_e/k_r = (a - x)\{1 - K_e x^2/w(a - x)\}/(a_e - x) \quad . \quad . \quad (5)$$

On the assumption that k_r is the true velocity coefficient of the hydrolytic reaction, the ratios k_0/k_r and k_e/k_r show to what extent equations (2) and (3) may be used in substitution for equation (1). When the ester concentration is small, *e.g.*, $a = 0{\cdot}05$, the difference between the coefficients is not a matter of importance, but it may be readily shown that the difference is considerable for higher ester concentrations.

The comparison we have instituted has reference to the ester concentration used in our experiments, *viz.*, $a = 0{\cdot}4$; under these conditions $w = 53{\cdot}0$, and if $K_e = 4{\cdot}0$, $a_e = 0{\cdot}3886$, corresponding with 97·15% hydrolysis. The relevant numbers are shown in Table I, from which it is apparent that equation (2) yields a

TABLE I.

Comparison of Velocity Coefficients.

x	0	0·05	0·1	0·15	0·2	0·25	0·3	0·35
k_0/k_r	1·0	0·999	0·997	0·993	0·985	0·969	0·932	0·815
k_e/k_r	1·029	1·033	1·037	1·040	1·044	1·048	1·052	1·055

" constant " which in the early stages of the reaction differs very little from the true coefficient k_r. On the other hand, equation (3) gives a " constant " which is very considerably greater than k_r, and such advantage as may be claimed for this equation is limited to the circumstance that the " constant " associated with it does not change very greatly even in the late stages of the reaction.

The relations disclosed by the above comparison have been of considerable assistance in deciding that equation (2) is to be preferred to (3) as a basis for the development of an integral formula to represent the earlier stages of the hydrolysis of ethyl acetate under the catalytic influence of acetic acid.

Results obtained in the study of the acetone–iodine reaction have shown that catalytic effects are produced by the undissociated acetic acid and the acetate ion as well as by the hydrogen ion, and if these are taken into account in the present case, the form assumed by equation (2) is

$$dx/dt = \{k_h[H^+] + k_a[A^-] + k_m[HA]\}w(a - x)$$

Experiments to be described in a subsequent paper show, however, that the coefficients k_a and k_m are very small, and that the terms $k_a[A^-]$ and $k_m[HA]$ can in general be neglected in comparison with $k_h[H^+]$ when acetic acid is used as catalyst in the absence of the corresponding salt. If b denotes the original concentration of the acetic acid, then $[H^+] = \sqrt{K(b + x - [H^+])} = \text{approx.}\sqrt{K(b+x)}$, and the previous equation becomes

$$dx/dt = k_h w\sqrt{K}(a - x)(b + x)^{\frac{1}{2}} \quad . \quad . \quad . \quad . \quad (6)$$

$$= k(a - x)(b + x)^{\frac{1}{2}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (6a)$$

By substituting $y = (b + x)^{\frac{1}{2}}$, equation (6a) becomes

$$k \,.\, dt = 2dy/(a + b - y^2)$$

which may be integrated by the method of partial fractions. We thus obtain

$$kt = \frac{1}{\sqrt{a+b}}\{\log(\sqrt{a+b} + y) - \log(\sqrt{a+b} - y)\} + \text{constant},$$

and since $y = \sqrt{b}$ when $t = 0$

$$\text{constant} = -\frac{1}{\sqrt{a+b}}\{\log(\sqrt{a+b} + \sqrt{b}) - \log(\sqrt{a} + b - \sqrt{b})\}$$

Replacing y by $(b + x)^{\frac{1}{2}}$ and transposing, we obtain

$$k = \frac{1}{t\sqrt{a+b}}\left\{\log\frac{\sqrt{a+b} + \sqrt{b} + x}{\sqrt{a+b} - \sqrt{b} + x} - \log\frac{\sqrt{a+b} + \sqrt{b}}{\sqrt{a+b} - \sqrt{b}}\right\} \quad (7)$$

This equation will be applied to experiments for which $a = 0{\cdot}4$, and $b = 0{\cdot}1$.

Preliminary observations under these conditions showed clearly that the reaction velocity increases in the early stages and this circumstance suggested a further analysis of equation (6a). By differentiation we obtain

$$dv/dx = \tfrac{1}{2}k(a - x)(b + x)^{-\frac{1}{2}} - k(b + x)^{\frac{1}{2}} \quad . \quad . \quad . \quad (8)$$

according to which the velocity passes through a maximum when $a - x = 2(b + x)$, *i.e.*, when $x = x_m = (a - 2b)/3$. If $a = nb$, x_m becomes $(n - 2)b/3$, and since this must be a positive quantity, it follows that a maximum velocity will only be obtained when the ester–acetic acid ratio is greater than 2. If $n =$ or < 2, the velocity should fall continuously as the reaction proceeds.

In terms of n and b, the initial velocity v_0 is given by

$$v_0 = knb^{\frac{1}{2}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

and the maximum velocity, v_m, by

$$v_m = 2k\{(n + 1)b/3\}^{\frac{1}{2}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

whence for the ratio of maximum to initial velocity we obtain

$$v_m/v_0 = 2/n \, . \, \{(n + 1)/3\}^{\frac{1}{2}} \quad . \quad . \quad . \quad . \quad . \quad (11)$$

according to which this ratio depends only on n or a/b. Table II shows how the relative magnitude of the maximum velocity and the point at which it occurs depend on the value of n. The values of n, x_m, and v_m/v_0 are recorded in the first, second, and fourth horizontal lines; the third line gives the % of ester, 100 x_m/a, which has been hydrolysed when the velocity attains its maximum value.

EXPERIMENTAL.

The velocity measurements were made at 25°. The ethyl acetate was a fractionated research chemical which on saponification was found to contain 99·9% of ester. Preliminary observations showed that greatly increased accuracy could be obtained by the use of weight-volumetric methods and that this mode of procedure was essential in so far as the determination of the average speed at successive stages of the reaction was attempted.

In the recorded experiments, a 25 (or 10) c.c. sample of the ester solution was introduced into a weighed flask containing water and a measured quantity of phenolphthalein, the flask and its contents being re-weighed before and after the addition of the 0·1*N*-sodium hydroxide necessary to produce the tint accepted as an indication of the end-point. Using every precaution, it was found that titration results were reproducible within limits of $\pm$ 0·02 c.c. The influence of the titration error on the value of x varies with the progress of the reaction, but is in all cases such as

to warrant the belief that the accuracy of the analytical procedure was sufficient for the purpose of the inquiry.

Table III gives the detailed record of an experiment the data for which have been examined in reference to equation (7). Col. 1 gives the time in minutes, col. 2 the weight of solution titrated, and col. 3 the weight of standard alkali solution (0·0996*N*-NaOH) required. Col. 4 records the values of $(b + x)$ in mols. per litre, and col. 5 gives the values of k calculated from equation (7).

106,870	9·985	40·760	0·4066	(2·52)

In accordance with the preceding analysis (compare Table I), the value of k would be expected to remain sensibly constant until about half of the original ester has been hydrolysed. As the figures in the last column of Table III indicate, this anticipation is fully realised within the limits of experimental error. The steady fall in the later (bracketed) values of k is quite in accordance with expectation.

If the experimental data for the later stages of the reaction are to be analysed with any degree of precision, it is essential that consideration should be given to the reverse reaction, but this does not necessarily imply the use of the complex integration formula (compare p. 2107). On the contrary, if the measurements of the reaction velocity are sufficiently accurate and the variations in the velocity are relatively small, the experimental results may be tested by comparing the observed average velocity for successive time intervals with the calculated velocity for the middle of each such interval. In so far as the variation of the velocity is concerned, the reaction investigated by us fulfils the stipulated requirement until the latest stages are reached, in that the effect of diminishing ester concentration is counteracted by the effect of

increasing concentration of the acetic acid. If $\bar{v} = \Delta x/\Delta t$ is the average velocity for an interval in which x increases from x_1 to x_2, and $\bar{x} = (x_1 + x_2)/2$ represents the mean value of x, then in accordance with equation (6) we have

$$\bar{v} = k_h w\sqrt{K}(a - \bar{x})(b + \bar{x})^{\frac{1}{2}} - k'_h\bar{x}\sqrt{K}(b + \bar{x})^{\frac{1}{2}}$$

and since $$k_h w\sqrt{K} = k \text{ and } k'_h = K_e k_h$$

this may be written

$$\bar{v} = k\{(a - \bar{x})(b + \bar{x})^{\frac{1}{2}} - K_e/w \,.\, \bar{x}(b + \bar{x})^{\frac{1}{2}}\} \quad . \quad . \quad (12)$$

The application of equation (12) to the experimental data is shown in Table IV. Col. 1 gives the length of the time interval (Δt) between each successive pair of readings in Table III, col. 2 the mean concentration of the ester ($a - \bar{x}$), col. 3 the mean concentration of the acetic acid ($b + \bar{x}$), col. 4 the observed mean velocity, col. 5 the velocity calculated from equation (12) with $k = 2{\cdot}61 \times 10^{-5}$ (see Table III), whilst col. 6 gives the values of k obtained by dividing the observed average velocity by $(a - \bar{x})(b + \bar{x})^{\frac{1}{2}} - K_e/w \,.\, \bar{x}(b + \bar{x})^{\frac{1}{2}}$.

TABLE IV.

Δt (mins.).	$(a - \bar{x})$.	$(b + \bar{x})$.	$\bar{v} \,.\, 10^6$ (obs.).	$\bar{v} \,.\, 10^6$ (calc.).	$k \,.\, 10^5$.

11,920	0·1145	0·3962	1·74	1·73	2·62

In reference to the above table, it may be noted that the observations cover a period of 75 days, at the end of which about 75% of the ester had been hydrolysed. The original intention was to make the successive time intervals approximately equal, but various circumstances intervened to prevent the carrying out of this proposal. The close agreement of the observed and calculated velocities shows that the reaction proceeds throughout in accordance with the requirements of equation (12). This is further shown by the constancy of the k values in the last column.

The estimated probable error in the determination of the interval velocities is about 2% and this corresponds fairly well with the

deviations of the separate k values from the mean. The arithmetic mean of all the recorded numbers is $k = 2{\cdot}60 \times 10^{-5}$, which is almost identical with the mean value of the coefficient derived from the application of the integration formula (7) to the first half of the reaction (see Table III).

In this connexion it may be noted that equation (12) involves the assumption that the hydrogen-ion concentration is given by $[H^+] = \sqrt{K(b + \bar{x})}$. If this were replaced by the more accurate value derived from $[H^+] = \sqrt{K(b + \bar{x} - [H^+])}$, the average value of k would be increased by about 0·4%. The use of the simpler expres-

FIG. 1.

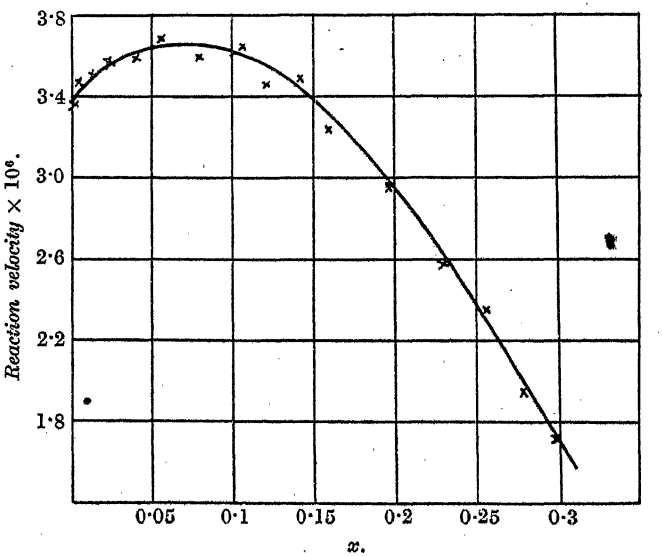

Diagram showing the variation of the reaction velocity with the proportion of ester hydrolysed.

sion is justified by the fact that the difference involved is probably within the limits of error of the mean value of k.

The observations recorded in Table IV do not actually give the initial velocity v_0. To obtain this, measurements were made with solutions for which the initial concentrations of ester and acetic acid were so adjusted that $(a - \bar{x})$ and $(b + \bar{x})$ were equal to the initial values (a and b) in the experiment of Tables III and IV. The velocity derived in this way was $v_0 = 3{\cdot}34 \times 10^{-5}$, which compares with the calculated value, $v_0 = 3{\cdot}37 \times 10^{-5}$.

The course of the reaction may be clearly visualised with the aid of the diagram. The curve on this shows the variation of the

velocity as expressed by equation (12), whilst the points represent the measured average velocities for the successive time intervals. Equations (8) and (11) give $x_m = 0{\cdot}072$ for the point at which the velocity reaches its maximum value and $v_m/v_0 = 1{\cdot}087$ for the ratio of the maximum to the initial velocity. Although direct comparison between theory and experiment is not possible, it is apparent that these numbers are in general agreement with the observed course of the reaction.

Substituting $K = 1{\cdot}85 \times 10^{-5}$ and $w = 53{\cdot}2$ in the expression $k = k_h w\sqrt{K} = 2{\cdot}61 \times 10^{-5}$, we obtain $k_h = 1{\cdot}14 \times 10^{-4}$ as the value of the catalytic coefficient for the hydrogen ion in the hydrolysis of ethyl acetate at 25°.

Summary.

An examination has been made of the extent to which the neglect of the reverse reaction interferes with the derivation of true velocity coefficients in the process of ester hydrolysis. It is shown that the usual procedure does not yield the required coefficients unless the ester concentration is very small.

Accurate measurements of the rate of hydrolysis of ethyl acetate in presence of acetic acid have been made which permit of a direct comparison of the observed and calculated velocities at successive stages of the reaction.

Under the experimental conditions (ester, 0·4 molar; acetic acid, 0·1 molar), the velocity passes through a maximum in accordance with the theoretical predictions.

The value of the catalytic coefficient obtained for the hydrogen ion at 25° is $k_h = 1{\cdot}14 \times 10^{-4}$.

THE UNIVERSITY, LEEDS. [*Received, June 7th*, 1927.]

CCLXXX.—*The Action of Hydrazines on Semicarbazones. Part III.*

By WILLIAM BAIRD and FORSYTH JAMES WILSON.

IN Part II (J., 1926, 2369) it was shown that acetophenone- and benzophenone-δ-anilinosemicarbazones on heating gave the phenylhydrazones and 4-aminourazole,* the reaction probably taking place in two stages:

$$2CRR'{:}N{\cdot}NH{\cdot}CO{\cdot}NH{\cdot}NHPh = CO(NH{\cdot}N{:}CRR')_2 +$$
$$CO(NH{\cdot}NHPh)_2 = 2CRR'{:}N{\cdot}NHPh + CO\langle^{NH{\cdot}NH}_{N(NH_2)}\rangle CO$$

* In Part II this compound was erroneously described as 1-aminourazole; the name and formula should be as now given.

From acetophenone-δ-anilinosemicarbazone, some ketazine was also produced, probably by the thermal decomposition of the intermediate carbohydrazone (compare Brown, Pickering, and Wilson, this vol., p. 107). This interpretation of the reaction has now been confirmed by heating together diacetonecarbohydrazone and diphenylcarbohydrazide, the products being acetonephenylhydrazone, 4-aminourazole and dimethylketazine. The thermal decomposition of acetone-, pinacolin-, and benzylidene-δ-anilinosemicarbazones followed the same course, no diphenylcarbohydrazide being actually isolated. In the case of acetone-δ-diphenylaminosemicarbazone, the thermal decomposition of which conformed to the general scheme, some tetraphenylcarbohydrazide, $CO(NH\cdot NPh_2)_2$, was actually isolated.

In the expectation of obtaining δ-anilinothiosemicarbazones, the behaviour of acetone-, acetophenone-, and dibenzyl ketone thiosemicarbazones on heating with phenylhydrazine was investigated in the usual manner. In each case, however, the phenylhydrazone and thiosemicarbazide were produced, the reaction being $CRR'{:}N\cdot NH\cdot CS\cdot NH_2 + NH_2\cdot NHPh = CRR'{:}N\cdot NHPh + NH_2\cdot NH\cdot CS\cdot NH_2$. Since acetophenone- and dibenzyl ketone semicarbazones gave excellent yields of δ-anilinosemicarbazones, the thiosemicarbazide residue is evidently more easily replaced than the semicarbazide residue.

Experimental.

Thermal Decomposition of δ-Anilinosemicarbazones.—In the preparation of δ-anilinosemicarbazide hydrochloride already described, it was found more advantageous to hydrolyse the acetophenone derivative (3·3 g.) by boiling under reflux for 20 minutes with 6% hydrochloric acid (75 c.c.) and to remove the acetophenone from the hot liquid by three extractions with carbon tetrachloride. The aqueous solution on cooling deposited the hydrochloride, the remainder of which was obtained by evaporating the filtrate under reduced pressure.

Acetone-δ-anilinosemicarbazone was prepared by mixing acetone with a concentrated aqueous solution of the hydrochloride and gradually adding a slight excess of solid potassium acetate with shaking. After cooling in ice for 5 hours, the product was collected (yield 94%). It crystallises in plates, not needles as formerly described (J., 1924, **125**, 2146). The m. p. varies somewhat with the rate of heating; this preparation had m. p. 170°, which was not depressed on admixture with the specimen previously described. (Found: N, 27·1. Calc.: N, 27·2%). *Methyl ethyl ketone δ-anilino-*

semicarbazone (plates from alcohol, m. p. 137°) was prepared in the same way (Found: N, 25·4. $C_{11}H_{16}ON_4$ requires N, 25·4%).

Acetone-δ-anilinosemicarbazone was heated at 180° for 5 hours in a distillation flask with occasional evacuation until distillation ceased. The small quantity of distillate, after hydrolysis with dilute hydrochloric acid, yielded acetone on fractionation; the remainder of the liquid gave with benzaldehyde and potassium acetate a mixture of benzaldehydephenylhydrazone and benzalazine. The semi-resinous product remaining in the reaction flask was extracted with boiling absolute alcohol, which left a residue of 4-aminourazole. The alcoholic extract would not crystallise, but gave the usual diphenylcarbohydrazide colour reactions. Hence the products were acetonephenylhydrazone, dimethylketazine, and 4-aminourazole.

An intimate mixture of diacetonecarbohydrazone and diphenylcarbohydrazide (molecular quantities) was heated under the same conditions as before. The products were again acetonephenylhydrazone, dimethylketazine, and 4-aminourazole.

Pinacolin-δ-anilinosemicarbazone. The thermal decomposition was effected exactly as before. The distillate contained pinacolinphenylhydrazone and pinacolinazine, identified as such by hydrolysis with acid. The residue in the flask contained 4-aminourazole and gave the colour reactions of diphenylcarbohydrazide, which, however, could not be isolated.

Pinacolinazine was prepared by refluxing 11 g. of the ketone with 2·5 g. of hydrazine hydrate in 10 c.c. of absolute alcohol for 2 hours. After evaporation of the solution, the residual oil was dried over potassium carbonate and distilled; it was an almost colourless oil, b. p. 213—216°, 103°/17 mm., smelling somewhat like acetamide, insoluble in water and easily hydrolysed on boiling with acid (yield 77%) (Found: N, 14·3. $C_{12}H_{24}N_2$ requires N, 14·3%).

Benzylidene-δ-anilinosemicarbazone was heated for 1 hour at 230°. Since benzaldehydephenylhydrazone decomposes at about this temperature, the reaction was carried out under reduced pressure in a flask of the Anschütz type, in the collar of which a distillate, which soon solidified, collected. The whole reaction mass was extracted with boiling absolute alcohol; benzaldehydephenylhydrazone passed into solution whilst 4-aminourazole, the only other product, remained undissolved.

Acetone-δ-diphenylaminosemicarbazone. The reaction was carried out as usual: 4 hours' heating at 190—195°. The distillate on hydrolysis with hydrochloric acid gave acetone, diphenylhydrazine hydrochloride, and hydrazine hydrochloride. The dark residue in the flask was extracted with boiling absolute alcohol and then with

boiling water; the alcoholic extract on concentration deposited small needles of tetraphenylcarbohydrazide (Acree, *Ber.*, 1903, **36**, 3157) (Found: N, 14·4, 14·3. Calc.: N, 14·2%), and evaporation of the aqueous extract left 4-aminourazole. The products were therefore acetonediphenylhydrazone, dimethylketazine, 4-aminourazole, and tetraphenylcarbohydrazide.

Action of Phenylhydrazine on Thiosemicarbazones.—Molecular quantities of the reactants were heated in toluene solution or suspension at 135°.

Acetonethiosemicarbazone (6½ hours). A little ammonia was evolved, but the only products isolated were thiosemicarbazide, acetonephenylhydrazone, and a little unaltered substance.

Acetophenonethiosemicarbazone (5 hours). This compound dissolved completely and after some time thiosemicarbazide began to separate; some hydrogen sulphide and ammonia were evolved. The substances isolated were thiosemicarbazide, acetophenonephenylhydrazone, and a small quantity of an orange-coloured *substance*, m. p. 171—172°.

Dibenzyl ketone thiosemicarbazone (which crystallises in silvery leaves, m. p. 165—166°, from alcohol or benzene), was obtained by refluxing 2·1 g. of the ketone in 15 c.c. of alcohol with 0·9 g. of thiosemicarbazide in the minimum quantity of hot water for ¾ hour (Found: N, 14·9. $C_{16}H_{17}N_3S$ requires N, 14·8%). The reaction with phenylhydrazine (4 hours) gave thiosemicarbazide, dibenzyl ketone phenylhydrazone, and some unaltered substance only.

In conclusion, we wish to thank the Carnegie Trust for the Universities of Scotland for a research grant which has partly defrayed the cost of this work. We wish also to thank the Governors of this College for a research assistantship which has enabled one of us (W. B.) to share in the investigation.

THE ROYAL TECHNICAL COLLEGE,
GLASGOW.

CCLXXXI.—*The Systems* B_2O_3–SO_3–H_2O *and* B_2O_3–P_2O_5–H_2O.

By MIRIAM LEVI and LIONEL FELIX GILBERT.

(i) *The System* B_2O_3–SO_3–H_2O.

MERZ (*J. pr. Chem.*, 1866, **99**, 81) stated that when equal weights of boric and concentrated sulphuric acids were heated to constant weight at 250—280° a substance was obtained of composition $5B_2O_3,2SO_3,2H_2O$. Gmelin reported (*Ann. Supp.*, 1867, **5**, 169),

that boron trioxide and boric acid dissolved extensively in concentrated sulphuric acid on heating, and that on cooling a thick syrup was obtained which deposited hydrates of boric acid on standing in moist air. Schultz-Sellack (*Ber.*, 1871, **4**, 12) found that the solution of boric acid in concentrated sulphuric acid gave on evaporation a viscous or glassy mass, which was not of constant composition. If, however, the sulphuric acid solution was treated with sulphur trioxide, or if boron trioxide was added to fuming sulphuric acid, leafy crystals, of composition $B_2O_3,3SO_3,H_2O$, were obtained on evaporation.

D'Arcy (J., 1889, **55**, 155) could not confirm the existence of Merz's or Schultz-Sellack's compounds. He reports that on mixing boric acid with excess of sulphur trioxide a violent reaction occurs; on heating the mixture at 100° till no more fumes are evolved and then cooling, a white substance separates of composition $B_2O_3,6SO_3,3H_2O$. Herz (*Z. anorg. Chem.*, 1903, **34**, 205) has made solubility measurements of boric acid in four different concentrations of sulphuric acid, 9*N* being the highest; no examination of the solid phases was made.

In the present work, a partial survey of the condensed ternary system has been made at 25° and 45° by the Schreinemakers method, supplemented by direct analyses of the solid phases. None of the above compounds has been found to exist under our experimental conditions, but the new compounds $B_2O_3,SO_3,4H_2O$ and $3B_2O_3,SO_3,3H_2O$ appear to be definitely characterised.

The reactants supplying the components were, in addition to water, concentrated sulphuric acid, fuming sulphuric acid, boric acid, and a specimen of powdered boron trioxide containing about 13% of water. These substances were in each case of a satisfactory degree of purity.

The boric–sulphuric acid mixtures examined were analysed by Herz's method (*Z. anorg. Chem.*, 1903, **33**, 353), which was tested and found to be very accurate, although the few solubilities recorded by that author do not agree with ours (see below), possibly owing to the fact that in determining them he used a less accurate method (compare Kendall and Andrews, *J. Amer. Chem. Soc.*, 1921, **43**, 1550). The procedure was to titrate suitably diluted solutions with 0·1*N*-sodium hydroxide in the presence of *p*-nitrophenol as indicator until the first yellow colour appeared, corresponding with the neutralisation of the sulphuric acid; 10 c.c. of a neutral, saturated solution of mannite and two drops of phenolphthalein solution were then added, and the titration was continued until a definite pink colour persisted for 3 minutes. This latter amount of alkali was equivalent to the boric acid present.

The solubility determinations were complicated, when high concentrations of sulphuric acid were concerned, by the ease with which highly supersaturated solutions were obtained, even when solution was effected at room temperatures. This tendency was especially marked in the region relating to the solid phase, $B_2O_3,SO_3,4H_2O$.

In some cases, solutions stood for several weeks before any solid phase commenced to separate, and the further precipitation was also very slow. None of the usual methods for overcoming this type of difficulty, *viz.*, cooling, heating, or the addition of foreign bodies or of the appropriate solid phase, seemed to have any marked effect.

Three methods of obtaining the necessary data for the ternary diagram were employed.

(*a*) The well-known method of agitating in a thermostat sealed glass tubes containing the reactants mixed in suitable proportions was employed for low concentrations of sulphuric acid, where equilibrium was easily attained. As soon as a tube was opened, the liquid and the wet solid were rapidly sampled and the samples were transferred to a specific-gravity bottle in the thermostat and to a weighing bottle, respectively.

(*b*) The reactants were stirred with dry air in an apparatus similar to that used by Donnan and White (J., 1911, **99**, 1788), the Gooch crucible used by these authors for separating solid and liquid being here replaced by a glass filter-funnel with a permanently fixed filter-plate of fritted glass. This method was used with some of the higher concentrations of (non-fuming) sulphuric acid, where the attainment of equilibrium was too slow by the tube method.

(*c*) The reactants were placed in a glass bottle of about 500 c.c. capacity, fitted with a glass stirrer passing through a mercury seal. After long stirring, the solid was allowed to segregate and samples of liquid and solid were taken. This method was used for mixtures containing fuming sulphuric acid, and for some other mixtures of high viscosity.

Compositions of saturated solutions and of their respective wet solids are shown in Table I and Fig. 1 for 25°, and in Table II for 45°. Although Herz's solubilities were determined at 26°, they are consistently lower than our values for 25°; *e.g.*, the concentration of boric acid in 8·75*N*-sulphuric acid is 0·092*N* (Herz) and about 0·37*N* by interpolation from our results. Areas corresponding to three distinct solid phases will be observed in Fig. 1, *viz.*, $B_2O_3,3H_2O$ (*i.e.*, H_3BO_3), $B_2O_3,SO_3,4H_2O$, and $3B_2O_3,SO_3,3H_2O$, but there is no evidence here for any of the ternary compounds described by other authors. On plotting the 45°-data, a similar

solubility curve to that at 25° is obtained, but the tie-lines corresponding to the two new compounds are not so satisfactorily convergent. The attainment of equilibrium was too slow for more satisfactory data to be obtained, but it is considered that there is little doubt that the above compounds are also obtained at 45°. The quite characteristic appearances of the solid phases were also similar to those obtained at 25°.

Samples of the two new solids, prepared by the interaction of boric acid with 88% sulphuric acid, and of boron trioxide (87%)

FIG. 1.

The system B_2O_3–SO_3–H_2O *at* 25°.

with concentrated sulphuric acid, respectively, and kept in desiccators on carefully dried porous plates, gave the following analyses:

	$B_2O_3,SO_3,4H_2O$.				$3B_2O_3,SO_3,3H_2O$.			
	I.	II.	III.	Calc.	I.	II.	III.	Calc.
% SO_3	36·6	36·1	36·6	36·0	22·1	25·4	24·9	23·3
% B_2O_3	31·2	32·3	32·0	31·5	64·8	61·9	59·5	61·0

It is considered that discrepancies between observed and calculated results can fairly be ascribed to a certain amount of hydrolysis which may have occurred on sampling, and also to the difficulty of draining the viscous adherent liquids, the viscosity of which is especially high in the case of the second compound.

$B_2O_3,SO_3,4H_2O$ is a white, finely-divided, crystalline substance; $3B_2O_3,SO_3,3H_2O$ consists of larger, colourless crystals. Both compounds rapidly absorb moisture from the atmosphere, with consequent decomposition.

Viscosities of Solutions of Boric Acid in Concentrated Sulphuric Acid.—A few determinations were made at 25° of the viscosities of solutions of boric acid in concentrated sulphuric acid compared with that of the solvent, by the capillary flow method. No great accuracy is claimed for these measurements, which, however, help to emphasise some of the difficulties experienced when working with this system. The results obtained were:

% H_3BO_3	0	8·5	15·9	24·5	30·0	37·6	42·7
Relative time of flow	1	3·96	12·5	40·1	84·0	219	440

(ii) *The System* B_2O_3–P_2O_5–H_2O.

Vogel (*Z. anal. Chem.*, 1870, **9**, 376) obtained a compound containing "an equal number of equivalents of boric and phosphoric acids" by strongly heating mixtures of these substances. Meyer (*Ber.*, 1889, **22**, 2919), Mylius and Meusser (*Ber.*, 1904, **37**, 397), and Prescher (*Arch. Pharm.*, 1904, **242**, 199) all obtained a substance of empirical composition BPO_4 by methods similar to that of Vogel, whose compound, therefore, was probably the same (compare Comey, "Dictionary of Chemical Solubilities," 1921, p. 668). BPO_4, thus prepared, is insoluble in water and only slowly decomposed by boiling alkalis. Mylius and Meusser observed, however, that, when formed at comparatively low temperatures (80—100°) from the above reactants, or from solutions of metaboric acid in acetic and phosphoric acids or from solutions of boric acid in phosphoric and concentrated sulphuric acids, BPO_4 is soluble in water with decomposition, but becomes insoluble on heating to 400°. Gustavson (*Ber.*, 1871, **4**, 975) made BPO_4 by heating boron trioxide with phosphorus pentachloride, and boron trichloride with phosphorus pentoxide. Apparently here, too, the soluble compound was first formed and became insoluble on further heating.

The ternary system B_2O_3–P_2O_5–H_2O at 25° has now been partially investigated, and BPO_4 occurred as the solid phase in one of the regions under examination.

Well-boiled syrupy phosphoric acid, free from phosphorous acid, was employed as the source of phosphorus pentoxide, and was suitably diluted as required. The boric acid and boron trioxide used were similar specimens to those mentioned previously.

On examination of the literature, Kolthoff's method (*Chem. Weekblad*, 1922, **19**, 449) appeared to be the most suitable for the rather difficult determination of mixtures of boric and phosphoric acids, but it was found not to give sufficiently accurate results. In addition to the difficulty of distinguishing between various shades of pink, it was found that the titration value for the phosphoric acid end-point varied with the amount of boric acid present

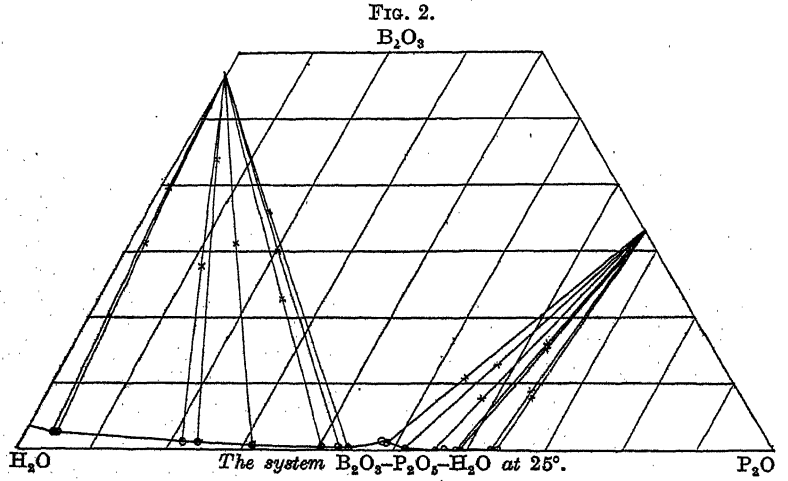
if the titration was carried on until the same p_H value was obtained in each case. Whilst retaining the use of sodium citrate and Kolthoff's p_H value for the total-acid end-point, which was found to be correct and unaffected by the relative amounts of the acids, a new procedure was adopted. 0·1*N*-Mixtures of known composition of boric and phosphoric acids were made up, 10 c.c. of 40% sodium citrate solution and thymol-blue were then added, followed by the appropriate amount of 0·1*N*-sodium hydroxide to convert all the phosphoric acid to the secondary sodium salt. The p_H numbers acquired by the solutions were then determined by comparison with a colour chart, and plotted against the % of boric acid molecules in the total acid molecules present.

The correction graph was plotted from the following data, of which the accuracy is considered sufficient for the purpose :

% H_3BO_3.....	100	96	82	70·5	58	52	40·5	35	26·3	15·5	0
p_H	8·2	8·3	8·4	8·5	8·6	8·7	8·8	8·9	9·0	9·1	9·2

In the analysis of an unknown mixture the % of boric acid was first determined roughly and the corresponding p_H number read off the graph. Exact determinations were then made on 25 c.c. of another sample by titrating with caustic soda (in presence of sodium citrate and thymol blue) to this p_H number, thus allowing the amount of phosphoric acid to be calculated; 10 c.c. of a saturated solution of mannite were then added and the solution was titrated until the colour corresponding to p_H 8·7 lasted for at least a minute. This latter volume of sodium hydroxide was equivalent to the boric acid present. A test of the method over a wide range of relative concentrations of the acids indicated that it gave very accurate results.

The first two methods employed in the preceding system were found suitable for obtaining the solubility and wet-solid data. Some difficulty was experienced in filtering satisfactorily mixtures made with high concentrations of phosphoric acid. Large quantities of boric acid and boron trioxide will dissolve in such phosphoric acid solutions with the formation of clear liquids from which a new, very finely divided, solid phase slowly separates. This coagulates slightly and settles after 3 or 4 days, but still passes through filters of average pore diameter 35—40 $\times$ 10^{-4} and in some cases even 4—5 $\times$ 10^{-4} cm.



The results obtained are shown in Table III and partly in Fig. 2. The solid phase in equilibrium with solutions containing up to about 48% of P_2O_5 is boric acid, after which BPO_4 or some polymeride is formed. The BPO_4 thus obtained is the water-soluble variety. Attempts to prepare a pure dry specimen have so far

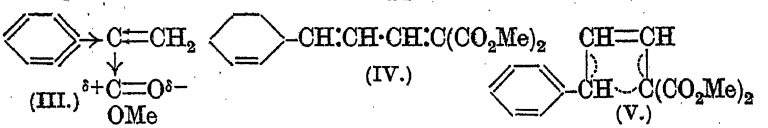
CCLXXXII.—*The Nature of the Alternating Effect in Carbon Chains. Part XXI. The Directive Influence of the Groups* $-CH_2\cdot CH(CO_2Me)_2$, $-CH{:}C(CO_2Me)_2$, $-C(CO_2Me){:}CH_2$, *and* $-CH{:}CH\cdot CH{:}C(CO_2Me)_2$ *in Aromatic Substitution.*

By JOHN WILLIAM BAKER and ALFRED ECCLES.

IT has already been shown (Baker and Wilson, this vol., p. 842) that mechanisms depending on complete co-valency changes between the side-chain and the benzene nucleus probably play, at the most, a subsidiary part in the propagation of meta-orienting influences. Thus, electron attraction due to the integral positive charge on the nitro-group is more readily propagated to the nucleus in the ω-nitroethyl than in the corresponding ω-nitrovinyl side-chain. In the present communication, an attempt is made to confirm the previous conclusion by a study of the nitration of the analogous compounds, methyl benzylmalonate (I) and methyl benzylidenemalonate (II), in which the *gem*-dicarbomethoxyl grouping replaces the nitro-group of the previous cases. On the view that the meta-orienting influence of the carboxyl group is due to the presence of a permanent fractional dipole in the resting state of the group (Baker and Ingold, this vol., p. 832), it is to be expected that the effects produced would be much smaller in magnitude than those due to the integral dipole charge on the nitro-group.

Again, however, on any mechanism of meta-substitution which depends on the alternation of single and double bonds, a larger proportion of meta-nitration should occur in the unsaturated compound (II), in which there is an unbroken conjugated system extending from the polar group throughout the nucleus, than in the corresponding saturated compound (I). Actually, in confirm-



(I.)  (II.) 

ation of previous results, we find the reverse to be the case, since, on nitration, methyl benzylmalonate yields 8% of meta-derivative, whilst methyl benzylidenemalonate yields only 3%.* Thus, here

* This value is somewhat higher than that expected (1—2%). It is possible that addition of nitric acid to the double bond precedes nitration and slightly increases the proportion of meta-isomeride produced.

also the electron attraction due to the fractional positive charge on the carboxyl groups is neutralised in passing through the field of the double bond.

As in the case of the nitro-compounds previously studied, the possibility of the double linking itself acting as a dominating electron-source towards the nucleus was negatived by a study of the nitration of methyl atropate (III), in which the double bond is no longer in the path of transmission from the (single) carbomethoxyl group. We find that, on nitration, this ester yields about 5% of meta-isomeride, although, owing to the small amount of material available, the figure must be considered as approximate only.

One other case was investigated, *viz.*, that of methyl cinnamylidenemalonate (IV). The point of interest here is that there might be the possibility of valency tautomerism in the side-chain leading to the cyclic form (V), in which electron-strain might conceivably be transmitted to the nucleus through two carbon atoms only, *via* the $\alpha : \delta$ partial valency, and the proportion of *m*-isomeride produced might then be more or less comparable with that obtained on nitration of methyl benzylmalonate. Actually, however, we find no evidence of this type of transmission, since the proportion of *m*-isomeride produced is less than 1%. The electron attraction of the carbomethoxyl group is thus completely neutralised by the fields of the unsaturated chain in (IV).

Experimental.

A. *Preparation of Materials.*

Methyl Benzylidenemalonate.—This was obtained by the condensation of benzaldehyde and methyl malonate, as described by Claisen and Crismer for the ethyl ester (*Annalen*, 1883, **218**, 132; compare Liebermann, *Ber.*, 1894, **27**, 289). The product had b. p. 174—177°/15 mm., m. p. 41° (Found: C, 65·6; H, 5·5. Calc.: C, 65·4; H, 5·5%).

The methyl *o*-, *m*-, and *p*-nitrobenzylidenemalonates were obtained by the condensation of the appropriate nitrobenzaldehyde with methyl malonate in the presence of piperidine as a condensing agent (compare Knoevenagel, *Ber.*, 1898, **31**, 2593).

Methyl p-*Nitrobenzylidenemalonate.*—A mixture of *p*-nitrobenzaldehyde (7·6 g.), methyl malonate (6·6 g.), and two drops of piperidine was heated to 60° for 6 hours. On cooling, the mixture

solidified, and the *nitro-ester* was recrystallised from hot alcohol; needles, m. p. 136—137° (Found: C, 54·4; H, 4·2. $C_{12}H_{11}O_6N$ requires C, 54·3; H, 4·2%). The yield is quantitative.

Methyl m-*nitrobenzylidenemalonate*, prepared similarly but in smaller yield from *m*-nitrobenzaldehyde, has m. p. 99—100° (Found: C, 54·2; H, 4·2%).

Methyl o-*nitrobenzylidenemalonate*, m. p. 65—66° (Found: C, 54·3; H, 4·3%).

Methyl benzylmalonate was prepared by esterification of the pure acid with methyl alcohol and hydrogen chloride.

Methyl o-*Nitrobenzylmalonate*.—*o*-Nitrobenzylmalonic acid (Reissert, *Ber.*, 1896, **29**, 644) was esterified through its silver salt. The *methyl* o-*nitrobenzylmalonate* was obtained as a pale yellow, viscous oil, which did not solidify on cooling to −10°, and could not be purified by distillation (Found: C, 53·8; H, 5·1. $C_{12}H_{13}O_6N$ requires C, 53·9; H, 4·9%). On oxidation with boiling 2% permanganate, it gave an acid product contaminated with gummy material in 73·3% yield (calculated as *o*-nitrobenzoic acid). By crystallisation from ether, this was shown to contain *o*-azoxybenzoic acid. Reissert (*loc. cit.*) records the formation of the latter compound by the oxidation with permanganate of 1-hydroxyindole-2-carboxylic acid formed from *o*-nitrobenzylmalonic acid by the action of potash.

Methyl m-*Nitrobenzylmalonate*.—To a solution of 4·6 g. of sodium in 50 g. of methyl alcohol, 26·4 g. of methyl malonate were added, quickly followed by a saturated solution of 17·15 g. of *m*-nitrobenzyl chloride in methyl alcohol; the mixture was heated on the steam-bath for ½ hour and filtered from sodium chloride and the *methyl di*-m-*nitrobenzylmalonate* formed as a by-product. The salt was extracted with cold water, and the dried residue crystallised from benzene; m. p. 162—162·5° (Found: C, 56·9; H, 4·6. $C_{19}H_{18}O_8N_2$ requires C, 56·7; H, 4·5%). The alcoholic mother-liquor was concentrated, poured into water, and extracted with ether. After drying the extract and evaporating the ether, the excess of methyl malonate was separated by distillation under reduced pressure. The residue, which cannot be distilled without decomposition, was dissolved in alcohol, and the solution saturated with ammonia. After standing for several days, m-*nitrobenzylmalonamide* separated as a flocculent precipitate. After several crystallisations from water, it had m. p. 203° (Found, by microcombustion: C, 51·0; H, 4·4. $C_{10}H_{11}O_4N_3$ requires C, 50·6; H, 4·6%). The amide was hydrolysed by heating at 100° with a slight excess of 10% caustic soda. On acidification of the cooled solution, m-*nitrobenzylmalonic acid* separated, and after crystallisation from water it had m. p. 164° (decomp.) (Found, by

combustion: C, 50·5; H, 4·0. $C_{10}H_9O_6N$ requires C, 50·2; H, 3·8%). A further small quantity of the acid may be obtained by extracting the mother-liquors with ether. The yield of recrystallised acid was 2 g. Conversion of the crude methyl *m*-nitrobenzylmalonate into the amide is necessary, as treatment of the ester itself with alcoholic potash yields a very tarry product. The *m*-nitrobenzylmalonic acid was esterified through its silver salt, and *methyl* m-*nitrobenzylmalonate* obtained as a pale yellow, viscous oil, which did not solidify on cooling to −10° (Found: C, 54·2; H, 5·1%). On oxidation with boiling 2% potassium permanganate, it gave *m*-nitrobenzoic acid, m. p. 139°, in 90% yield.

Methyl p-*nitrobenzylmalonate*, m. p. 82·5—83·5° (Found: C, 53·85; H, 5·0%) was isolated from the reaction products by crystallisation from methyl alcohol (compare Section C). On oxidation, it gave *p*-nitrobenzoic acid, m. p. 237—239°, in 99% yield.

Methyl Cinnamylidenemalonate.—This was obtained by esterification of the acid (compare Liebermann, *Ber.*, 1895, **28**, 1439) by the method of Thiele and Meisenheimer (*Annalen*, 1899, **306**, 253) and had m. p. 67° (Found: C, 68·1; H, 5·9. Calc.: C, 68·3; H, 5·7%).

The isomeric nitro-derivatives were prepared by condensation of the appropriate nitro-cinnamaldehyde with methyl malonate in the presence of piperidine.

Methyl m-*Nitrocinnamylidenemalonate.*—A mixture of 8·85 g. of *m*-nitrocinnamaldehyde (Kinkelin, *Ber.*, 1885, **18**, 484), 6·6 g. of methyl malonate, and two drops of piperidine was heated to 60—70° for 5 hours. The cooled mixture, when treated with a few c.c. of ether and scratched, partly solidified. The separated crystals were washed with ether, recrystallised from alcohol, and obtained as felted needles, m. p. 125—126° (Found: C, 57·9; H, 4·6. $C_{14}H_{13}O_6N$ requires C, 57·7; H, 4·5%). The yield was small (about 15%). On oxidation with potassium permanganate, it gave *m*-nitrobenzoic acid, m. p. 129—132° (mixed m. p. 136—139°) in 76% yield.

Methyl o-*nitrocinnamylidenemalonate*, obtained in a similar manner from *o*-nitrocinnamaldehyde, and crystallised from methyl alcohol, had m. p. 114° (Found, by micro-combustion: C, 57·7; H, 4·6%). On oxidation it gave *o*-nitrobenzoic acid, m. p. 133—137° (mixed m. p. 139—141°), in 80% yield.

Methyl p-*nitrocinnamylidenemalonate* has m. p. 146—147° after crystallisation from methyl alcohol (Found: C, 57·8; H, 4·7%). On oxidation it gave *p*-nitrobenzoic acid, m. p. 229—231°, in 77% yield.

Methyl Atropate.—Tropic acid was converted into atropic acid by

the method of Hesse (*J. pr. Chem.*, 1901, **64**, 287), who, however, gave no details. The tropic acid (10 g.) was refluxed with 60 c.c. of a 50% aqueous solution of potassium hydroxide for 40 minutes, the solution extracted with ether, acidified with hydrochloric acid, and again extracted with ether. The crude atropic acid obtained from this dried ethereal extract was purified by crystallisation (twice) from dilute alcohol. The acid (4·5 g.) was dissolved in a large volume (1200—1500 c.c.) of very dilute ammonia solution, boiled to expel the excess of ammonia, and a slight excess of a hot solution of silver nitrate added. On cooling, the silver salt crystallised out, and was filtered and washed in succession with water, alcohol, and ether. Treatment of the dry silver salt with an excess of methyl iodide yields the *methyl atropate* in an almost pure state as a colourless, mobile liquid, b. p. 95—98°/6 mm. (Found: C, 73·6; H, 6·2. $C_{10}H_{10}O_2$ requires C, 74·1; H, 6·2), which polymerises on keeping.

B. *Conditions of Nitration.*

In all cases, the ester was slowly added at the rate of 1—2 g. per hour to about 10 times its quantity of nitric acid (*d* 1·49) at −15— −10°. Isolation of the product was effected by pouring on crushed ice, exactly neutralising the solution, first with 10% sodium hydroxide solution and finally with sodium carbonate solution, filtering off any solid product, and extracting the mother-liquors with ether. Special precautions were necessary in the case of methyl cinnamylidenemalonate (see Section C).

C. *Details relating to Individual Cases and Determination of the Proportions of the Isomerides formed.*

Since the methods employed in the separation of the isomerides are those which have been described in detail in earlier papers in this series, details of procedure are omitted in the following pages.

Nitration of Methyl Benzylmalonate.—In this case, it was found that the yield of mixed acids obtained by oxidation of the nitration mixture was only about 80—85% of that calculated from the percentage oxidation yields of the pure isomerides (compare Section A) and their estimated relative proportions. This may be due to the *o*-nitrobenzylmalonate being converted into an indole derivative under the influence of alkali (Reissert, *loc. cit.*; compare p. 2127). The proportion of *m*-nitro-ester in the nitration mixture, as calculated from the quantity of *m*-nitrobenzoic acid isolated, is probably too low, since the total oxidation yield is less than the calculated yield, but it is still considerably greater than that present in the nitration of the benzylidenemalonate. The authors are of the opinion that the percentage of *m*-nitrobenzoic acid isolated from

the mixed acids obtained on oxidation represents fairly closely the proportion of meta-derivative formed by nitration. The presence of the azoxybenzoic acid did not interfere with the separation of the mixed acids, except that sometimes it was found necessary to crystallise the *p*-acid from water.

(Expt. 31.) The yield of mononitro-compounds was 93% (Found: C, 53·4; H, 4·9. Calc. for $C_{12}H_{13}O_6N$: C, 53·9; H, 4·9%), a further 2% of the material being accounted for as acid products produced by oxidation. On oxidation, the mixed nitro-compounds yielded acids in 70% yield, which on separation by the usual method gave nitrobenzoic acids thus: para-, m. p. 234° (either alone or mixed), 70·4%; meta-, m. p. 128—135° (mixed m. p. 141°), 7·5%; ortho- (by difference), 22·1%.

A second portion of the same nitration product was crystallised from methyl alcohol, whereby 58·8% of practically pure methyl *p*-nitrobenzylmalonate, m. p. 82°, was isolated. On oxidation of the residue, some accidental loss occurred and only a 64% yield of mixed nitrobenzoic acids was obtained; these comprised: para-, m. p. 220—223°, 30%; meta-, m. p. 124—127° (mixed m. p. 138°), 16·5%. Hence the composition of the whole nitration mixture was: para-, 71·3%; meta-, 6·8%; ortho- (by difference), 21·9%.

(Expt. 33.) The yield of mono-nitration products was 93% (Found: C, 54·2; H, 4·9%), from which 56% of pure methyl *p*-nitrobenzylmalonate was isolated by crystallisation. The residues gave a mixture of acids (*M*, by titration, 165) in 72% yield, which on separation was found to contain: para-, m. p. 233—235°, 19·2%; meta-, m. p. 123—128° (mixed m. p. 133—137°), 20·9%; ortho- (by difference), 59·9%; whence the composition of the nitration mixture was: para-, 64%; meta-, 9%; ortho- (by difference), 27%.

(Expt. 34.) The yield of mono-nitration product was 95% (Found: C, 53·3; H, 4·9%), which on oxidation gave a mixture of nitrobenzoic acids (*M*, by titration, 169) in 77% yield; this on separation was found to contain: para-, m. p. 210—215° (mixed m. p. 227—229°), 68·6%; meta-, m. p. 122—125° (mixed m. p. 135—137°), 8·4%; ortho- (by difference), 23%.

(Expt. 35.) Nitration yields, 95% (Found: C, 53·9; H, 5·1%). On oxidation the nitration mixture gave acids in 71% yield, which on separation gave: para-, m. p. 236° (alone or mixed), 68%; meta-, m. p. 126—128° (mixed m. p. 138—140°), 7·0%; ortho- (by difference), 25%.

Nitration of Methyl Benzylidenemalonate.—(Expt. 21.) The yield of mononitro-product was 96% (Found: C, 53·9; H, 4·2. Calc.: C, 54·3; H, 4·2%). The whole product was oxidised with 2%

potassium permanganate and gave nitrobenzoic acids in 93% yield (*M*, by titration, 164), the bulk of the *p*-nitrobenzoic acid being allowed to crystallise out in the pure state. Separation by the usual methods gave: para-, m. p. 235° (alone or mixed), 67%; impure meta-, m. p. 104—110°, 5·8%. The meta-acid was recrystallised from a small quantity of ethyl acetate–ligroin, and a quantity corresponding to 2·4%, m. p. 122—126° (mixed m. p. 133—138°) was obtained. Hence the composition of the nitration mixture is: para-, 67%; meta-, 2·4%; ortho- (by difference), 30·6%.

A second portion of the nitration product was crystallised from absolute alcohol before oxidation, and 61% of pure methyl *p*-nitrobenzylidenemalonate, m. p. 134° (either alone or mixed with a synthetic specimen), separated out. The residue from the mother-liquor on oxidation gave nitrobenzoic acids in 96% yield (*M*, by titration, 168·5), which on separation gave a further 5·2% of *p*- and 5·3% of *m*-nitrobenzoic acid, m. p. 113—120° (both calculated on whole nitration product); the latter on recrystallisation from ethyl acetate–ligroin gave 3%, m. p. 134—136° (mixed m. p. 137—139°). Hence the composition of the nitration product was: para-, 66·6%; meta-, 3%; ortho- (by difference), 30·8%.

(Expt. 22.) The yield of mononitration product was 96% (Found: C, 54·0; H, 4·2%), which on oxidation gave nitrobenzoic acids in 84% yield (*M*, by titration, 166); these on separation gave: para-, m. p. 238°, 67·8%; meta- (after crystallisation), m. p. 134—136°, 3·3%; ortho- (by difference), 28·9%. A second portion of the nitration product was crystallised from alcohol, and 65·4% of nearly pure methyl *p*-nitrobenzylidenemalonate separated, m. p. 133—134° (mixed m. p. with a synthetic specimen, 135—136°). The residue on oxidation gave nitrobenzoic acids in 82% yield, which on separation yielded a further 2% of para-, m. p. 220—223°, and 3% of meta- (after crystallisation), m. p. 133—135° (mixed m. p. 137—139°) (both calculated on the whole nitration product). Hence the composition of the nitration product is: para-, 67·4%; meta-, 3·0%; ortho- (by difference), 29·6%.

Nitration of Methyl Atropate.—(Expt. 41.) The yield of mononitro-products was theoretical (Found: C, 57·4; H, 4·5. Calc. for $C_{10}H_9O_4N$: C, 57·9; H, 4·4%), and crystallisation from absolute methyl alcohol gave 16·3% of pure *methyl* p-*nitroatropate*, m. p. 110° (unchanged by further crystallisation). The residue from the mother-liquor on oxidation gave nitrobenzoic acids in 85% yield (*M*, 173; benzoic acid, by sublimation, 3%), which on separation were found to contain 44% of *p*-nitrobenzoic acid, m. p. 220° (mixed m. p. 221—225°), and 9% of *m*-nitrobenzoic acid. The latter, however,

was slightly sticky, and was therefore converted into its methyl ester through the acid chloride, and the residue washed with a drop of methyl alcohol on porous porcelain; the residual ester had m. p. 75—78° (mixed m. p. 78°, with a synthetic specimen of methyl *m*-nitrobenzoate). Hence the composition of the nitration product is: para-, 16·3% + (44% of 83·7%) = 53%; meta-, approx. 9% of 83·7% = approx. 7%; ortho- (by difference), 40%.

(Expt. 42.) The yield of mononitro-product was 99% (Found: C, 57·4; H, 4·7%), which was completely oxidised to the mixed nitrobenzoic acids. These, on separation, gave para-, m. p. 220—222° (alone or mixed with a genuine specimen), 57%; meta-, m. p. 110—115° (mixed m. p. 133—135°), 4·7%; ortho- (by difference), 39·3%.

Nitration of Methyl Cinnamylidenemalonate.—In a preliminary experiment, the nitration product, on being poured on ice, gave a yellow, flocculent solid, which became sticky on filtering, and on drying overnight in a vacuum desiccator over phosphoric oxide decomposed to a semi-solid gum. The whole product was therefore oxidised with potassium permanganate, but gave only a 69% yield of mixed nitrobenzoic acids. On separation, this was shown to contain less than 2% of the meta-derivative. Under the following conditions, however, it was found possible to isolate the solid nitration product.

(Expt. 12.) The nitration was carried out with nitric acid (*d* 1·46), and the product was poured on ice, *partially* neutralised with a 10% solution of sodium hydroxide, and the separated solid rapidly filtered through a Buchner funnel surrounded with ice. After being washed with ice-cold water, the solid was quickly transferred to a vacuum desiccator over phosphoric oxide, and when dry was found to be quite stable. The aqueous mother-liquor and washings were extracted with ether, the ether extract washed five times with 2*N*-sodium carbonate solution, dried over calcium chloride, and the ether evaporated at the ordinary temperature. The yield of mono-nitration product was 103% (slight dinitration) (Found: C, 56·6; H, 4·5. Calc. for $C_{14}H_{13}O_6N$: C, 57·7; H, 4·5%). After two recrystallisations from methyl alcohol, 33·3% of practically pure methyl *p*-nitrocinnamylidenemalonate, m. p. 139—143°, separated, which after crystallisation from ethyl acetate–ligroin had m. p. 146°, either alone or mixed with a synthetic specimen. The residue from the combined mother-liquors was oxidised with a boiling 2% solution of potassium permanganate, and gave nitrobenzoic acids in 78% yield (*M*, by titration, 165). On separation, this fraction gave 9·5% of *p*-nitrobenzoic acid, whilst the meta-isomeride present was less than 1·5%, since only a negligible quantity

of the meta-barium salt crystallised out, the amount present, therefore, only being represented by the solubility correction. The composition of the nitration product was thus: para-, 33·3% + (9·5% of 66·6%) = 40% ; meta-, <1%; ortho- (by difference), 59%.

Summary.

Substance nitrated.	Proportion of isomerides present, *o*-.	*m*-.	*p*-.	Mean % of *m*-.	*p*-.

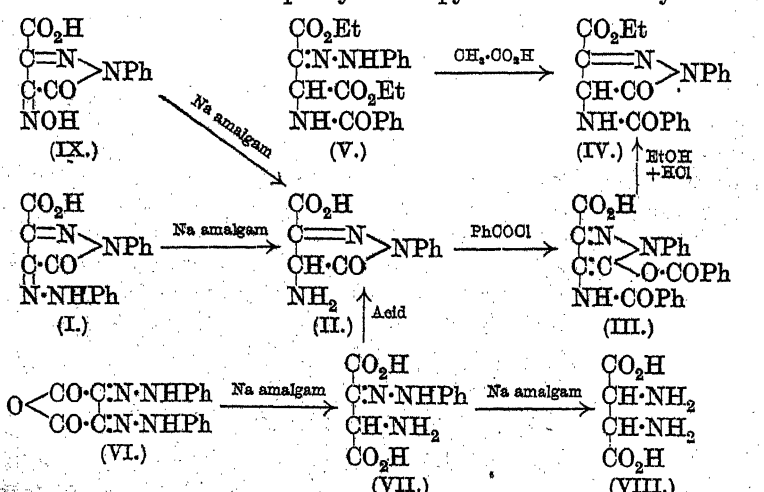
The authors desire to express their thanks to Professor C. K. Ingold, F.R.S., for his interest and advice during the progress of this investigation, and to the Royal Society for defraying part of the expense incurred.

THE UNIVERSITY, LEEDS. [*Received, July 6th*, 1927.]

CCLXXXIII.—1-*Phenyl*-4-*amino*-5-*ketopyrazoline*-3-*carboxylic Acid.*

By FREDERICK DANIEL CHATTAWAY and WILLIAM GERALD HUMPHREY.

ALTHOUGH it is well established that under the influence of acids, diketosuccinic acid phenylosazone is converted into 1-phenyl-4 : 5-diketopyrazoline-3-carboxylic acid 4-phenylhydrazone (I), the reduction of this compound to 1-*phenyl*-4-*amino*-5-*ketopyrazoline*-3-*carboxylic acid* (II) has never been satisfactorily effected (compare Bernthsen, *Chem.-Ztg.*, 1898, 457; Eibner and Laue, *Ber.*, 1906, **39**, 2022). If, however, reduction is effected by using the theoretical amount of sodium amalgam, and the amino-acid is liberated in the presence of some excess of sulphur dioxide (to prevent oxidation), it can be isolated in a pure condition.



1-Phenyl-4-amino-5-ketopyrazoline-3-carboxylic acid is a white, crystalline solid of neutral reaction. It is very sparingly soluble in all ordinary organic solvents, but dissolves readily both in aqueous acids and in alkalis, such solutions oxidising rapidly in presence of

air, especially when warm. Alkaline solutions are the more readily oxidised, giving a silver mirror with ammoniacal silver oxide, and precipitating cuprous oxide from warm Fehling's solution. Acid solutions reduce ferric chloride and potassium permanganate in the cold.

It combines with 1 mol. of hydrogen chloride yielding a comparatively stable *hydrochloride*, which, however, turns violet on exposure to air. With acetic anhydride it gives a soluble, well-crystallised *acetyl* derivative of marked acid character. With benzoyl chloride it yields a *dibenzoyl* derivative, and on boiling this for a short time with alcohol containing a little hydrogen chloride, it is converted into ethyl benzoate and the ester of a monobenzoyl derivative (IV), identical with the compound obtained by Wislicenus by boiling ethyl oxalylhippurate phenylhydrazone (V) with acetic acid (*Ber.*, 1891, 24, 1260).

1-Phenyl-4-amino-5-ketopyrazoline-3-carboxylic acid may be obtained in several other ways. For example, it is formed when the alkaline solution of amino-oxalacetic acid phenylhydrazone (VII), obtained by partial reduction of anhydrodiketosuccinic acid phenylosazone (VI) by sodium amalgam, is acidified, ring closure occurring under the influence of acids, just as in the case of diketosuccinic acid phenylosazone.

The amino-ketopyrazoline has also been prepared by reduction of the corresponding oximino-compound (IX), obtained by the action of nitrous acid on 1-phenyl-5-ketopyrazoline-3-carboxylic acid.

The action of bromine upon 1-phenyl-4 : 5-diketopyrazoline-3-carboxylic acid 4-phenylhydrazone has been re-examined and

the product shown to be 1-*phenyl*-4 : 5-*diketopyrazoline*-3-*carboxylic acid* 4-p-*bromophenylhydrazone*, since on reduction it yields *p*-bromoaniline and 1-phenyl-4-amino-5-ketopyrazoline-3-carboxylic acid. This constitution has been confirmed by its synthesis from 1-phenyl-5-ketopyrazoline-3-carboxylic acid and *p*-bromobenzenediazonium chloride.

Anhydrodiketosuccinic acid phenylosazone, like the corresponding halogenated derivatives (Chattaway and Humphrey, this vol., p. 1327), reacts with alcohols containing hydrogen chloride to give esters of the isomeric pyrazoline derivative. Several of these esters have been prepared, and it is noteworthy that the n-*propyl* and n-*butyl* esters have almost the same melting points.

EXPERIMENTAL.

Reduction of 1-*Phenyl*-4 : 5-*diketopyrazoline*-3-*carboxylic Acid* 4-*Phenylhydrazone* (I) *to* 1-*Phenyl*-4-*amino*-5-*ketopyrazoline*-3-*carboxylic Acid* (II).—17 G. of the phenylhydrazone were dissolved in 500 c.c. of a hot 1% solution of sodium hydroxide and placed in a wide-necked bottle closed by a cork, through which passed a wide glass tube reaching to the surface of the liquid and loosely stoppered at its upper end. The bottle was placed in a freezing mixture until about half of the liquid had frozen, and the air above the liquid was displaced by loosening the cork and passing a rapid stream of hydrogen down the tube. Successive small quantities of 2½% sodium amalgam were then introduced down the tube, and the mixture was vigorously shaken after each addition until the solution just became colourless and turbid due to the separation of aniline; about 250 g. of amalgam were required, and the reduction occupied 2—3 hours. The mixture was poured immediately into 800 c.c. of 2½% sulphuric acid (saturated with sulphur dioxide) and cooled to 0°. The 1-*phenyl*-4-*amino*-5-*ketopyrazoline*-3-*carboxylic acid* at once separated as a white, crystalline precipitate. It was filtered off immediately, washed thoroughly with air-free water, alcohol, and ether, and dried in a vacuum desiccator over calcium chloride; yield, 10 g.; m. p. 225° (decomp.; with darkening from 215°) (Found: C, 54·6; H, 3·9; N, 18·8. $C_{10}H_9O_3N_3$ requires C, 54·8; H, 4·1; N, 19·2%). This acid is comparatively stable when dry, but slowly oxidises and turns brownish-pink on keeping. It is very sparingly soluble in water or ether, and only sparingly soluble in boiling alcohol, benzene, chloroform, or acetone; such solutions rapidly oxidise and turn brown on exposure to air; it was therefore impossible to purify the compound by crystallisation.

The *hydrochloride* separates on cooling a hot saturated solution of the amino-ketopyrazoline in concentrated hydrochloric acid.

It forms long, colourless prisms which begin to darken and decompose at 160°; it is fairly stable when dry, but its aqueous solution darkens on keeping and the crystals themselves slowly become pale violet (Found: C, 13·7. $C_{10}H_{10}O_3N_3Cl$ requires Cl, 13·9%).

Acetyl derivative. 1-Phenyl-4-amino-5-ketopyrazoline-3-carboxylic acid dissolves apparently unchanged in boiling acetic anhydride, the solution rapidly turning dark reddish-brown owing to oxidation. On adding a drop of concentrated sulphuric acid, a vigorous reaction occurs; on adding a few drops of water and cooling, the *acetyl* compound crystallises out. It is easily soluble in hot acetic acid, from which it separates in long, colourless prisms, m. p. 216° (Found: C, 55·0; H, 4·2; N, 16·0. $C_{12}H_{11}O_4N_3$ requires C, 55·2; H, 4·2; N, 16·1%).

Dibenzoyl derivative (III). When an alkaline solution of 1-phenyl-4-amino-5-ketopyrazoline-3-carboxylic acid is shaken with excess of benzoyl chloride, it is converted into a *dibenzoyl* derivative. The same compound is more readily prepared by heating the amine (2 g.) with benzoyl chloride (3 c.c.) until hydrochloric acid is no longer evolved, cooling, and adding ether. It was recrystallised from boiling acetic acid, in which it is easily soluble and from which it separates in long, colourless prisms, m. p. 205° (Found: C, 67·7; H, 3·9; N, 10·0. $C_{24}H_{17}O_5N_3$ requires C, 67·5; H, 4·0; N, 9·8%).

Ethyl ester of 1-phenyl-4-benzamido-5-ketopyrazoline-3-carboxylic acid (IV). When the dibenzoyl derivative (III) is boiled for a short time with alcohol containing 1% of hydrogen chloride, an ethyl group is introduced and one benzoyl group removed. The bright yellow solution thus obtained smells strongly of ethyl benzoate, and on cooling, the *ethyl* ester separates in long, slender, canary-yellow prisms, m. p. 195° (Found: N, 12·1. $C_{19}H_{17}O_4N_3$ requires N, 12·0%).

Preparation of 1-Phenyl-4-amino-5-ketopyrazoline-3-carboxylic Acid by Reduction of Anhydrodiketosuccinic Acid Phenylosazone.—The reduction of anhydrodiketosuccinic acid phenylosazone proceeds in two stages. The reduction by alkaline reducing agents of one phenylhydrazone group must first give amino-oxalacetic acid phenylhydrazone; this, however, cannot be isolated, for on acidification ring closure and pyrazoline formation occur and 1-phenyl-4-amino-5-ketopyrazoline-3-carboxylic acid is produced. This change was to be expected, since the disodium salt of the osazone is itself converted quantitatively into a pyrazoline derivative on acidification.

The reduction of both phenylhydrazone groups by alkaline reducing agents yields the two stereoisomeric diaminosuccinic acids, which separate when the solution is acidified. These compounds

were prepared by Farchy and Tafel by reduction of the osazone (*Ber.*, 1893, **26**, 1980).

Partial reduction. A fine suspension of 17 g. of anhydrodiketosuccinic acid phenylosazone in 500 c.c. of 1% sodium hydroxide solution was cooled in a freezing-mixture and treated with successive small quantities of 2½% sodium amalgam in the apparatus described above, until the yellow colour had just disappeared; about 250 g. of the amalgam were required. The colourless liquid was then decanted from the remaining mercury and slowly poured into 800 c.c. of ice-cold 2½% sulphuric acid saturated with sulphur dioxide; 1-phenyl-4-amino-5-ketopyrazoline-3-carboxylic acid then separated as a white precipitate which was filtered off, washed, and dried as before; yield, 9 g. It was shown to be identical with the compound previously described, since it melted at 215—225° with complete decomposition, and yielded an identical acetyl derivative, m. p. 216°.

Complete reduction. A fine suspension of 19 g. of the anhydride in 500 c.c. of a 1% aqueous solution of sodium hydroxide was cooled and reduced with a considerable excess of 2½% sodium amalgam (650 g.) in the manner described by Farchy and Tafel for the corresponding osazone. From the alkaline solution thus obtained, the two stereoisomeric diaminosuccinic acids were isolated and purified in precisely the same manner as described by Farchy and Tafel. The two isomerides were identified by conversion to their dibenzoyl derivatives; the dibenzoyl derivative of the *meso*-modification melts with decomp. at 213°, and that of the *r*-acid at 183°.

1-*Phenyl*-4-*oximino*-5-*ketopyrazoline*-3-*carboxylic Acid* (IX).—10 G. of 1-phenyl-5-ketopyrazoline-3-carboxylic acid (prepared from ethyl oxalacetate phenylhydrazone, as described by Wislicenus, *Annalen*, 1888, **246**, 319) and 5 g. of sodium nitrite were dissolved in 150 c.c. of 30% aqueous potassium hydroxide; the solution was cooled to 0° and added slowly to 200 c.c. of 10% hydrochloric acid. The *oximino*-compound separated as a red precipitate, which after 12 hours was filtered off and crystallised from acetic acid, in which it is easily soluble, and from which it separates in glittering, red, slender prisms, m. p. 209° (decomp.); yield, 9 g. (Found: N, 17·8. $C_{10}H_7O_4N_3$ requires N, 18·0%).

When reduced it yields 1-phenyl-4-amino-5-ketopyrazoline-3-carboxylic acid. A solution of 2 g. of the oximino-compound in 100 c.c. of a 1% aqueous solution of sodium hydroxide was cooled in a freezing mixture and reduced with 40 g. of 2½% sodium amalgam. The colourless solution was then poured into 120 c.c. of 3% sulphuric acid, saturated with sulphur dioxide. The amino-keto-

pyrazoline separated as a white, crystalline powder, which was filtered off, washed, and dried as before. Yield 1·7 g. It was identified by its acetyl derivative, m. p. 216°.

Bromination of 1-Phenyl-4 : 5-diketopyrazoline-3-carboxylic Acid 4-Phenylhydrazone.—In view of recent work on the bromination of phenylhydrazones (J., 1925, 127, 975, 1687, 2407; this vol., p. 1323), it was of interest to determine to what extent bromine would enter the phenylhydrazone residue in 1-phenyl-4 : 5-diketopyrazoline-3-carboxylic acid 4-phenylhydrazone. 6 G. (1 mol.) of the hydrazone were suspended in 400 c.c. of glacial acetic acid containing 4 c.c. (4 mols.) of bromine, and boiled for 8 hours. Hydrogen bromide was evolved, and on cooling, the *bromination product* separated as a yellow solid. It was crystallised from boiling acetic acid, in which it is sparingly soluble, and from which it separates in short, yellow prisms, m. p. 258° (decomp.). Yield, 6 g. (Found : Br, 20·6. $C_{16}H_{11}O_3N_4Br$ requires Br, 20·7%).

The bromine was shown to have entered the para-position by the production of *p*-bromoaniline on reduction : 5 G. of the bromination product were dissolved in 150 c.c. of 1% aqueous sodium hydroxide and reduced as before with 80 g. of 2½% sodium amalgam; when this was poured into 200 c.c. of 2½% sulphuric acid, saturated with sulphur dioxide, 1-phenyl-4-amino-5-ketopyrazoline-3-carboxylic acid separated as a white precipitate (yield, 2 g.; acetyl derivative, m. p. 216°). The acid filtrate was concentrated, made alkaline with caustic soda and steam-distilled. *p*-Bromoaniline (m. p. 63°) distilled over, and was identified by conversion to its acetyl derivative, m. p. 167°.

The constitution of the bromination product was further established by its synthesis from 1-phenyl-5-ketopyrazoline-3-carboxylic acid by the action of *p*-bromobenzenediazonium chloride. 2 G. of *p*-bromoaniline were suspended in 3·5 c.c. of concentrated hydrochloric acid and diazotised with 1 g. of sodium nitrite in 25 c.c. of water; the small excess of nitrous acid was removed by bubbling air through the solution, which was then added to a solution of 2 g. of 1-phenyl-5-ketopyrazoline-3-carboxylic acid in 100 c.c. of a 2% aqueous solution of potassium hydroxide. 1-Phenyl-4 : 5-diketopyrazoline-3-carboxylic acid 4-*p*-bromophenylhydrazone separated as a yellow precipitate, which, after the addition of excess of hydrochloric acid, was filtered off, washed with hot alcohol, and crystallised from acetic acid. It melted at 258° (decomp.) and was identical in all respects with the compound obtained by the direct bromination (above).

In the course of this investigation, several esters of 1-phenyl-4 : 5-diketopyrazoline-3-carboxylic acid 4-phenylhydrazone have

been prepared by the action of alcohols containing hydrogen chloride on anhydrodiketosuccinic acid phenylosazone. The *methyl* ester, obtained by boiling the phenylosazone (2 g.) for 24 hours with methyl alcohol (30 g.) saturated with dry hydrogen chloride, crystallises from alcohol, in which it is easily soluble, in fine, yellow needles, m. p. 138° (Found: N, 17·4. $C_{17}H_{14}O_3N_4$ requires N, 17·4%). The ethyl ester (Wislicenus and Scheidt, *Ber.*, 1891, **24**, 4210), m. p. 153°, is obtained in a similar manner. The n-*propyl* ester crystallises from acetic acid, in which it is easily soluble, in long, deep yellow prisms, m. p. 116·5° (Found: C, 65·0; H, 4·9; N, 16·1. $C_{19}H_{18}O_3N_4$ requires C, 65·1; H, 5·1; N, 16·0%). The n-*butyl* ester crystallises from acetic acid in long prisms, not quite so deep in colour as those of the *n*-propyl ester but melting at practically the same temperature, 117° (a mixture of these two esters had m. p. 112°) (Found: C, 66·2; H, 5·5; N, 15·5. $C_{20}H_{20}O_3N_4$ requires C, 65·9; H, 5·5; N, 15·4%).

THE QUEEN'S COLLEGE, OXFORD. [*Received, June 29th*, 1927.]

CCLXXXIV.—*The Action of Hydrogen Iodide on Nitroso-compounds.*

By JOHN CAMPBELL EARL and JAMES KENNER.

THE observation of the ortho-para directive influence of the nitroso-group in aromatic substitution was considered by Ingold (J., 1925, **127**, 513) to be in conflict with the theory of induced alternate polarity, but a theoretical discussion of the nitroso-group by Robinson (*Chem. and Industry*, 1925, **44**, 456) showed this to be at least not necessarily the case. In addition, it was pointed out (Kenner, Tod, and Witham, J., 1925, **127**, 2343) that, quite apart from any purely theoretical considerations, the well-known liberation of iodine from hydrogen iodide by nitrous acid, by hypochlorous acid, and by hydrogen peroxide is a simple experimental indication of possible similarity in polar properties of the nitroso-group, the chlorine atom, and the hydroxyl group. The analogy is not perfect, since in the case of nitrous acid the primary nitrogenous product undergoes a further reaction with formation of nitric oxide, but a parallelism also exists between the behaviours of the nitroso-group and chlorine, in that each is readily displaced from *N*-nitroso- or -chloro-amines and -acetanilides (von Pechmann and Frobenius, *Ber.*, 1894, **27**, 651).

It seemed that further evidence in regard to the nature of the nitroso-group might be obtained from a study of the action of

hydrogen iodide on nitroso-compounds in general. Reference to the literature showed that among aliphatic compounds, iodine is liberated from hydrogen iodide by the nitrosochlorides of tetramethylethylene (I) (Thiele, *Ber.*, 1894, **27**, 456) and $\Delta^{4(8)}$-menthen-1-ol (γ-terpineol) acetate (II) (Baeyer, *ibid.*, p. 446). Later, Baeyer showed the

(I.) $Me_2C(NO)\cdot CMe_2Cl$ $\qquad$ $Me_2C(NO)\cdot C(Cl)<\begin{matrix}CH_2\cdot CH_2\\CH_2\cdot CH_2\end{matrix}>C<\begin{matrix}Me\\OAc\end{matrix}$ (II.)

$Me_2C(NH\cdot OH)\cdot C(Br)<\begin{matrix}CH_2\cdot CH_2\\CH_2\cdot CH_2\end{matrix}>C<\begin{matrix}Me\\Br\end{matrix}$ (III.)

nitrosobromide of 1-bromo-$\Delta^{4(8)}$-menthene to be converted into the hydroxylamino-derivative (III) by hydrogen bromide, in the presence of red phosphorus as an absorbent of the bromine liberated, and concluded that the reaction with hydrogen iodide follows a similar course. Baeyer observed (*loc. cit.*) that the nitrosochlorides of tetramethylethylene and menthenol acetate behaved differently towards hydrogen bromide in acetic acid. There is, however, no essential difference between the two reactions. The product derived from tetramethylethylene nitrosochloride is a basic substance, which, like the compounds examined by Baeyer, loses the elements of hydrogen chloride when it is liberated in the presence of alkali. The colourless *hydrochloride* of the resulting unsaturated base exhibits reducing properties and its composition corresponds with the formula (IV). In further support of the constitution

$Me_2CCl\cdot Me_2C\cdot NO \longrightarrow Me_2CCl\cdot Me_2C\cdot NH\cdot OH \longrightarrow MeC{:}CH_2\cdot Me_2C\cdot NH\cdot OH,HCl$ (IV.)

assigned to this compound, it was shown to furnish a *condensation product* with salicylic aldehyde, the composition of which was in accord with the formula (V) (compare Bamberger, *Ber.*, 1894, **27**, 2556).

(V.)

There seemed also a possibility that the negative character of the nitroso-group might induce positive polarity in the chlorine atom, which, in the presence of hydrogen iodide, would render it liable to displacement by hydrogen. It was, however, shown that this does not occur in either of the above instances, since the quantity of iodine liberated in the reaction was found to correspond approximately with the decrease in the amount of halogen ion present in solution. The slight discrepancy was shown to be attributable to formation of chlorine ions by hydrolytic action, which

occurred in absence of hydrogen iodide under otherwise similar experimental conditions.

Since the conditions for the transmission of the influence of the nitroso-group to the chlorine atom should be more favourable in the aromatic nucleus than in the above compounds, the behaviour of *p*-chloronitrosobenzene towards hydrogen iodide was investigated. Here also reduction occurred, being immediately followed by condensation of the hydroxylamine with the nitroso-derivative, so that 4 : 4′-dichloroazoxybenzene was produced in excellent yield. No elimination of halogen occurred from *p*-chloronitrosobenzene or from its meta-isomeride under the conditions employed. The nitroso-group itself is therefore the sole point of attack by hydrogen iodide in such cases. Doubtless its reactivity in the aromatic compounds is affected by the position of the chlorine atom, but our hopes of demonstrating this relationship could not be realised owing to the uncertainty as to the relative proportions of polymerised and unpolymerised material present in solution, and to the condensation of nitroso- with hydroxylamino-derivatives just mentioned.

In order further to demonstrate the general character of the reaction here discussed, δ-nitroso-δ-methylpentan-β-one (VI) (Harries, *Ber.*, 1898, **31**, 1379), 8-nitrosomenthone (VII) (Harries and Rolder, *Ber.*, 1899, **32**, 3365), and 4-nitrosomenthone (VIII) (Baeyer, *Ber.*, 1894, **27**, 1912; 1895, **28**, 1586) were examined qualitatively in respect of their behaviour towards hydrogen iodide.

(VI.) $CMe_2(NO)\cdot CH_2\cdot COMe$ $\quad$ $Me_2C(NO)\cdot CH<\begin{matrix}CH_2\cdot CH_2\\ CO-CH_2\end{matrix}>CHMe$ (VII.)

$Me_2CH\cdot C(NO)<\begin{matrix}CH_2\cdot CH_2\\ CO-CH_2\end{matrix}>CHMe$ (VIII.)

In each case, iodine was liberated, but the rate of reaction, as in other cases, was affected by the degree of polymerisation of the nitroso-compounds.

It may therefore be concluded that nitroso-compounds, in general, are reduced by hydrogen iodide to the corresponding hydroxylamines. The facility with which this occurs is in remarkable contrast to the behaviour of carbonyl compounds, with which nitroso-compounds are in some respects comparable. The significance of this contrast will be dealt with in a subsequent paper discussing the chemistry of nitroso-compounds. Meanwhile, the possibility must be entertained in the case of nitrous acid, also, that

$$HO\cdot NO \longrightarrow HO\cdot NH\cdot OH \text{ (IX.)} \qquad H\cdot NO \text{ (X.)}$$

the primary action leads to the formation of dihydroxyammonia (IX) rather than of nitroxyl (X), as might be anticipated from the

analogy between the nitroso- and hydroxyl groups or the chlorine atom mentioned at the outset of this paper. This possibility must also be regarded as the more probable, when it is recalled that the ultimate nitrogenous product of the reaction is nitric oxide, the formation of which could be represented by the equation $NH(OH)_2 + HO{\cdot}NO \longrightarrow 2NO + 2H_2O$ (compare Raschig, "Schwefel und Stickstoffstudien," Leipzig, 1925, p. 19; Angeli and Angelico, *Gazzetta*, 1900, **30**, i, 593; *Ber.*, 1904, **37**, 2390).

EXPERIMENTAL.

Reduction of Tetramethylethylene Nitrosochloride by Hydrogen Bromide.—A concentrated glacial acetic acid solution of hydrogen bromide (42 c.c.) was mixed with red phosphorus (1·4 g.) and cooled in ice-water until crystallisation commenced (12°); tetramethylethylene nitrosochloride (7 g.) was then added with thorough stirring. The reaction was completed by passing a stream of hydrogen bromide into the ice-cooled mixture during a period of 1 hour, and stirring for another 2 hours. The liquid was then added to a mixture of ice (60 g.) and water (60 g.), and the undissolved material filtered off. Benzene (50 c.c.) was added, together with sufficient sodium hydroxide solution to render the aqueous layer strongly alkaline. The liberated base passed into solution in the benzene, and after further extraction of the alkaline solution with benzene, the united extracts were shaken four times with hydrochloric acid (25 c.c.) diluted with an equal volume of water. The solid residue obtained by evaporating the united acid extracts to dryness under reduced pressure was purified by filtering its solution in alcohol, and again evaporating to dryness. The *hydrochloride* of *β-hydroxyl-amino-βγ-dimethyl-Δ$^{\gamma}$-butene* so obtained (4·5 g.) was further purified by recrystallisation from alcohol (Found: N, 9·5; Cl, 23·1. $C_6H_{13}ON,HCl$ requires N, 9·2; Cl, 23·2%). The base reduced Fehling's solution in the cold.

When the hydrochloride (0·8 g.) was dissolved in water (5 c.c.) with the addition of crystalline sodium acetate (1·2 g.), salicylic aldehyde (0·65 g.), and alcohol (5 c.c.), condensation readily occurred at the ordinary temperature. After 19 hours, the mixture was poured into ice water, and an oil separated which soon crystallised. The solid (0·55 g.) was filtered off, and a further quantity (0·2 g.) separated on saturating the filtrate with salt and cooling in ice. After one crystallisation from alcohol, the *condensation product* melted sharply at 53° (Found, by micro-analysis: N, 6·4. $C_{13}H_{17}O_2N$ requires N, 6·4%).

Reduction of Tetramethylethylene Nitrosochloride by Hydrogen Iodide.—A solution of the nitrosochloride (0·1355 g.) in pure benzene

(10 c.c.) was shaken with a mixture of an approximately $N/5$-solution of potassium iodide (corresponding to 19·94 c.c. of accurately $N/5$-solution) and an approximately $N/2$-solution of sulphuric acid (20 c.c.). After 3½ hours, the benzene layer, which contained the bulk of the liberated iodine, was separated, and the aqueous layer extracted with benzene until practically colourless. The halogen ion in the aqueous solution was then titrated with silver nitrate and potassium thiocyanate in the usual way, and found equivalent to 13·12 c.c. of $N/5$-solution. The united benzene solutions were shaken with excess of standard sodium thiosulphate, the excess being titrated with standard iodine. The iodine thus determined corresponded to 7·43 c.c. of $N/5$-solution.

It would thus appear that halogen corresponding to 0·61 c.c. of $N/5$-solution had been furnished by elimination of chlorine from the nitrosochloride. This occurred by hydrolysis, for when a similar benzene solution of the nitrosochloride was shaken for 3½ hours with dilute sulphuric acid under very similar conditions, the aqueous layer contained halogen corresponding to 2·0 c.c. of $N/5$-solution. In this case, of course, there was no decrease in the concentration of the nitrosochloride solution owing to reduction during the experiment, so that the amount of hydrolysis is higher than in the reduction experiments.

Reduction of γ-Terpinyl Acetate Nitrosochloride by Hydrogen Iodide.—The reaction was slower than in the case of the tetramethylethylene derivative so that a higher concentration of the nitrosochloride (0·2466 g. in 10 c.c. of benzene) was employed, and the shaking was continued for 5 hours. In other respects, the experimental conditions were similar to those described above.

Halogen originally present in aqueous solution = 19·94 c.c.
" finally " " " " = 18·75 c.c.
Iodine liberated = 1·37 c.c.

Here, again, there is evidence of slight hydrolysis.

Reduction of Chloronitrosobenzenes by Hydrogen Iodide.—Both the *m*- and *p*-isomerides were examined in the usual way, 0·5 g. of the substance in benzene (10 c.c.) being used, and the shaking being continued for 4 hours.

	m-.	*p*-.
Halogen originally present in aqueous solution (c.c. of $N/5$)	19·94	19·94
" finally " " " "	17·82	18·72
Iodine liberated (c.c. of $N/5$)	2·08	1·57

These results indicate a similarity in behaviour to the two nitrosochlorides, but in neither case was there any evidence of the removal of chlorine by hydrolysis.

An attempt was made to modify the reduction in such a way that

the isolation of the reduction products would be possible. For this purpose, it was necessary to introduce some substance to remove the iodine as formed. Red phosphorus, mercury, and sodium thiosulphate were all successfully employed. Thus a mixture of *p*-chloronitrosobenzene (1 g.) red phosphorus (1 g.), and glacial acetic acid (25 c.c.) was well stirred at room temperature, and hydriodic acid (*d* 1·7; 5 c.c.) added drop by drop during 5 minutes. The mixture became warm and a mass of crystalline material separated. After a further 5 minutes, water was added, and the precipitated material was filtered off and washed thoroughly with water. The *pp'*-dichloroazoxybenzene was extracted from the residue by repeated maceration with ether, and the solvent allowed to evaporate at room temperature. The product so obtained (0·83 g.) melted at 153—154°, and at 154° after one recrystallisation from alcohol (Found, by micro-analysis: N, 10·7. Calc. for $C_{12}H_8ON_2Cl_2$: N, 10·5%). In another experiment the azoxy-compound (0·7 g., m. p. 153°) was obtained from the nitroso-derivative (0·85 g.), glacial acetic acid (25 c.c.), mercury (9·5 g.), and hydriodic acid (*d* 1·7; 3 c.c.).

From *m*-chloronitrosobenzene by means of phosphorus, *mm'*-dichloroazoxybenzene, m. p. 96°, was obtained (Found: N, 10·1%).

Action of Hydriodic Acid on the Nitroso-derivatives.—δ-Nitroso-δ-methylpentan-β-one yielded a colourless solution in acetone, which only reacted very slowly at the ordinary temperature with hydriodic acid, but when the solution was first warmed until a definite blue colour had developed, and then cooled, liberation of iodine occurred much more rapidly. 8-Nitrosomenthone, though blue when first prepared, slowly polymerises and therefore also reacts comparatively slowly with hydriodic acid in acetone solution. 4-Nitrosomenthone was definitely recognised by Baeyer (*loc. cit.*) to be a bis-compound, but nevertheless has some tendency towards dissociation since its solution in xylene became blue when heated. Although no similar development of colour occurred in boiling acetone solution, yet iodine was slowly liberated when a cold solution in acetone was treated with hydriodic acid.

Note on the Action of Hydriodic Acid on Ether.—Whilst it is well known that hydrogen iodide reacts with ethyl ether to form ethyl iodide, it is not recorded in the standard work of reference that they react in some way at the ordinary temperature with formation of iodine. This was observed in connexion with the experiments now described, and prevented the use of ether as solvent in cases where it would otherwise have been very desirable. The only reference to this reaction which we have been able to find is a statement by Hantzsch, who experienced the same difficulty and stated

that "Jodwasserstoff in diesem Medium schon durch unvermeidliche Spuren von Sauerstoff zum Trijodwasserstoff oxydiert wird" (*Z. Elektrochem.*, 1923, **29**, 232). In a quantitative experiment with ether purified in the usual manner (20 c.c.), aqueous potassium iodide solution (*N*/5, 20 c.c.), and dilute sulphuric acid (*N*/2, 20 c.c.), the iodine liberated after some days at the ordinary temperature required 8·5 c.c. of *N*/10-thiosulphate.

THE UNIVERSITY, SYDNEY. [*Received, June 27th*, 1927.]

CCLXXXV. — *Co-ordination Compounds of Quinquevalent Molybdenum.*

By ROBERT GILBERT JAMES and WILLIAM WARDLAW.

ONE important result of the application of electronic theories of valency to co-ordination compounds has been to indicate the relative stabilities of the systems within the co-ordination sphere. The marked stability of the ion $Mo(CN)_8''''$, present in an aqueous solution of the complex salt $K_4Mo(CN)_8$, can be readily appreciated when it is seen that the effective atomic number of the molybdenum is 54—that of the next inert gas—and that the associating units are regularly distributed. The stability of complex salts is not, however, the same for all associated units, the order of decreasing stability being cyanides, fluorides, thiocyanates, chlorides, bromides, and iodides, and this third factor must always have consideration. In a recent investigation (this vol., p. 512) on the complex chlorides of tervalent molybdenum, such as K_3MoCl_6 and K_2MoCl_5,H_2O, it was shown that ionisation in dilute aqueous solution produced initially four and three ions, respectively, but that the complex ions were gradually decomposed. Here, the effective atomic number of the metallic atom is 51 and the decreased stability of the complex ion $MoCl_6'''$, compared with that of the ion $Mo(CN)_8''''$, is due primarily to the smaller number of electrons associated with the molybdenum atom, but also to the replacement of the cyanide by the chloride radical. With the chlorides of quinquevalent molybdenum of the general formula $R_2[MoOCl_5]$, the effective atomic number of the central atom has fallen to 49, and this is reflected in the marked changes which occur when these green, crystalline substances are dissolved in water. They give, immediately, brown solutions with acid reactions, from which it is impossible to obtain the original salt satisfactorily by crystallisation. Although these facts are well known, no systematic examination of this decomposition has hitherto been attempted. In the present research,

this has been done, and not only has it yielded information as to the course of the reaction in aqueous solution, but it has resulted in the evolution of improved methods of preparation for the complex salts themselves, and in the isolation of new series of co-ordination compounds characteristic of the intermediate stages of the hydrolytic decomposition.

EXPERIMENTAL.

Chilesotti (*Z. Elektrochem.*, 1906, **12**, 173) first showed that by electrolytic reduction of molybdenum trioxide, dissolved in hydrochloric acid of appropriate concentration, a solution containing quinquevalent molybdenum could be obtained if a platinised platinum cathode was used, whereas with a cathode of polished platinum, reduction to the tervalent state resulted. This observation has been utilised in the following preparations.

Molybdenum trioxide solution. Molybdenum trioxide (100 g.) was heated with 500 c.c. of hydrochloric acid (*d* 1·16) till dissolved; the solution was evaporated to 250 c.c., filtered, and made up to 500 c.c. with hydrochloric acid, and thus contained molybdenum trioxide (20%) in 9*N*-hydrochloric acid.

Salts of the Type $R_2[MoOCl_5]$.

Diammonium Molybdenyl Pentachloride.—Klason (*Ber.*, 1901, **34**, 148) and Nordenskjold (*ibid.*, p. 1572) obtained this salt by reducing ammonium molybdate in concentrated hydrochloric acid with hydrogen iodide, whilst Foerster and Fricke (*Z. angew. Chem.*, 1923, **36**, 458), using Chilesotti's results (*loc. cit.*), prepared it by the electrolytic reduction method, of which the following is a variation: 75 C.c. of the molybdenum trioxide solution, diluted with an equal volume of water, were placed in the cathode chamber of a diaphragm cell, of which the anode chamber contained hydrochloric acid (5*N*). A polished platinum electrode served as the anode, whilst the cathode was of platinised platinum, 5 cm. square. A current of 2·5 amp. was employed, and on electrolytic reduction to the quinquevalent stage, a reddish-brown cathode solution was obtained. This was concentrated to 50 c.c. under diminished pressure, 30 c.c. of ammonium chloride solution (containing 9 g.) were admitted, and the mixture was heated for about a minute. On saturating with hydrogen chloride and cooling, emerald-green crystals separated. These were recrystallised by dissolving in the minimum volume of water at *ca.* 80°, and saturating with hydrogen chloride until cold. The crystals were washed with concentrated hydrochloric acid and dried in a vacuum over solid potassium hydroxide.

Analysis. The molybdenum was precipitated as sulphide (J., 1924, **125**, 1911), ignited, and weighed as the trioxide, the chloride

in the filtrate and washings being estimated as silver chloride. The ammonia was determined by the distillation method, the ammoniacal distillate being titrated continuously against standard acid with bromophenol-blue as indicator [Found: Mo, 29·5; Cl, 54·4; NH_4, 11·1. Calc. for $(NH_4)_2MoOCl_5$: Mo, 29·5; Cl, 54·5; NH_4, 11·1%].

A New Electrolytic Method.—150 C.c. of the prepared molybdenum trioxide solution were placed in the cathode chamber of the diaphragm cell, the anode chamber containing ammonia (10*N*) and a small quantity of ammonium chloride. On electrolysis with a current density of 0·1 amp. per sq. cm. and continuous saturation of the cathode liquid with hydrogen chloride, the diammonium molybdenyl pentachloride separated in good yield. After being washed and dried, the crystals gave Mo, 29·3; Cl, 54·6; NH_4, 11·1%.

Dirubidium Molybdenyl Pentachloride.—This salt was first prepared by Nordenskjold (*loc. cit.*) and later by Foerster and Fricke (*loc. cit.*). By the use of the first of the methods here described for the preparation of the ammonium salt, but adding 30 c.c. of a rubidium chloride solution (containing 14 g.), yellowish-green crystals were obtained, which were washed, dried, and recrystallised (Found: Mo, 20·9; Cl, 38·6; Rb, 36·9. Calc. for Rb_2MoOCl_5: Mo, 20·9; Cl, 38·5; Rb, 37·1%).

Dipotassium Molybdenyl Pentachloride.—The methods described by Nordenskjold and by Foerster and Fricke for the preparation of this salt were found always to give a product contaminated with potassium chloride. The following method gave an excellent yield of pure salt, which, being crystallised at a high temperature, was obtained free from the more soluble alkali chloride: 75 C.c. of molybdenum trioxide solution, diluted with 75 c.c. of water, were electrolytically reduced to the quinquevalent condition. The resulting solution was concentrated under diminished pressure to 50 c.c., 30 c.c. of potassium chloride solution (containing 6·5 g.) were added, and the solution was further concentrated to 70 c.c. The flask was now placed in a thermostat at 90°, and the solution saturated with hydrogen chloride. With the hydrogen chloride still passing through the solution, the temperature was lowered to 70°, whereupon the required green salt began to separate; the temperature of the thermostat was then altered to and maintained at 60° and a high yield of the complex salt was thus obtained. The dark green crystals were filtered through a hot filter, drained in a current of dry hydrogen chloride, and dried in a vacuum over solid potassium hydroxide and phosphoric oxide [Found: Mo, 25·8; Cl, 47·4; K, 20·9. Calc. for K_2MoOCl_5: Mo, 26·1; Cl, 48·

K, 21·3%; the presence of a small amount of water of crystallisation ($0{\cdot}25H_2O$) accounts for the slight difference].

Dipyridinium Molybdenyl Pentachloride.—The only method previously described for the preparation of this salt is that of Rosenheim and Koss (*Z. anorg. Chem.*, 1906, **49**, 148) and of Sand and Burger (*Ber.*, 1906, **39**, 1761), who obtained it by the action of hydrochloric acid on the complex compound $Mo(OH)_2(CNS)_3(C_5H_5N)_2$. The following method gave an almost theoretical yield of pure salt: 150 C.c. of the molybdenum trioxide solution, reduced electrolytically to the quinquevalent stage, were evaporated on a water-bath under diminished pressure almost to dryness; alcohol, saturated with hydrogen chloride, was now admitted, and after warming and agitation, the reddish-brown mass dissolved producing an emerald-green solution (100 c.c.). This was cooled to room temperature, saturated with hydrogen chloride, and filtered if necessary; one half of the filtrate was utilised for the preparation of the pyridinium salt, and the other half for the quinolinium derivative. By the addition of alcohol saturated with hydrogen chloride, the 50 c.c. of solution were made up to 100 c.c., and to this water-cooled solution pyridine was added, drop by drop, with constant stirring till no more green precipitate separated (excess of pyridine gives a red solution). This was filtered and dissolved in alcoholic hydrogen chloride (2 vols. of alcohol, saturated with hydrogen chloride at room temperature, and 1 vol. of absolute alcohol). On concentrating this solution, yellowish-green crystals separated; these were filtered, washed with alcohol saturated with hydrogen chloride, and dried over potassium hydroxide and phosphoric oxide in a vacuum [Found: Mo, 21·4; Cl, 39·6; N, 6·2; C, 26·8; H, 2·7. Calc. for $(C_5H_6N)_2MoOCl_5$: Mo, 21·4; Cl, 39·5; N, 6·2; C, 26·7; H, 2·7%].

Diquinolinium molybdenyl pentachloride was prepared by adding pure quinoline (18 g.) with constant stirring to the boiling molybdenum solution previously mentioned. On evaporation and crystallisation, a large amount of the required substance was obtained, which was recrystallised and dried as in the case of the pyridinium compound [Found: Mo, 16·9; Cl, 31·2; N, 5·0; C, 37·8; H, 3·3. $(C_9H_8N)_2MoOCl_5,H_2O$ requires Mo, 16·9; Cl, 31·3; N, 4·9; C, 38·1; H, 3·2%].

Ditrimethylammonium Molybdenyl Pentachloride.—Nordenskjold (*loc. cit.*) prepared this salt by employing hydrogen iodide as a reducing agent. Using the electrolytic reduction method under conditions to be described later, the present authors isolated the first chloride of the type $R[MoOCl_4,H_2O]$ as *mono*trimethylammonium molybdenyl tetrachloride, $NMe_3H[MoOCl_4,H_2O]$ (see below), and converted it into the ditrimethylammonium pentachloride by

dissolving it in alcoholic hydrogen chloride, evaporating to small bulk, saturating with hydrogen chloride, and allowing to crystallise. After recrystallisation, the light emerald-green crystals were washed with alcoholic hydrogen chloride and dried in a vacuum over solid potassium hydroxide and phosphoric oxide {Found: Mo, 23·5; Cl, 43·2; N, 6·9; C, 17·6; H, 5·1. Calc. for $[(CH_3)_3NH]_2MoOCl_5$: Mo, 23·5; Cl, 43·3; N, 6·8; C, 17·6; H, 4·9%}.

General Properties of the Complex Salts.—The salts described in this paper generally crystallise in the rhombic form and range in colour from dark green through shades of emerald-green to yellowish-green. The pyridinium salt exhibits a strong pleochroism and has a very high double refraction. When exposed to a moist atmosphere, these salts more or less rapidly turn reddish-brown, in which condition they are very susceptible to aërial oxidation, molybdenum blue being formed. The pyridinium and the ditrimethylammonium salts give a bright copper-red substance at one stage of these changes. The potassium and the substituted-ammonium salts are the most sensitive, and the quinolinium the least sensitive, to the action of moist air. All the complex salts are soluble in water, the concentrated solutions being reddish-brown, passing through orange to bright yellow on dilution. On saturation with hydrogen chloride, these aqueous solutions finally turn emerald-green and from sufficiently concentrated solutions the complex salts separate. Alcohol dissolves all these green salts, and from the solution of the alkali complex salts, alkali chlorides separate on heating. The pyridinium salt under these conditions yields a red precipitate which will be referred to in detail later. The addition of pyridine or quinoline to aqueous solutions of any of the complex salts gives a brown, insoluble precipitate.

Physico-chemical Measurements.

Molecular-weight Determinations.—The molecular weight was determined by the depression of the freezing point of air-free water.

The figures given on p. 2150 indicate that the complex salts $R_2[MoOCl_5]$ undergo extensive ionisation in aqueous solution, and instead of yielding the (theoretical) 3 ions, furnish 9 ions in the reddish-brown solutions of concentrations *ca.* 0·02—0·05 g.-mol. per litre, and 10—11 ions in the bright yellow solutions obtained by further dilution. Additional evidence for this ionisation in aqueous solution is afforded by determinations of molecular conductivity. Table II gives the value of μ at 0° for various dilutions v (as litres per mol.).

A satisfactory explanation of the high molecular conductivity and the exceptional osmotic factor is forthcoming if it be assumed

μ	659·1	842·6	914·7	959	693	870	929	

that the complex ion $MoOCl_5''$ is unstable, and that ionisation and hydrolysis occur in accordance with the following scheme:

$$\begin{aligned}
R_2[MoOCl_5] + H_2O &\rightleftharpoons R[MoOCl_4,H_2O] + RCl,\\
R[MoOCl_4,H_2O] + H_2O &\rightleftharpoons [MoOCl_3,2H_2O] + RCl,\\
[MoOCl_3,2H_2O] + H_2O &\rightleftharpoons [MoO(OH)Cl_2,2H_2O] + HCl,\\
[MoO(OH)Cl_2,2H_2O] + H_2O &\rightleftharpoons [MoO(OH)_2Cl,2H_2O] + HCl,\\
&\rightleftharpoons [MoO_2Cl,3H_2O] + HCl,\\
[MoO_2Cl,3H_2O] + H_2O &\rightleftharpoons [MoO_2(OH),3H_2O] + HCl,
\end{aligned}$$

Whence, at infinite dilution:

$$R_2[MoOCl_5] + 5H_2O \rightleftharpoons [MoO_2(OH),3H_2O] + 2RCl + 3HCl.$$

In the first place, it is seen from such a scheme of ionisation that 10 ions should result at infinite dilution and that the osmotic factor should be 11. These theoretical deductions are in accordance with the experimental data. The ionic velocities at 0° deduced from the values at 18° (Landolt–Börnstein, "Tabellen," 1923, ii, 1104) are: $H^{\cdot} = 227{\cdot}6$; $Cl' = 40{\cdot}0$; $Rb^{\cdot} = 41{\cdot}5$; $NH_4^{\cdot} = 38{\cdot}4$. From the ammonium and rubidium salts, for example, which on the proposed scheme of ionisation should each yield at infinite dilution 2 metal (or ammonium), 3 hydrogen, and 5 chlorine ions, a molecular conductivity of 959·6 and 965·8, respectively, would be expected. Since, for the pyridinium ion an ionic velocity of 20 is obtained at 0° (Landin, *J. Chim. physique*, 1907, **5**, 592), the value of μ_∞ for the pyridinium complex salt should be 923. Reference to the experimental values shows that they are in good agreement with these theoretical values. Additional confirmation of this scheme of ionisation for the complex salts is afforded by the isolation of the intermediate products $R[MoOCl_4,H_2O]$, $R[MoO_2Cl_2,2H_2O]$, and an oxychloride, $[Mo_2O_4(OH)Cl,4H_2O]$, which may be considered as derived from the intermediate substances $[MoO_2Cl,3H_2O]$ and $[MoO_2(OH),3H_2O]$.

Salts of the Type $R[MoOCl_4,H_2O]$.

Hitherto only bromides of this type of co-ordination compound have been isolated. The first chloride of this type, *monotrimethylammonium molybdenyl tetrachloride*, was obtained as follows:

75 C.c. of the molybdenum trioxide solution, electrolytically reduced to the quinquevalent stage, were concentrated on a water-bath under diminished pressure to 20—25 c.c. 30 C.c. of a solution of trimethylamine hydrochloride (11 g.) were now admitted by releasing the vacuum, and the mixture was heated to boiling under diminished pressure. The solution was then saturated with hydrogen chloride while it was being cooled, finally in a freezing-mixture, and the emerald-green crystals thus obtained were filtered, washed with

concentrated hydrochloric acid, and dried in a vacuum over solid potassium hydroxide and phosphoric oxide {Found: Mo, 28·8; Cl, 42·6; N, 4·24; C, 10·8; H, 3·67. $(CH_3)_3NH[MoOCl_4,H_2O]$ requires Mo, 28·9; Cl, 42·7; N, 4·22; C, 10·9; H, 3·62%}.

Molecular-weight Determinations.—The molecular weight was determined by the depression of the freezing point of air-free water.

Molecular Conductivities.

v	35·6	71·2	142·4	284·8	569·6	1139·2	2278·4	4556·8
μ	580	614	657	706	773	832	849	874

The calculated value for μ_∞ at 0° is *ca.* 880 on the scheme of ionisation and hydrolysis previously outlined, for there are produced 1 trimethylammonium, 4 chlorine, and 3 hydrogen ions, whilst the osmotic factor should be 9. The experimental results are clearly in accordance with the theoretical predictions.

Salts of the Type $[MoO_2X_2,2H_2O]R$.

In the scheme of ionisation proposed for the complex salts of quinquevalent molybdenum, the co-ordination compound $[MoO_2Cl_2,2H_2O]H$ was postulated as an intermediate product. Although this acid has not been isolated, its derivatives have been obtained in reactions involving the green complex salts.

Barium Oxalomolybdite.—Bailhache (*Bull Soc. chim.*, 1903, **68**, 161) prepared this compound by reducing ammonium molybdate in hydrochloric acid with red phosphorus, and formulated it as $BaH_2(MoO)_2(OH)_6(C_2O_4)_2,H_2O$. Viewed in the light of Werner's co-ordination theory, however, a more rational formulation and name for the substance are obtained if the molybdenum is assigned a co-ordination number of six. The new formula $Ba[MoO_2(C_2O_4),2H_2O]_2,H_2O$ clearly shows the relationship to the co-ordination compound $H[MoO_2Cl_2,2H_2O]$, and requires the name barium molybdenum dioxyoxalate. The probable correctness of this formulation and the importance of this salt can be appreciated from Bailhache's statement (*loc. cit.*) that it is produced when diammonium molybdenyl pentachloride is treated with oxalic acid and barium chloride. No details of the method were given, but experiments showed that the salt could be satisfactorily isolated by the following method:

30 C.c. of an aqueous solution of oxalic acid (1·2 g.) were added to 30 c.c. of a solution of diammonium molybdenyl pentachloride (3·5 g.), and the mixture was warmed. To the dark red solution produced, barium chloride (1·1 g.) in 60 c.c. of water was added, and on boiling, with constant stirring, a red, crystalline solid separated in good yield, which was washed with warm water and dried; it proved to be the required compound {Found: Ba, 20·8; Mo, 29·0; C, 7·28; H, 1·50. Calc. for $Ba[MoO_2(C_2O_4),2H_2O]_2,H_2O$: Ba, 20·8; Mo, 29·1; C, 7·25; H, 1·52%}.

Pyridinium Molybdenum Dioxydichloride.—Sand and Burger (*loc. cit.*) noticed that when their green pyridinium molybdenyl pentachloride was boiled with alcohol, copper-red crystals separated on cooling. This compound contained Mo, 31·7; Cl, 23·68; N, 4·75; C, 22·05; H, 2·90%, and it was assigned the formula $Mo(OH)_3Cl_2,C_5H_5N$, which requires Mo, 32·32; Cl, 23·09; N, 4·71; C, 20·20; H, 2·69%. Although the analytical figures do not show very close agreement with those demanded by theory, yet the empirical formula assigned to the substance by Sand and Burger has now been shown to be correct. It should be written, however, as $C_5H_6N[MoO_2Cl_2,H_2O]$, whereby it is characterised as the pyridinium salt of the acid $H[MoO_2Cl_2,2H_2O]$. A pure product was obtained by the following method: Freshly prepared dipyridinium molybdenyl pentachloride was added to boiling alcohol (95%) until the solution turned dark red and further solid dissolved with difficulty. On filtering and allowing the clear liquid to cool, a light red substance separated which gave Mo : Cl = 1 : 2·1 and proved to be an impure product. This was removed, and the mother-liquor, on concentration to small bulk and cooling, gave copper-red needles, which were washed with alcohol (95%) and dried in a vacuum over phosphoric oxide. The water content of the crystals varied with different samples, whilst the colour deepened with increasing water content (Found: Mo, 33·88; Cl, 24·97; N, 4·93; C, 21·5; H, 2·34. Calc. for $C_5H_6N[MoO_2Cl_2],0·25H_2O$: Mo, 33·88; Cl, 25·02; N, 4·94; C, 21·2; H, 2·29%). That this pyridinium salt and barium molybdenum dioxyoxalate are similarly constituted is readily demonstrated as follows: 3 G. of pyridinium molybdenum dioxydichloride in 50 c.c. of water were warmed with an aqueous solution of oxalic acid (1·2 g. in 30 c.c.). 1·1 G. of barium chloride in 60 c.c. of water were now added and the mixture was heated to boiling. The corresponding barium compound separated in good yield (Found: Ba, 21·4; Mo, 29·7. Calc. for $Ba[MoO_2(C_2O_4),2H_2O]_2$: Ba, 21·4; Mo, 29·9%). It will be noticed that the water content is less than that in the sample prepared from the green complex salt.

Molecular-weight Determinations.

G. of substance per 100 g. of water.	Conc. (mol. per 1000 g. water).	Osmotic factor.	Apparent mol. wt.
2·489	0·0838	3·45	86·06
1·148	0·0387	3·73	79·60
0·692	0·0233	3·90	76·12
0·222	0·0075	4·82	61·60

M for $C_5H_6N[MoO_2Cl_2,H_2O]$ = 296·9.

Molecular Conductivity.—This was determined at 0°:

v	20·56	41·12	164·5	329	1316
μ	185	210·6	275·1	312·0	336·0

These two results find an adequate explanation on the assumption that in aqueous solution the pyridinium salt undergoes ionisation and hydrolysis in accordance with the scheme:

$$[MoO_2Cl_2,2H_2O]C_5H_6N + H_2O \rightleftharpoons C_5H_6NCl + [MoO_2Cl,3H_2O]$$
$$\rightleftharpoons C_5H_6N^{\cdot} + Cl' + [MoO_2Cl,3H_2O],$$
$$[MoO_2Cl,3H_2O] + H_2O \rightleftharpoons [MoO_2(OH),3H_2O] + H^{\cdot} + Cl'.$$

Hereby, in dilute solutions, an osmotic factor of 5 should be obtained, whilst conductivity measurements, due to a pyridinium ion, 2 chlorine ions, and 1 hydrogen ion, should give μ_∞ = approx. 327·6. The experimental results are in close agreement with the theoretical values and support the scheme of hydrolysis outlined above.

Dimolybdenum Tetraoxyhydroxychloride.—The isolation of this salt, $Mo_2O_4(OH)Cl$, formed an important link in the chain of evidence for the scheme of ionisation and hydrolysis proposed for the green complex salts.

Preparation. The reddish-brown solution of quinquevalent molybdenum, obtained by the electrolytic reduction of 150 c.c. of molybdic acid solution, was concentrated on a water-bath under diminished pressure until a dark, viscous mass was obtained. Pure, dry acetone was admitted in small portions with frequent shaking and warming, until the mass just dissolved, giving a deep brown solution. This was poured with constant stirring into a large volume of dry ether and a bulky reddish-brown precipitate separated, which was washed with dry ether and kept over solid potassium hydroxide in a vacuum [Found: Mo, 51·6; Cl, 9·54; Mo : Cl = 2 : 1. $Mo_2O_4(OH)Cl,3{\cdot}5H_2O$ requires Mo, 51·7; Cl, 9·55%].

Valency. A solution of the compound in dilute sulphuric acid was titrated with standard permanganate according to Reinhardt's method, and required t_1 c.c. A solution of the same concentration was passed through the reductor (J., 1923, **123**, 969) and required

t_2 c.c. of permanganate. The valency is given by $(6 - 3t_1/t_2)$. Found: $t_1 = 7{\cdot}58$ c.c.; $t_2 = 22{\cdot}79$ c.c. Hence the molybdenum is quinquevalent.

Properties. The new chloride is a reddish-brown powder, readily soluble in water and in alcohol, giving deep reddish-brown solutions which on dilution become bright yellow. The aqueous solution is acid to litmus and reduces solutions of silver salts. The brown aqueous or alcoholic solutions of the compound turn emerald-green on saturation with hydrogen chloride, and complex salts of the type R_2MoOCl_5 may be isolated from them. On heating, the chloride decomposes with evolution of hydrogen chloride.

Molecular-weight Determinations.—These were determined in air-free water.

G. of substance per 100 g. of water.	Conc. (mol. per 1,000 g. water).	Osmotic factor.	Apparent mol. wt.
1·193	0·0314	1·85	205·7
0·656	0·0172	2·03	187·5
0·483	0·0127	2·41	157·9

M for $Mo_2O_4(OH)Cl,4H_2O = 380{\cdot}5$.

These results indicate that two ions are present in the more concentrated solutions and three individuals in the more dilute. This is satisfactorily explained by the progressive hydrolysis

$$[Mo_2O_4(OH)Cl] + H_2O \rightleftharpoons [Mo_2O_4(OH),H_2O]Cl \rightleftharpoons [Mo_2O_4(OH),H_2O]^{\cdot} + Cl',$$

or $$[Mo_2O_4(OH)Cl] + H_2O \rightleftharpoons [Mo_2O_4(OH)_2] + H^{\cdot} + Cl'.$$

Conclusions.

The results obtained from the determinations of molecular weights and molecular conductivities of a wide range of co-ordination compounds of the formula $R_2[MoOCl_5]$ leave little doubt that the scheme of hydrolysis and ionisation outlined in this paper substantially explains their behaviour in aqueous solution. It receives added support from the physico-chemical measurements made with compounds typical of the intermediate stages of the hydrolysis. Still more convincing proof of the correctness of the scheme is that it allows the formulation and characterisation of salts previously known, and derived from the green complex salts, but which had hitherto lacked systematisation. In a paper by Scagliarini (*Atti R. Accad. Lincei*, 1925, **1**, 676), the isolation of two salts, formulated as $MoOCl_3,C_5H_5N$ and $2\left[(NH_4)_2\left\{Mo\begin{matrix}(OH)_4\\Cl_3\end{matrix}\right\}\right] + C_6H_{12}N_4,HCl$, by

reactions involving the complex salt $(NH_4)_2[MoOCl_5]$ has been made the basis of the following scheme of hydrolytic decomposition :

$$R_2MoOCl_5 + H_2O = R_2Mo(OH)_2Cl_5 \xrightarrow{H_2O} R_2Mo(OH)_3Cl_4 + HCl \xrightarrow{H_2O}$$
$$R_2Mo(OH)_4Cl_3 + HCl \xrightarrow{H_2O} R_2Mo(OH)_5Cl_2 + HCl \xrightarrow{H_2O}$$
$$R_2Mo(OH)_6Cl + HCl.$$

Such a scheme does not adequately explain the physico-chemical results obtained in the present paper, nor does it elucidate the constitution of intermediate products, which are assigned co-ordination numbers of 7. The analyses quoted by Scagliarini (*loc. cit.*) for the compounds he isolated involve only determinations of molybdenum, chlorine, and nitrogen, and do not show very satisfactory agreement with the calculated values. Confirmation of the isolation of the salt $MoOCl_3,C_5H_5N$ would be of interest, for as yet $MoOCl_3$ has not been obtained.

The authors wish to express their thanks to the Chemical Society and the University of Birmingham Research Committee for grants in aid of this investigation.

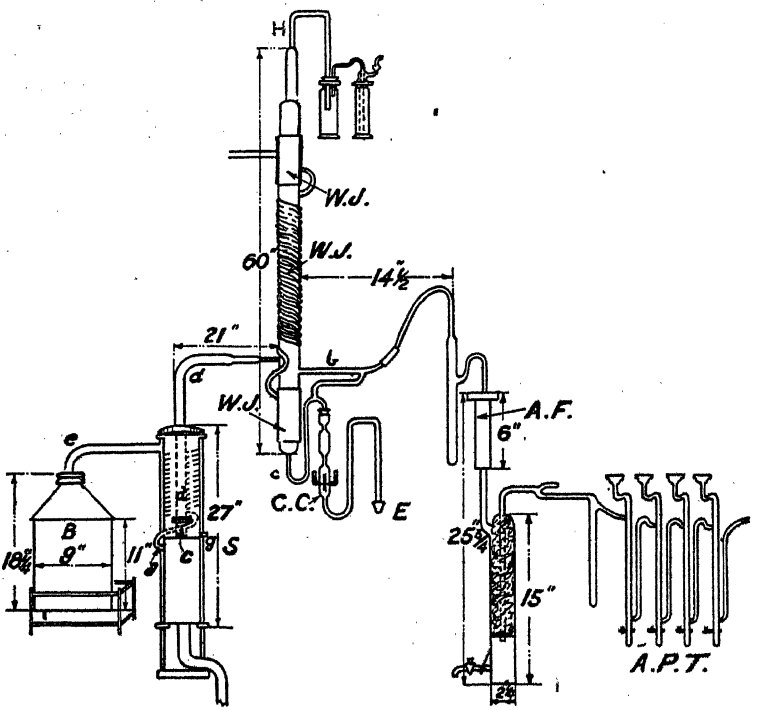
CCLXXXVI.—*The Routine Preparation of Low-conductivity Water.*

By GUY D. BENGOUGH, JOHN M. STUART, and ALFRED R. LEE.



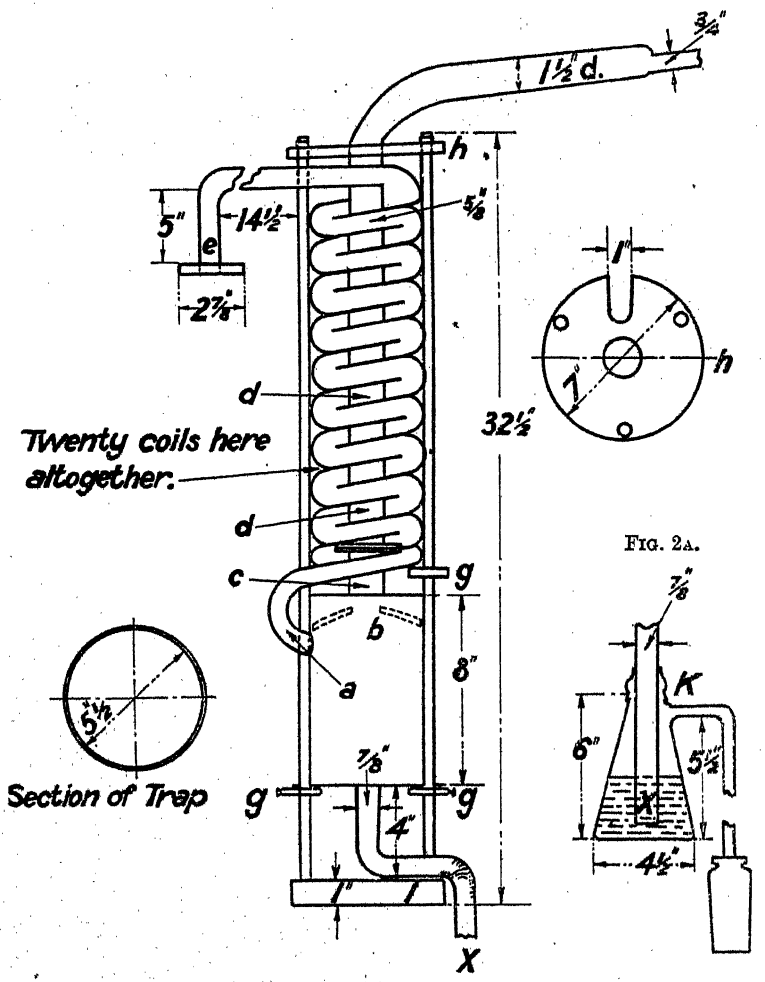
THE present communication gives details of improvements in the construction of Bourdillon's still for conductivity water (J., 1913, **103**, 791), by which it has been found possible to produce a large daily supply of such water of high quality.

Bourdillon's still delivered 7—8 litres of 0·2 gemmho conductivity in a single distillation from Oxford tap-water, and, although even the best water obtained showed conductivities as high as 0·11 gemmho from tap-water and 0·09 from distilled water at 18°, the authors constructed a precisely similar still with a view to effect improvements.

The water from this still sometimes had conductivities similar to those obtained by Bourdillon, but a regular daily supply did not maintain this degree of purity for any considerable period, even with frequent attention to small adjustments. The causes of the rises in conductivity appeared to be (*a*) minute air-leaks in some parts of the apparatus, *e.g.*, round the rubber stoppers, (*b*) inadequate trap-

ping of spray, or (c) "creeping" of water from the trap to the condenser. Air-leaks generally occurred between the spray-trap and the rest of the apparatus even when the rubber stoppers used by Bourdillon were replaced by pipe-unions, and "creeping" of water took place to a surprising extent, especially when there were considerable fluctuations of pressure in the still.

FIG. 1.



B. Boiler.
S. Spray trap.
W.J. Water jacket and cooling coils.
C.C. Conductivity cell.
A.F. Air filter.
A.P.T. Air purification train.
E. Outlet for purified water.

To eliminate these causes of trouble, the whole of that part of the still between the boiler and the block-tin condenser was redesigned; at the same time, some improvements were made in the air-purification train. The still in its final form is shown in Fig. 1.

The boiler, *B*, is made of 18-gauge (1·2 mm. thick) copper sheet, tinned on the inside. It is connected to the rest of the apparatus by two circular flanges, 7·0 cm. in diameter, soldered both to it and to the copper pipe, *e*. A ring of "hallite" packing is used between the flanges, which are held together by six bolts. (A

flange is shown in Fig. 2, *e*.) The boiler holds 10 litres of water, which is introduced, together with the ground potassium bisulphate, by separating the flanges. This is the only joint on the still that

FIG. 2.

Dimensioned sketch (not drawn to scale).

need be broken during several months' running. The available waters were a hard London tap-water, and a supply which contained traces of oil. The former was objectionable owing to the possible formation of heavy boiler-scale, so the latter was used

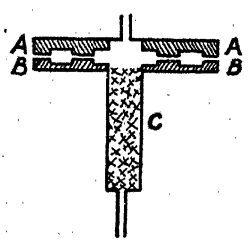
after a preliminary rough distillation with potassium permanganate and caustic potash in a simple form of still.

From the boiler, the steam passes through the copper tube, *e* (Figs. 1 and 2), to the trap, which has been redesigned and very solidly constructed, as shown on an enlarged scale in Fig. 2. The tube, *e*, is of 1·3 cm. internal diameter and is bent into 20 coils each of 12·5 cm. diameter, and its end is brazed into the copper trap tangentially so as to give circular motion to the steam entering the trap at *a*. A circular conical baffle-plate, *b*, is inserted above this. The steam outlet at *c* is provided with a 7 cm. circular flange (not shown in Fig. 2) which is bolted to "hallite" jointing and a similar flange on the block-tin tube, *d*. This tube has an internal diameter of 4 cm. and is soldered to the condenser. The ample width of this tube prevents any trapping of water; in the earlier still, a long, narrow, coiled tube was used and arranged outside the copper coil, but water occasionally accumulated in the bends and caused violent fluctuations of pressure in the still.

The copper coil and trap are lagged with cotton waste and asbestos sheet and are held in place by three adjustable supports, *g*, which can be clamped to three vertical brass rods. These brass rods are rigidly fixed into a heavy cast iron base, *I* (Fig. 2).

A brass plate, *h*, is bolted to the tops of the rods, and, together with a flange, provides support for the central tin tube. At first, the water from the submerged outlet tube, *X* (Fig. 2), was merely allowed to run into an open beaker, but the best water was not obtained until a definite air-trap and non-return valve were used, as shown in Fig. 2A.

The main block-tin condensing column is similar to that of Bourdillon, but the arrangements at the lower end have been altered as shown in Fig. 1; *d* is the steam inlet leading from the trap and is soldered into the main column, *b* is the inlet for purified air, and *c* the outlet for the conductivity water; *W.J.* consists of two glass water-jackets connected together by a long coil of compo-tubing carrying a stream of water. The conductivity-measuring vessel *C.C.* is fixed on to *c* by a rubber stopper. The advantage of this arrangement is that the water does not become saturated with air in the cold as in Bourdillon's method, and consequently air-bubbles do not form on the electrodes of the conductivity cells.



On the upper part of the tin condenser is a narrow tin tube, *H*, soldered to the main column and joined by a rubber connexion to a glass tube leading into a bottle. A second bottle is connected so that the escaping air bubbles out through a shallow layer of distilled water. If a sudden diminution of pressure occurred in the

still, the water in the second bottle would merely be sucked back into the first and not into the still.

The rate at which bubbles pass through the water serves as a rough indication that the purified air is passing satisfactorily through the still. Before distillation is stopped, the second bottle should be replaced by a soda–lime tube.

The Weiland purification trains, *A.P.T.* in Fig. 1, contain *N*-sulphuric acid, caustic potash solution, and distilled water; two are used in parallel, as it was found advisable to use a much faster stream of air than that used by Bourdillon. Recently Weiland's design has been modified: the columns containing the glass beads are now 2·5 cm. in diameter and are pinched in near the tops to retain the beads; the funnels and taps have been increased in size. The air passes through a dust-filter (*A.F.*, Fig. 1) constructed as shown in Fig. 3. This filter is a modification of one described in the Meteorological Office Report of the Advisory Committee on Atmospheric Pollution, 1916—17. It is constructed of brass, and the air first passes through the tube *C*, which is filled with special jewellers' wool, and then through a disc of special blotting paper (Ford 428 Mill) inserted between brass discs *A* and *B*, which have circular and radial grooves cut in them as shown. *A* and *B* are bolted together and the joint is waxed over externally.

FIG. 3.

The course of an actual distillation was as follows: Ten litres of laboratory distilled water were placed in the boiler with 20 g. of powdered potassium bisulphate, and heated to boiling; the "hallite" joint softened in the steam, and the boiler was then connected with the still.

The heating was adjusted so that the conductivity cell was filled and emptied every 9 or 10 minutes. This rate of delivery corresponds to the production of about 0·75 litre of water per hour and should not be greatly exceeded; if the still is run too rapidly, a trace of spray seems to get into the condenser during distillation.

The conductivity of the water was determined by the standard bridge method, a galvanometer being used to detect the zero position. This was possible because the conductivity was so low that only very small currents passed, and polarisation effects were negligible. The cells in which measurements were made were standardised with *N*/50-solutions of potassium chloride. The possible errors in the values for conductivities given in Table I are within $\pm$ 5%. The table gives the values (in gemmhos) of the specific conductivity, κ,

of each batch of water reaching the conductivity cell in a typical run of the still, the purified air being supplied at a rate of about 22·5 litres per hour, and the temperature of the water being about 15°.

TABLE I.

Batch No.	κ.	Batch No.	κ.	Batch No.	κ.	Batch No.	κ.
1	0·17	10	0·057	19	0·055	28	0·054
2	0·13	11	0·055	20	0·055	29	0·055
3	0·078	12	0·062	21	0·055	30	0·059
4	0·077	13	0·057	22	0·055	31	0·063
5	0·062	14	0·052	23	0·054	32	0·067
6	0·059	15	0·050	24	0·054	33	0·071
7	0·055	16	0·052	25	0·054	34	0·084
8	0·072	17	0·054	26	0·065		
9	0·059	18	0·055	27	0·054		

Batches 3—33 inclusive, amounted to 4040 c.c. The volume of waste water collected at the "run off" from the steam trap was 2485 c.c.

In other runs, conductivities as low as 0·045 gemmho at 18° have been obtained. This figure is not much inferior to the best values of Kohlrausch and Heydweiller (0·040 at 18°) (*Pogg. Ann.*, 1894, **53**, 223) who distilled in a vacuum in an apparatus which was only adapted to give a small quantity of the purified water. The authors' still has been in constant use for more than 2 years and requires very little attention other than the periodic renewal of the solutions in the air-purification train. It will regularly produce about four litres a day of water with a conductivity of about 0·065 gemmho.

The authors wish to express their grateful thanks to Mr. H. R. Raikes, who placed his great experience at their disposal when constructing both the still and the apparatus for measuring conductivities.

The work was carried out in the Metallurgical Laboratory of the Royal School of Mines, as part of a research directed by the Corrosion of Metals Research Committee of the Department of Scientific and Industrial Research, and the authors wish to thank the Chairman, Professor H. C. H. Carpenter, for the many facilities afforded.

[*Received, June 18th*, 1927.]

CCLXXXVII.—*The Action of Bromine on Dimethylpyrone.*

By JOHN NORMAN COLLIE and LOUIS KLEIN.

THE constitution of the pyrone nucleus is of importance in that many interesting compounds are derived from it. Bromine reacts with it at once, but does not give ordinary addition products, and similarly there is no indication that any ethylenic linkages are present in dimethylpyrone.

10 G. of dimethylpyrone (1 mol.) and 13 g. of bromine (1 mol.) were allowed to react in chloroform solution, and the mixture became orange-coloured and slightly warm. The solvent was evaporated at the ordinary temperature, and the resulting bright orange-coloured, crystalline solid was washed with water, which removed dimethylpyrone hydrobromide, together with a small quantity of some pyrone compound containing bromine—this was probably the bromodimethylpyrone, but owing to its high solubility it could not be separated from the hydrobromide.
